0.000014 degrees of arc. (0.000014°)(3600 arc-seconds / 1°) =~ 0.05 arc-seconds. This telescope launched in 1990 was repaired by astronauts in1993 due to producing out of focus images that some might say look slightly "blurry", and has since made many important discoveries not yet practical with most telescopes on Earth. The diameter of the main mirror of the HST is about 7.9 feet wide and which can gather much light and therefore resolve faint (received low light) or "dim" objects of which may be due to their great distance away from Earth. The Webb telescope is composed of several mirrors with a common focus, and its total light gathering ability or area is about 5.4 times more than that of the Hubble telescope, and that Webb was made to be more sensitive to infra-red light. The maximum magnification power of the HST is 1440, but say 400 is often used for faint objects so as to obtain a brighter image, hence often no more power than that of a quality, consumer grade, land based telescope. **HST** has a low Earth orbit altitude of about 340 miles = 550 km. It has an orbit inclination with respect to the equator of about 28.5° Its focal length is about 190 ft.

Image resolution is much like or analogous to the precision or "fineness" of a number and-or measurement.

Image Resolution = Pixels / Image Size , ex. 200 pixels/inch , and Pixel Resolution can be defined as:
Pixel Resolution = Real Distance / Pixel , ex. 1 foot / pixel , and **Angular Resolution** = Angle / Pixel

* Of all the planets, Mars has the most elliptical (non, circular) orbit. Mars has a axial tilt similar to that of the Earth, and the value for Mars is about 25.$\underline{2}$° Mars also has a day or axis-rotation length just slightly longer than that of the Earth. This value for Mars is 1.026 days which is about a Earth day plus a half an hour.

* Jupiter, Saturn, Uranus, and Neptune are often called "gas giants" since their gas atmospheres are very thick.

* The distance a planet is from the Sun is noted above as an average distance which is the average of its closest and farthest orbital distances from the Sun. For example, Mars has a perihelion of about 128 million miles, and an aphelion of about 154 million miles from the Sun, and the average is about: (128Mm + 154Mm)/2 = 282Mm/2 =~ 141 million miles, and this is the value seen in the list above.

* At about 14 days past the winter **solstice** (ie. max. apparent tilt of Earth's pole axis, about 23.4° on about Dec 21, "the Sun (travel and-or height) stopping"), about Jan 4, Earth has an aphelion of about 94.5Mmi, and a perihelion of about 91.4Mmi at about 14 days past the summer Solstice (abut June 21) at about July 4. The average distance Earth is from the Sun is therefore usually noted as about 93Mmi. The perihelion and aphelion dates are also an average or typical value due to the small, but constant, gravitational (force) influences of other orbiting planets slowing down or speeding up the orbit of Earth around the Sun.

* Two planets are theoretically closest when they are both at their perihelion distance from the Sun, and at the same time and same side of the Sun in alignment like a line. For example, Earth's perihelion is about 91.4Mm, and Mar's perihelion is about 128Mm, and the difference between these two distance is about: (128Mmi - 91.4Mmi) = about 36.6Mmi

* The average distance between two stars is about 5 light-years. The average distance between two galaxies is about 1 million light-years.

* The distance to the closest star, and not including the Sun, Proxima Centauri is about: 4.24 light years. In theory, it will therefore take light and-or a radio signal from Earth a total of 4.24 years to reach Proxima Centauri, and vice-versa.

* The distance to AlphaCentauri is about: 4.37 light years.

* There is a rough estimated 10 stars within 10 light-years radius about Earth, 100 stars within 20 light-years radius about Earth, 1000 stars within a 100 light-year radius about Earth. The stars we see are usually withing the Milky-Way galaxy and less than 1000 light-years away. The density of stars in a galaxy is about 0.0035 stars / 1 cubic light-year, and with an equivalent fraction of about 1 star / 286 cubic light-years. By taking the cube root of 286, we have about 1 star at a average separation distance of abut 6.$\underline{6}$ light-years from the closest star to it. Stars can be gathered by together by gravity into groups called clusters which are then called a galaxy of stars. Galaxies can also be gathered together into super clusters.

* The distance to the center of the Milky Way Galaxy, from the position of Earth in it, is about 26000 light years.
* It has been estimated that it takes the Sun about 225 million years to orbit the Milky-Way galaxy.
* The diameter of the Milky Way Galaxy that out Sun is in, is estimated to be 75000 to 100000 light years across.
* The attractive force that holds the orbiting stars in a galaxy is often a **black-hole** which is a dense mass so large, its gravity force even stops light from going outward from it. The center of the Milky Way Galaxy is located in the direction of the constellation (ie., a unique pattern, group or arrangement of stars) called Sagittarius. This center is obscured by what can be called clouds of dust and debris, and can be viewed by some large radio and infrared (ie., heat) light capable telescopes using certain plastic and-or specialized types of glass since regular glass absorbs the infrared radiation and converts it to heat. This black-hole or theoretical dark, collapsed star which ran out of fuel that expanded it, and then having a very higher than average level of local amount of gravity (from a mass greater than an estimated 2.5 times that of the mass of our local Sun star) of which not even light has enough kinetic energy to be emitted from, and is called **Sagittarius A**. This black-hole has been imaged over several years of time using special infra-red sensitive telescopes. This black-hole currently has several high velocity stars in an elliptical orbit about it. This black-hole was discovered in 1974 by radio astronomers (**Dr. Kwok-Yung** aka. **Fred Lo**, **Bruce Balick**, and later, **Robert Brown**, and **Andrea Ghez**, the scientists for for the verification, and noticing a more than the average amount of star radio noise and-or or energy coming from this location.

* Radio astronomy was formally started in 1931 by **Carl Jansky** of the **Bell Labs** company, and who built a radio-telescope which was basically a large antenna construction on the ground that was tuned to receive a high frequency. This antenna (ie.,here, a radio energy receiver) could be rotated so as to be pointed in a desired directions in outer-space. He later noticed that there was always more radio noise in the direction of the Sagittarius constellation in our Milky-Way star galaxy. The ratio of black-holes to stars is estimated at about: 0.005 black-holes / 1 star =~ 0.5% , and which can also be stated by using division as about 1 black-hole among 200 stars. The distance to the center of the Milky-Way star galaxy and-or black hole is estimated at 25000 light years. In the northern hemisphere of Earth, and during the summer months, people can see the direction of Sagittarius-A in the in the southward direction in the constellation of Sagittarius (aka, The Archer). Sagittarius-A has galactic coordinates of about 17 hours and 45 min. and 40.041 sec. right ascension, and -29° , 0 arc-minutes and $28.1\underline{2}$ arc-seconds of declination. Sagittarius-A is about -5.6 degrees from the ecliptic, hence it is below it or at a lesser altitude in the sky.

* The latest estimated distance to the (current) "North Star" = "Pole Star" or **Polaris** is about 323 light years. Polaris is actually a 3 star system. Polaris actually differs by a small angle of 0.735° from the true location of Earth's north pole axis. The farther a person goes more south on the southern hemisphere of Earth, the less stars visible around the Polaris region since the Earth's bulge at the equator is essentially blocking the view. This book contains basic star maps. Throughout the year of Earths travel about the Sun, the stars will appear to have a counter-clockwise (ie., to the left from the top reference) circular orbit about Polaris which will still appear (nearly) fixed at its location, and this circular path is due to that Earth is rotating on its north to south, polar axis. As Earth orbits about the Sun during the yearly orbit, all the stars at day and-or night will shift in position along the solar plane (ie., the east to west, "ecliptic" line), and about Polaris by about (360°/365 days) =~ 1 degree per day.

* Due to Earth's 365 day, or yearly, orbit about the Sun, we will gradually see other stars in the Milky-Way galaxy at night.

* Most Comets have a highly eccentric (ie., "off from center". elongated, non-circle) orbit about the Sun. After studying the motion of comets, astronomer **Edmond Halley** (1656-1742), from England, predicted that they orbit the Sun like a planet. This was proven when (post named) **Halley's Comet** would return in 1758, and after previously been viewed by others every 76 years, hence Haley's comment was periodic, hence, it is in an (stable, elliptical) orbit about the Sun.

* It has been estimated that for a body to become **naturally round** due to its own gravity, it must have enough mass so as to be about 600 miles in diameter or greater.

* It has been estimated that for a body to have a hot, **molten liquid core** (usually of a metal(s), it must be at least 2000 miles in diameter or greater. This size is also the modern definition needed for a planet.

* The presence of large sized pieces of metal meteorites that landed on Earth suggest there was once another large body

in our solar system that probably collided with another and then fragmented into **asteroids** - perhaps as the "asteroid belt" or zone between Mars and Jupiter.

* The average distance between small pebble sized **asteroids** and large asteroids in the asteroid belt between Mars and Jupiter is about 500000 miles. As for smaller particles, this distance may be much less and since there are many more smaller particles, perhaps ten time more at least, hence having an average distance between these particles as being ten times less at 50000 miles.

* Using the distance to the Sun, and the **diameter of the Sun**, and using some right angle trigonometry, you can calculate the apparent width angle of the Sun as seen in the sky from Earth or any other planet. The Sun appears to be 0.5 degrees = half a degree, wide in the sky from Earth. For an example, knowing the distance from the Sun and the diameter of the Sun, you may solve this value for Mars. Another similar calculation is from the trigonometric concept that if you double (a factor or multiple of 2) the distance of the base of a right triangle, the height corresponding to that distance will likewise double (2). If the height is to remain constant, such as the diameter of the Sun, if the distance doubles (2), the angle will be divided by that same factor (2). For Mars, being a factor of 1.5AU from the Sun, the apparent angle of the Sun seen in the sky from the surface of Mars will be divided by that same factor. For Earth, the apparent solar angle or size is about 0.5°. For Mars, it is about 0.5° / 1.53 = $0.3\underline{3}$° on average since orbits are elliptical and the distance to the Sun changes varies.

From Earth's surface, the Sun appears to have a relative area of: (pi)(r^2) = 3.14 (0.5^2) units^2 = 0.785 degree units^2
From Mars's surface, the Sun appears to have a relative area of: (pi)(r^2)= 3.14 (0.327^2) units^2 = 0.336 degree units^2

Since Earth is at 1AU from the Sun, and Mars is at 1.53AU from the Sun, the average distance to Mars from Earth is: (1.53AU - 1.0AU) = 0.53AU. In terms of miles, this would be: (0.53)(AU distance) = (0.53)(93 million miles) = 49.3 million miles. This minimum distance is always changing to a larger value as the planets orbit about the Sun, especially when Mars is on the opposite side of the Sun and its distance from Earth is:
Earth's distance to Sun + Mars's distance to Sun = 1AU + 1.53AU = 2.53AU = 235.3 million miles.

The ratio of the relative apparent Solar areas of Mars to that of the Earth is: 0.336 units / 0.785 units = 0.43
The relative solar radiated energy (light, heat) reaching Mars will therefore be about 43% that of the Earth.
At 1AU in space from the Sun, and which is Earth's location or distance from the Sun, and when above the (energy absorbing) atmosphere, solar radiation is about **1370W/m^2** (yearly, orbit average). Due to Earth's atmosphere absorbing and-or reflecting some solar radiation, there is about **1000W (max.)** of solar radiation per square meter at Earth's surface at solar noon (considered 12 pm, and the start of the afternoon or evening) where the Sun is directly overhead. The ratio of: 1370w/m^2 / 1000w/m^2 = 1.37 and indicates there is 37% more solar energy per square meter above Earth's atmosphere and-or 37% less solar energy per square meter at Earths' surface at solar noon, and this equates to about 1000 w/m^2 / 1370 w/m^2 = 0.73 =~ 73% of the total available energy above Earth's surface. Due to the Moon having no atmosphere, the amount of solar radiation on the surface of the Moon is that reaching the upper atmosphere of Earth at 1 AU during its orbit, hence 1370 W/m^2 (yearly average). Due to the Moon's surface receiving much more ionizing radiation (including cosmic or galactic rays which are mostly the nucleus particle of ionized atoms, and free electrons which can break apart molecular bonds) from the Sun, other stars, nova, etc. than the surface of Earth, to protect an astronaut requires thicker and-or denser physical shielding so as to greatly reduce this type of harmful radiation.

Assuming low atmospheric losses on Mars, there will be about (1370W)(0.43) = 489W (max.) of solar radiation per square meter at the surface at Mars noon (ie., 12pm) when the Sun is directly overhead. Relatively, or comparatively, this is about only 49%, or about half, of that on Earth.

Another calculation for the solar or Sun radiation intensity per unit area at the surface of Mars is from the fact that it is at a distance of 1.53AU from the Sun. Since Earth is 1AU from Mars its relative solar radiation can be said to be a reference of 100% = 1.0. From the concepts of the inverse square law with energy and its intensity from the source, the intensity at Mars in relationship or comparison to that of the Earth can be calculated as:

Intensity at Mars = Intensity at Earth / 1.53^2 = 1.0 / 1.53^2 = 1 / 2.3409 = 0.427 =~ 43%

* The (Earth's) Moon orbital "tilt" (ie., inclination and-or declination) with respect to the solar or ecliptic plane as it orbits around Earth is a constant value of about 5.145° above or below that plane it during its orbit. The specific distance above the solar plane is sinusoidal in value and is constantly changing as the Moon orbits about Earth about every 30 days. The Moon's orbit about the Earth is nearly circular, and having only a very slight ellipse shape with a low eccentricity of e = 0.0549, however, if this is compared to other moons and planets, it is relatively large. Due to this fact, he Moon should and does appear as slightly larger when it is closer to Earth during its orbit about Earth which is at one focus of the Moon's orbit.

* If two ideal spherical objects have the same mass, they will each have the same amount of gravity attracting the other, and if given the proper circumstances (velocities, gravity, directions), they will orbit each other, and with the center of that orbit called the **barycenter** being located half-way between their center points, and as a point in empty space. If one mass is much larger, the barycenter of orbit will then be closer to that larger mass. The barycenter of the Earth and its distant Moon system is actually located in the Earth, and the Earth does not then appear much to be orbiting an empty point in space.

* When the Moon is said to be a "new moon" it is not illuminated. The Moon will afterwards be illuminated on its right or eastward side as viewed from the Earth. This begins the "phases of (illumination) of the Moon", and it is called "waxing". After a "full Moon" where it is fully lit or illuminated, the right or eastward side will then get dark throughout the next 14 days, and this is called "waning". The line between illuminated (lit) and not illuminated (dark) part of the Moon is called the "terminator line" and this appears to go from the north pole to the south pole of the Moon. When the Moon is highest in the sky as viewed by a person in the northern hemisphere on Earth, this north to south line will point to the southward direction on Earth, and this is another reference direction and way to navigate. Though we may see the Moon as being only partially lit, in reality, half the Moon which has a sphere or ball shape, is always illuminated by the Sun and its light, and half of the Moon is always in the dark or shadow of itself. As the Moon rotates on its own axis, a different portion of the Moon will be illuminated, and throughout its orbit about the Earth. When a new Moon or phase is viewed from Earth, the "far", "dark" or "back-side" of the Moon is completely illuminated.

Where did all the matter in the universe come from?

* The science of astronomy has shown that on average, galaxies are expanding outward from each other as if they were on the surface of an expanding balloon. The matter then has kinetic energy if it is moving. Where did all this matter and energy come from? Considering the **Big-Bang** (explosion) theory or not, it is thought by some that matter is natural and was always here in the universe, and it cycles through condensing, new big-bangs, and expansions. Many believe a "higher power", God and-or intelligence created the universe. That is, a God of the universe created the initial matter and-or energy. After all, consider that matter and-or energy just cannot create themselves from nothing, and even if the universe always existed, and that there has to be a source of them. Here, it is thought that a very large amount of condensed energy had a chain reaction of creating matter, heat, and the expansion (movement) of that matter away from that central location. Some say matter is a form of condensed and-or concentrated energy when we consider the equation E = mc^2. After this matter cooled, it began to collect together by the force of gravity. Large amounts of it eventually became dense enough so as to be ignited as stars, and with the left-over or remaining matter about that star collecting into orbiting planets, asteroids, comets etc. By gravity, stars eventually collected together into galaxies (groups of stars) that orbit a central point and-or core that is very large in mass and has a stronger gravitational field. This core is thought to be a black-hole which was created by the collision of many stars and the collection of that matter then having a very high gravitational field, and probably magnetic and electric fields, and that light cannot even escape from its strength. A black-hole has been found at the center of our Milky Way galaxy that the Sun is in and orbits about. We know its direction and-or location of it in space amongst the (night) sky and stars. This brings about a reasonable question as to whether we can find the direction and-or location in the (night) sky, stars and space as to where the Big-Bang originated at.

How the speed of light was first determined or estimated

The speed of light was once thought to be so high that it could not be known. In 1676, **Ole Romer**, (1644-1710), which is pronounced with a long-o sound such as used for "row", and may be spelled as Roemer. and he was an astronomer from Denmark, and who made the first close estimate as for the speed of light. With a telescope, he was studying the orbit of one of **Jupiter's moons called Io**, and noticed that it took about 1.7 days and would also periodically go behind Jupiter at this same time of 1.7 days, hence it was therefore a constant and could be seen to happen at a certain predictable time on Earth. The distance (93 million miles) to the Sun as known today, and which is also the radius of Earth's orbit about it was already previously estimated to be a lesser value. The diameter of Earth's orbit about the Sun is twice this distance, hence 186 Million miles. Roemer noticed that Io was "late" and that there was a several minute difference when Io was to go behind Jupiter. This happened when the Earth was on the opposite sides of the Sun every six months of time. Roemer understood that this time difference (16.7min, change in time, modern estimate) was most likely due to that light had a longer distance to travel and therefore took more time to reach Earth. Roemer's estimate for the speed of light was about 130000 miles per second, and this value is about (130000mi / 186000 mi) =~ 0.70 = 70% of the speed of light, and is fair or good estimation considering the (limited) knowledge available at those times.

In a more modern estimate and calculation of the speed of light, and using more accurate values, we have a closer estimate of the modernly accepted speed of light of: 186000 miles / second =~ 300,000,000 meters / second:

speed = distance / time = (change in distance) / (change in time) we have:

(2 x 93 million) / 16.7minutes = 186 million miles / 1002 seconds = 0.1856287 million miles / second
= 185,628.7 miles / second = (c) = light speed
= 299792458 meters / second = m/s

The above value for the speed of light is for when it is traveling through a vacuum medium that has no matter in it. Just like the speed of sound can change (increase) traveling through mediums (matter) such as air, water or metals, the speed of light can also be altered (slowed, decreased) as it travels through a medium such as glass. Though the frequency(s) and-or the colors seen of the light will remain the same, the wavelength distance of the light frequency(s) will be decreased in the glass and will resume light speed when it exist the glass material and into another material such as air.

Time	**Distance Light Will Travel (approximate) = (speed) (time)**
1 second	186,000 miles = 300,000 km = **"1 light-second" = distance light travels in 1 second**
1 minute	11,160,000 miles = 17,960,279 km =~ 18 million kilometers = **"1 light-minute"** = (c)(1 min)
1 hour	669,600,000 miles = 1,077,616,742 km =~ 1 billion kilometers = "**1 light-hour**" = (c)(1 hr)
1 day	16,070,400,000 miles = 25,862,801,808 km = "**1 light-day**" =~ 26 (10^9) km = 26 billion kilometers
1 year	5.88 trillion miles = 5.88 (10^12) miles = "**1 light-year**" ~= 9.5 trillion km =~ 9.5 (10^12) km

The distance to the Sun was first reasonably estimated by **Eratosthenes** by using observations, right-angle trigonometric calculations and geometry long before Roemer's speed of light discovery. Since ancient times, it was known that the Sun was farther than the Moon due to that during any eclipse seen, the Moon is always seen as covering the Sun. Since Roemer, the Earth to Sun distance had some better approximations. Once this distance was found, the diameter of the Sun could also be estimated using basic trigonometry using the Sun's observed angle of 0.5 degrees: Tan ¢ = Tan 0.5° = opposite side / adjacent side = Sun's diameter / distance to the Sun. Sun's diameter = Tan 0.5 (distance to the Sun) = 0.008726867 (93000000 mi) =~ 811600 mi , with a modern, actual value at: ~ 865000 mi

Roemers analysis for the speed of light was very creative and helpful, but it needed to be verified. **Armand Hippolyte Fizeau** (1819-1896), from France, made a novel, incredible and historic measurement method, and then a calculation with the measured value so as to estimate the speed of light in the year 1849. It is also of historic note that Hippolyte Fizeau and Leon Foucault took the first photograph of the Sun with sunspots on April 2, 1845. In brief, Fizeau's light speed measuring system used a high speed rotating disk that had equally spaced holes through it near its edge, much like a gear wheel with its protrusions or "teeth", and with each set being equidistant form the center of the disk. The spinning disk had to be large, and the holes farther from the center have a higher effective linear velocity than it would nearer to the center as it rotates. This device allowed for the observation and calculation of the time it took for a nearby bright light to travel to a distant location (here, about 5 miles away) and then be reflected back and seen directly through the next hole in the rotating disk. While the light is traveling, the disk continues to rotate, and that disk will only move a small angle of rotation and-or linear distance between each hole during the total time of that distance of light travel. This linear distance between each hole can be measured and-or calculated, and then the time it took for the hole to move that total distance can then be calculated.

For example: From: total distance = (speed)(total time) , we have: (total time) = (total distance) / speed :

rotation time = (total rotations) / (speed of 1 rotation) , Ex: (100 rotations or revolutions) **/** (5 rotations / 1 second) = 20s
Ex. 100 rps = 100 revolutions / 1 second , 1s / 100 revolutions = 0.01s / 1 revolution = 0.01s / 360°
= 0.0001s / 3.6° = $0.0000277\underline{8}$ s / 1°

equivalent linear time = Circumference / speed of linear travel , 1 rps = 360°/s = 2(pi) / s and 1 rps = 1C/s = 2(pi)r / s
From: time = distance / speed , solving for speed, we have for this example:
speed of light = (distance traveled) / time = is equivalent to this measurement :
= (distance of disk movement = arc length) / (calculated time of that disk or arc length movement)

Modern RADAR and-or an oscilloscope can be used to calculate the speed of radio wave (rf) and-or light energy. Fizeau measured the speed of light to be about only 4.3% greater than the modern accepted value of 186000 mi/s.

Taking Fizeau's and the modern accepted value of 186000 mi/s for the speed of light, we can then calculate and verify Earth's distance or radius of orbit from the Sun. First, as found by **Roemer**, the time difference across Earth's orbit distance is about 16.7minutes = (16.7 min)(60s/min) = 1002s , and:

Distance = (speed) (time) = (186000 mi/s)(1002s) = 186,372,000 mi : major axis length of Earth's Orbit
The above distance is like the diameter of Earth's nearly circular orbit about the Sun. Dividing this value by 2 to find the radius of orbit of Earth, we have: 186,372,000 mi / 2 = 93,186,000 mi =~ **93 million miles = 1 AU**

ORBITAL MOTION OF OBJECTS

Most orbits of the planets around are Sun are fairly circular with a low eccentricity (elongation [a greater distance than a circular radius] or shortening [a less distance than a circular radius] near the Sun). Still, all the orbits are periodic, and will predictably repeat every so many specific number of months or years. The position of a planet in its periodic orbit can still can speed up or slow down and this can make it difficult to predict an objects position. The reason for this is that the object was traveling (orbiting) around the Sun in a natural elliptical orbit with the Sun at one foci or focus point of that elliptical orbit. It is not difficult to understand that the closer the object is to the Sun, the faster it will be traveling. This is what happens when an object falls under the constant pulling influence of the force of gravity and it accelerates faster as it gets closer (perihelion) to the source mass of that gravity. Note that a circular orbit can be considered as a special instance of an elliptical orbit. It is not difficult to then understand that an object will then be traveling slower at the opposite end (aphelion) of this type of orbit, and again this is due to the constantly applied force of gravity constantly acting (pulling) upon the object and it decelerates. In 1609, **Johannes Kepler** (1571-1630), from Germany, published significant mathematical discoveries of orbital motion. Here are the three **Kepler's Laws** of orbital motion:

1. **Elliptical orbits**:
   Planets follow an elliptical orbit about the Sun at one foci point of that orbit. The speed of the object is not constant for objects in a natural gravitational induced (caused) orbit about the Sun. Speed increases near the Sun due to the increasing force of gravity of the Sun.

2. **Equal areas per same time**:
   From the orbiting object to the foci, equal orbital (planar, surface) areas will be covered in any specific amount of time.

   This coincides with a concept called **angular momentum** which essentially means rotational or orbiting momentum. Momentum = mv can be considered as a measurement of the amount of movement, and more technically, it is a measurement of the amount of inertia (resistance to a change in motion and direction) it has and the more energy required to change it's velocity and-or direction.. In terms of an orbiting body such as a planet about the Sun, the speed and kinetic energy (KE) of the object increases as it gets closer towards closer towards the Sun due to its gravity, and this "linear momentum" increases since the product of (mv) will now be larger, however, if the product now includes the radius distance from the Sun, this value is a constant (ie. "conserved" or "maintained") for the object. **angular momentum = mvr** : v and r are inversely related, and m is a constant. Note: mv = momentum . The product of (v) and (r) is a constant, and if the mass is constant, the angular momentum (mvr) value is constant for an orbiting object. If the mass of the object changes, the angular momentum will change.

3. In 1619, Kepler found that the orbital period (P) time of an object's orbit is proportional to, or directly (but not linearly) related to the objects farthest distance of the elliptical orbit. Basically, this states that more distant planets take longer to go around the Sun. For the specific and precise mathematical relationship: P^2 is directly related to the cube of (a) which is $(a)^3$. **For objects orbiting the same focus such as the Sun: P^2 / a^3 is a constant (ratio) value of 1** and regardless of its mass. **$P = \text{square-root}(a^3 \text{ au})$**. Kepler found this by applying Newtons law of gravitation, and it resulted in this equation below, and here using Earth's 1 year orbit time as a reference, and taking a ratio value:

$$\frac{(P = \text{orbital period yrs})^2}{(a = \text{semi-major axis in AU units})^3} = k = 1 \quad , \text{ or } = \frac{(\text{orbital years})^2}{(\text{average distance to the Sun in AU})^3} = \overset{\text{Ex: for Earth}}{\frac{(1\text{year})^2}{(1\text{au})^3}} = 1$$

(a) is essentially equal to the (average) radius (r) distance between the orbiting object and Sun.
Clearly, because of the definition, for Earth: $P^2 = k\,(1\text{ AU})^3. = 1$:k is a constant equal to 1 for Earth

Saturn which has an average AU of 9.537 , $P^2 = (a^3) =\tilde{}\ 9.537^3$, $P = \sqrt{9.537^3} = 29.45$ earth years (e.y.)

With Newton's motion and gravity laws in about year 1687, **Kepler's Third Law** can be shown as:

$P^2 = r^3 \dfrac{4(\pi)^2}{G(M1 + M2)}$: If M2 is a the mass of a planet or moon, its mass, maybe unknown, and is practically insignificant (as if 0kg) as compared to and-or combined (added) to the mass (Ms) of the Sun. We can let $Mt = (M1 + M2) = (Ms + 0) \cong Ms$. The multiplying factor to r^3 is a constant (k) for our solar system and Sun. Here (a) = semi-major axis of the elliptical orbit. a = r for a circular orbit, otherwise use the semi-major axis (and average orbit) distance with its regular units used, and not in (relative) AU units.

Solving for P, we have:

$$P = \text{time} = 2\,(\text{pi})\, r \sqrt{r} \;/\; \sqrt{GMs} = C \,/\, \sqrt{GMs / r} = \text{distance / velocity}$$

:use r = (a) for elliptical orbits
C = total distance traveled per orbit

From this equation, many calculations can be made about the planets and moons, such as their mass.
If needed, the mass of the Sun is: 1.989 (10^30) kg = about 2 (10^30) kg = 1 solar mass unit = 1 Msun = 1 Ms.
The mass of large astronomical objects is often measured (ie., compared to) and expressed with solar mass units.
Extra: Small, but dense stars can have as much or a greater amount of gravity than a large stare.

Kepler's Third Law is theoretically accurate, however it is only a very close approximation in actual reality due to that the gravity of planets slightly affect each other over long periods of time and so as to then be more noticeable. This is the case when trying to explain some orbit anomalies of some of the planets, and implied some unknown planets.

An object 2 orbiting about object 1 is in orbit due to the gravitational force of attraction. Object 2 is technically in a type of "free fall" about object 1 so as to remain in perpetual (non-ending) orbit, not escaping orbit, and not colliding into object 1. If you were to orbit a ball attached to the end of a string, wire or metal rod, the force of gravity between you and the object is insignificant, however, the there is a significant amount of **centripetal force** (ie., inward, centrally directed force, such as the gravity of a spherical planet or mass). This force is centrally directed about a point, and here, it is you. This force can be felt as the tension in the string pulling upon your hand, and it also pulls the same amount upon the ball in an equal and opposite manner. This force is perpendicular to the direction and motion of the ball and effectively produces a circular orbit or direction, and which can be thought of as like the average direction (like a 45° angle) due to the instantaneous forces upon it, which have a direction of straight downward (gravity) and straight horizontally (linear momentum). For a circular orbit due to a centralized force of gravity, this gravitational force can be considered as equivalent to a centripetal force:

When: centripetal force = gravitational force

$$Fc = Fg$$

, and:

$$\text{force} = (m)(a) = \frac{mv^2}{r} = mrw^2 = \frac{GM1M2}{r^2}$$

: where w is the angular or rotational velocity
v = wr , v^2 = (wr)^2 = w^2 r^2 , and
a = acceleration = v^2 / r
G is the universal gravitational constant.

$$\text{Note that angular velocity} = \frac{\text{angle traveled}}{\text{time}} = \frac{2(\text{pi})r}{\text{Period of rotation}} = \frac{6.28r}{P} = w$$

, therefore:
: t = P = T

$$\text{force} = mrw^2 = \frac{mr(2\ \text{pi})^2}{P^2} = \frac{4(\text{pi}^2)\ mr}{P^2}$$

: P is sometimes expressed as T since P is a time variable

$$\frac{4\ (\text{pi}^2)\ M1a}{P^2} = \frac{GM1M2}{a^2}$$

: after setting a=r , After solving for the P and (a) variables:
M1 = mass of the planet , M2 = Ms = mass of the Sun , and:

$$\frac{P^2}{a^3} = \frac{4(\text{pi}^2)M1}{GM1M2} = \frac{4(\text{pi}^2)}{GM2}$$

: the ratio value is a constant for our solar system with M2 = Msun , and all objects orbiting the Sun will have this same constant value for P^2 / a^3

For Earth , a = r = 1 AU , hence 1.0 = 100% of the relative distance to the Sun.

From the above equation for Fc = Fg, we have $\frac{mv^2}{r} = mrw^2$, and some variables can be solved for such as:
: r = orbit distance from the center of the Earth

$v = r w = \sqrt{GM / r}$: effective linear velocity for a object rotating or in circular orbit about another.
: This is also derived in the angles and rotation section in this book.
Also consider: $\mathbf{v = d / t = C / t = 2(pi)r / t}$: let t = Period of orbit or rotation = $T = P$
Mass of Earth = $Me = (5.9722)(10^{24})$kg , radius of Earth = $Re = r = 6378$km
Due to the inverse relationship, farther orbits with a larger radius will have a lower (ie., slower) effective linear velocity of travel, and a longer time period of orbit.

An orbiting object or mass held by gravity (ie, a centripetal force) obviously does travel in a straight line above the center point of Earth, but if the centripetal force was released, the object would leave or "escape" orbit and continue on in a straight line direction and which is perpendicular (ie., 90 degrees) or tangent to the orbit radius line at that instant.

Extra: From: $d = v t$, we have: $v = d / t = C / P$ =
= Average velocity of orbit = Circumference distance of orbit / Period time of orbit . $\mathbf{P = C / v = 2(pi) r / v}$

While orbiting, the object is always, slightly changing direction (ie., rather than going straight) in every instant of time, and for a change in direction, a force is needed such as the (constant) centripetal force due to gravity at that height or distance.

Force = (mass)(acceleration) = (mass)(change in velocity / change in time) = $(m)(v^2 / r)$:

a = (change in velocity) / (change in time)

Due to centripetal force, there is a change in direction toward the center, hence the radius (r) changes very slightly to a lesser value:

From: distance = (velocity)(time) or: (change in distance) = (velocity)(change in time) with substitution:
(change in r) = (v)(change in time) = (v) (change in velocity / a) solving for (a) , we have:

a = (change in velocity) (velocity) / (change in radius) , and for this situation with constant values for orbiting:

Since: (change in velocity) / (change in radius) is equivalent to the same ratio value of (velocity / radius) = v / r :

Then simplifying the equation for (a), it can then be shown that :

$\mathbf{a = v^2 / r}$ and that **Fc = centripetal force = ma = m v^2 / r** : $\mathbf{v = \sqrt{a r}}$ or $\mathbf{v = \sqrt{g r}}$
Such as for finding geostationary velocity when ($a=g$) is known at that altitude (r).

Centrifugal force is an outward directed force of a rotating object or material. It could be thought of as the equal and outward (from the center) opposite force of the centripetal force. It is sometimes used to separate materials that have different densities and-or to strain (ie., remove) liquids away and out from a more solid material. A motorized machine that is designed to do this is caused a centrifuge. When material is spinning like a flywheel, the outer rim portion is going at a higher velocity than the inner portion, and therefore it has more energy and pressure. This can sometimes be seen as an increase in the height of a fluid material near the outer rim, and therefore a decrease of the height of the fluid material near the center of rotation. Centrifugal force can be used to create simulated gravity for astronauts in a large rotating spacecraft.

Estimating the orbit time of a planet, and its distance from the Sun:

To make an equation for a planets orbit, the position of a planet(s) is studied and recorded for many years and the equation is refined. An estimate for the time of orbit of a planet can be made by noting how many degrees the planet has moved with respect to the background of seemingly fixed position of very distant stars during say one or several year of time, and where the Earth is at the same position every year with respect to the stars. Considering a linear or circular analysis, if the planet moved 10° degree in 1 year, how many years will it take the planet to move 360° for a complete circular orbit? We can solve this using a proportions type of equation so as to have an initial estimate of a planets orbit:

$$\frac{1 \text{ year}}{10°} \text{ is to} \quad \text{as} = \quad \frac{x \text{ years}}{360°} \text{ is to} \quad , \quad x \text{ years} = \frac{(360°)(1 \text{ yr})}{10°} = 36 \text{ years to orbit}$$

In general, the more distant the planet, the less the gravitational acceleration and-or pull force from the Sun, and the planet will take longer to orbit the Sun. Each orbiting planet around the Sun is also in a free-fall elliptical orbit about the Sun. If the planet has a greater angle of movement at each periodic time it is seen, it is in an elliptical orbit and is going closer to the Sun.

It is possible to find the current distance to a planet using trigonometry which includes two distant observers on Earth, each viewing it at a slightly different angle. For a star, visual parallax can be used, whereas the apparently changing position of a star is seen to have moved with respect to more distant, ("background") stars during, say after 6 months of Earth's orbit about the Sun, and where there is a maximum possible parallax or difference in the apparent visible angle.

Now that we can estimate the period of orbit of a planet, we can then use that value for estimating the distance to a planet with an assumed circular orbit like Earth, and this can be found using Kepler's Law as shown previously:

$$1 = \frac{\text{period\^{}2}}{\text{semi-maj. axis}} = \frac{P\text{\^{}}2}{a\text{\^{}}3} \quad : a = \text{semi-major axis of orbit, hence its average radius} = r \text{ in AU units}$$

$$a\text{\^{}}3 = P\text{\^{}}2 \quad : a = r = \text{distance from the Sun, and with AU units} \quad , (1 \text{ AU} = 93 \text{ million miles})$$

And:

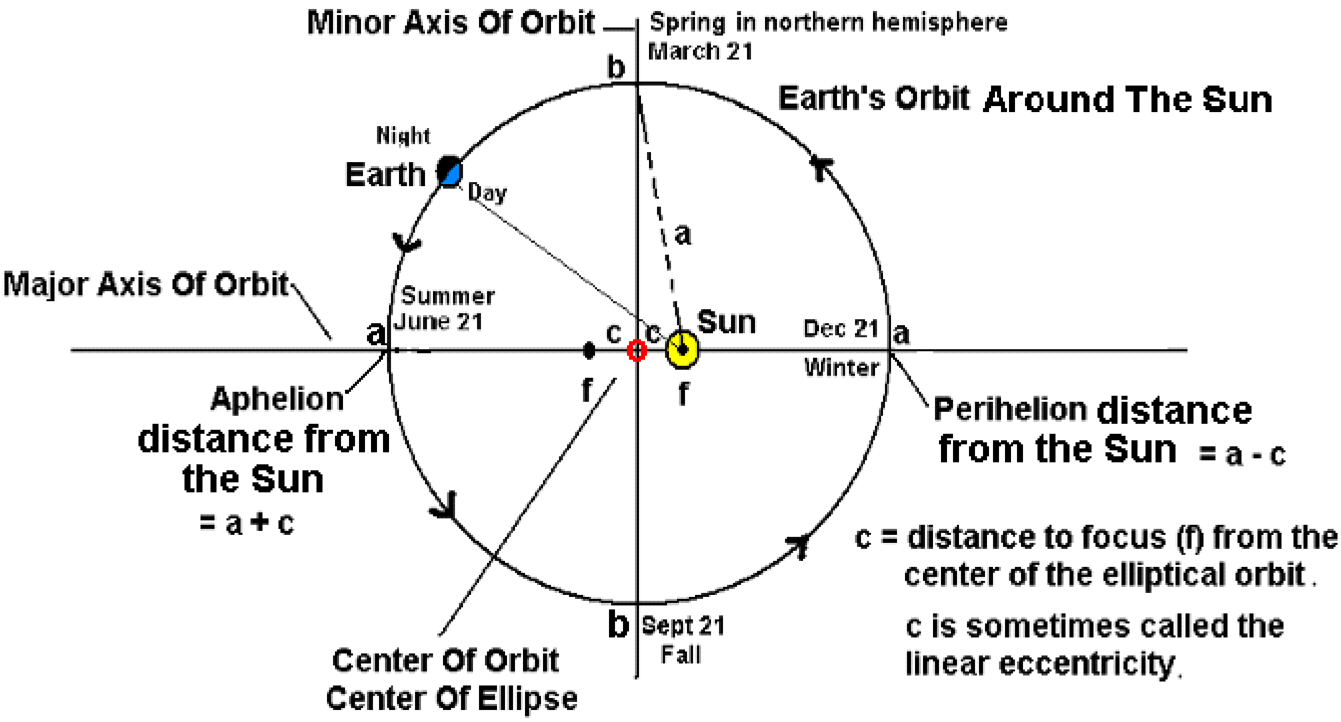
$$a = r = \text{distance from the Sun} = \sqrt[3]{P\text{\^{}}2} \text{ , and with AU units}$$

Extra: The Tides On Earth

As the Earth rotates on its axis once a day = 24 hours, the point on the Earth closest to the Moon, and on the opposite side of the Earth will experience a sea level or "tide" rise due to the gravity of the Moon attracting that water mass. The water at that location(s) will get deeper, and sometimes several feet deeper, and at several feet lower at other times of the day. The Moon also attracts the land mass of Earth just the same, but the liquid ocean and liquid interior of Earth are more easily moved because of their fluidity and-or its loose, less dense atomic structure. Due to what is mentioned, each point and-or longitude on the Earth facing the Moon will have 2 tides a day - a high tide, and a low tide. These tides actually help keep things in the ocean, and especially along the shores "churning" and "mixing", and this actually helps promote healthy life. Tides can also be dangerous if it is an "outgoing or receding" tide which can pull floating things farther out to sea. Tides can affect the bottom of a boat, essentially grounding it in shallow or no water. It is even possible to generate electricity by either water currents and-or tides. The Moon's gravity actually makes the orbit of Earth "wobble" periodically slightly nearer to and farther from the Sun, but in general, the path or orbit of the Earth around the Sun is nearly always considered as circular due to just the gravity of the Sun, and that the wobble motion is rather a negligible fraction of the distance to the Sun.

:

An illustration to describe many of the basic facts about the orbit of Earth: [FIG 257]



This view in the above image is as if looking down from far above the solar plane so as to view the entire ellipse of Earth's orbit. The image is a good and typical general approximation of Earth's orbit and the indicated days of the year.

The two foci on the major axis of an elliptical orbit are equidistant from the center of the ellipse where the major and minor axis intercept or cross. The center of the ellipse is also the center of orbit. Here (x) or the horizontal axis is the major axis, hence (a > b) and-or (b < a). Earth is closer to sun in the winter, but the northern hemisphere is effectively tilted away from the Sun. Using approximate values:

The eccentricity of Earth's orbit about the Sun is about: e = 0.01671
Earth's average orbit distance = a = (aphelion + perihelion) / 2 = 92.95M mi =~ 93M mi = major-axis / 2 = a
Perihelion distance, Earth's closest distance to the Sun is: 91.44 M mi = 93Mmi - (93Mmi * e)
Aphelion distance, Earth's farthest distance from the Sun is: 94.5 M mi = 93Mmi + (93Mmi * e)

c = Distance from the center of orbit to the focus = $\sqrt{a^2 - b^2}$ = (aphelion - perihelion) , and:

a^2 = b^2 + c^2 : c = foci distance is constant, and the length of the major and minor axis is constant, however, throughout the orbit, x or (current (a) value), and y or (current (b) value) are not constant.

$$a = \frac{\text{major axis}}{2} = \frac{(\text{aphelion} + \text{perihelion})}{2} = \sqrt{b^2 + c^2} = 92.95\text{M mi} =\sim 93\text{M mi}$$:average orbit distance from Sun

2a = total distance from any point on the ellipse to both foci = 2 (average distance) = 185.9M mi =~ 186M mi

$$\mathbf{e = eccentricity} = \frac{\mathbf{c}}{\mathbf{a}} = \frac{\sqrt{a^2 - b^2}}{a} = \frac{\sqrt{a^2 - b^2}}{\sqrt{\mathbf{a^2}}} = \sqrt{\frac{a^2 - b^2}{a^2}} = \sqrt{\frac{a^2}{a^2} - \frac{b^2}{a^2}} = \sqrt{1 - \frac{b^2}{a^2}}$$

$$\mathbf{e = \sqrt{1 - (b/a)^2}}$$

For the equivalence on the right side, since $b<a$, due to that the minor axis is always less than the major axis, their ratio will always be less than 1, and the difference from 1 of that ratio, will always be less than 1, and the square root of a value less than 1 will always be less than 1. (e) = eccentricity of an ellipse. ($e>0$) and ($e<=1$). (e) is between 0 and 1.

$e = c / a$: c = focus = (f) = $e a$, , and $a = c / e$

$$e = \frac{c}{a} = \frac{(\text{aphelion - perihelion}) / 2}{(\text{perihelion + aphelion}) / 2} = \frac{94.5\text{M mi} - 91.4\text{M mi}}{94.5\text{M mi} + 91.4\text{M mi}} = \frac{3.1\text{M mi}}{185.9\text{M mi}} = 0.01671$$

: c = center to foci = ea
a = semi-major axis
2a = major axis

aphelion + perihelion = 2a = major axis = 2(92.95M mi) = 185.9M mi
a = (aphelion + perihelion) / 2 = major axis / 2

aphelion = 2a - perihelion = a + c = a(1 + e)
perihelion = 2a - aphelion = a - c = a(1 - e)

aphelion + perihelion = (a + c) + (a - c) = a + c + a - c = **2a** : major axis
aphelion - perihelion = (a + c) - (a - c) = a + c - a + c = **2c** : distance between foci

c = aphelion - a
c = a - perihelion
c = a e = (92.95M mi) (0.01671) =~ 1.55M mi

a = c + perihelion
a = aphelion - c

aphelion distance = a + c = a + ae = **a(1 + e)** :a = semi-major axis = average or circular value, here extended by (ae)
perihelion distance = a - c = a - ae = **a(1 - e)** :a = semi-major axis, = average or circular value, here reduced by (ae)
:c = ae

2a = aphelion + perihelion = a(1 + e) + a(1-e) = a + ea + a -ea = 2a
aphelion - perihelion = a(1 + e) - a(1-e) = a + ae - a + ae = 2ae = 2c

$$e^2 = 1 - \frac{b^2}{a^2} = \frac{a^2 - b^2}{a^2} = \frac{c^2}{a^2} = \left(\frac{c}{a}\right)^2$$

: take the square root to find (e) , and mathematically:
: **e = c / a = f / a , c = e a , a = c / e**

$$b^2 = a^2 - e^2 a^2 = a^2 (1 - e^2) = a^2 - c^2$$

$$\mathbf{b} = \sqrt{a^2 (1 - e^2)} = \mathbf{a \sqrt{1 - e^2}}$$

: b = semi-minor axis , a = semi-major axis , the factor to a is < 1 , b < a
For Earth: e=0.01671 and e^2 = 0.0002792 , and:

b = 92.937M mi
Nearly Earth's average distance

$$\frac{b}{a} = \sqrt{1 - e^2} \qquad b = \frac{c\sqrt{1 - e^2}}{e}$$

(b) can also be shown to be the geometric mean of the aphelion and perihelion:

From the product of the aphelion and perihelion distances: (aphelion) (perihelion) =

$a(1 + e)\, a(1 - e) = (a + ae)(a - ae) = a^2 - a^2 e + a^2 e - a^2 e^2 = a^2 - a^2 e^2 = a^2 (1 - e^2)$

After taking the square root of the right side equivalence of their product, will result in the geometric mean type of expression of those two factors, and the result is (b) = semi-minor axis, as shown above, hence:

$$\mathbf{b = \sqrt{(aphelion)(perihelion)}}$$

For a practical verification of this, consider the special case of an ellipse where the aphelion = perihelion = radius = r, and this ellipse is actually a circle:

$$b = \sqrt{(r)(r)} = \sqrt{r^2} = r = a$$

In a similar manor to a previous derivation of (b) shown above: $\mathbf{a = \dfrac{b}{\sqrt{1 - e^2}}}$: the den. is < 1, therefore, a > b

If we let: $\mathbf{N} = \dfrac{\mathbf{aphelion}}{\mathbf{perihelion}} = \dfrac{a(1 + e)}{a(1 - e)} = \mathbf{\dfrac{(1 + e)}{(1 - e)}}$, also note here for example: aphelion = perihelion $\dfrac{(1 + e)}{(1 - e)}$

$N(1 - e) = (1 + e)$
$N - Ne = 1 + e$
$N - 1 = e + Ne$
$N - 1 = e(N + 1)$ and: $\mathbf{e = \dfrac{(N - 1)}{(N + 1)}}$: this value is always less than 1 as expected for (e)

The speed (Vp) of the orbit of Earth around the Sun will be the greatest when it is the Sun at perihelion, and the slowest speed (Va) when it is farthest away from the Sun at aphelion. The average or linear speed of Earth's orbit about the Sun can be calculated as:

$$Vo = \frac{\text{distance}}{\text{time}} = \frac{(2)(pi)(r\ mi)}{365.25\text{days}} = \frac{(2)(3.14159265)(92.9M\ mi)}{365.25\text{ days}} = \frac{583.708M\ mi}{365.25\text{ days}} = \frac{1.5981M\ mi}{1\text{ day} = 24hr} = \frac{66588\ mi}{1hr = 3600s}$$

$Vo = 18.497 mi/s \approx 18.\underline{5}\ mi/s$

Due to the force of gravity increasing nearer to the Sun, the average speed of orbit will increase by a factor of (e) at perihelion:

$Vp = Vo + \text{increase in } Vo$

$Vp = Vo + (Vo\, e) = Vo(1 + e) = 66588 mi/h + (1 + 0.01671) = 66588 mi/h\ (1.01671) = 67700 mi/h = 18.81 mi/s$

The average speed of orbit will decrease by a factor of (e) at aphelion:

$Va = Vo + \text{decrease in } Vo$

$Va = Vo - (Vo\, e) = Vo(1 - e) = 66588 mi/h + (1 - 0.01671) = 66588 mi/h\ (0.9833) = 65476 mi/h = 18.19 mi/s$

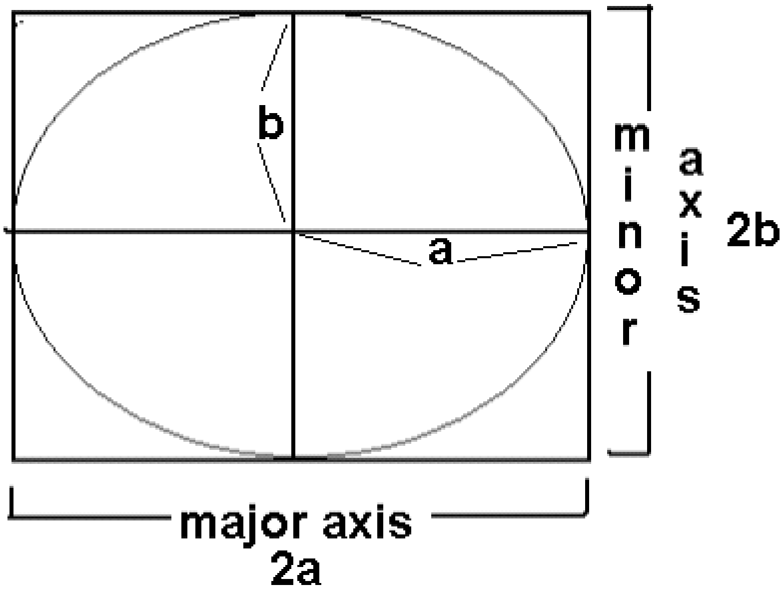
The distance between every planets can vary significantly throughout both of their elliptical orbits. For example, if a planet is on the same side of the Sun as Earth is, it will be closer to Earth, and it will be seen as bigger with a telescope, perhaps twice as big such as with planet Mars which is relatively close to Earth as compared to the more distant planets.

Most tables of information about the planets state the planets average orbit distance, and on occasion, you may need to know its actual position, and or its aphelion (farthest from Sun) and perihelion (closest to Sun) distances. As shown previously:

aphelion = 2a - perihelion = a + c = a(1 + e) : a = semi-major axis and average orbit distance
perihelion = 2a - aphelion = a - c = a(1 - e) c = distance from center of orbit to focus (Sun)
e = eccentricity of orbit value

THE PERIMETER AND AREA OF AN ELLIPSE

Although there are several successive approximation formulas, there is no simple and exact formula for the perimeter of an ellipse and-or the length of an elliptical orbit. The successive approximation formulas involve an infinite series of terms where the approximation gets ("converges", "approximates") closer and close to a specific value and true result.
[FIG 258]



$$\frac{\text{minor axis}}{\text{major axis}} = \frac{2b}{2a} = \frac{b}{a}$$

For a circle with e=0, the perimeter = circumference = 2(pi)r = 2(pi)a =~ 6.283$\underline{2}$a, where here (a)=the semi-major axis, and for a ellipse approaching a line shape with e=1, the perimeter approaches 4a. The ratio of these two values is a constant of about 0.66366$\underline{2}$ or its reciprocal of: ((2)(pi)(a)) / (4a) = **(pi) / 2** = (3.14159...) / 2 = 1.57$\underline{1}$. It is also of note that the ratio of the ellipse perimeter to that of corresponding rectangular perimeter will go from 1.57$\underline{1}$ at e=0 (ie., a circle) to 2 at e=1 (ie., a line). For a circle: a = b = radius = r , and (b / a) = 1 , but for an ellipse where b<a , then (b / a) <1 .

If the major and minor axis of an ellipse are changed by the same factor (n), their ratio will still be the same since it would create an equivalent fraction, and the perimeter of the ellipse will change by that same factor. Both of these ellipses will be similar ellipses that are simply like a magnified version of each other. The area of the ellipse will change by the square of this factor = n^2.

The author of this book has developed a crude formula for the perimeter length of an ellipse, but it is generally only close to the correct value when (b/a) <= 0.5, and the eccentricity (e) is then a fairly high value, say > 0.8. This formula is based on the above reasoning such as the difference between 6.2832a and 4a is 2.2832. This formula is initially based on the perimeter of the associated ("unsquashed", full amount) circle where r=a=semi-major axis, and it then includes a correction or adjustment. This formula is only a crude estimate, and should rather not be used:

An experimental formula for consideration and in general, DO NOT USE THIS FOR THERE ARE BETTER WAYS:
Rough Approximate Perimeter Of An Ellipse = $\frac{C}{e}$ - 2.2832a : typically where (b/a) <= 0.5, and where e >= 0.8,
, and-or its reciprocal where (a/b) >= 2 , and:
: C = circumference = perimeter = 2(pi)(a) , and

: (b) is not explicitly in this formula, but is in (e)

For lower eccentricities, where the ellipse is closer in shape to that of a circle, the above formula should rather consider Ce and not C/e as the basis of it, and due to the fact that when (e) is low, the value of (C/e) is very large. It is recommended to use the standardized formulas below for the perimeter or circumference of an ellipse:

Sir Ramanujan , is a historic mathematician from India and with a significant volume of work and with many being practical, created an amazing and very practical formula for the approximate perimeter length of an ellipse (such as of orbiting planets, etc.), and it has very good accuracy, and without using the somewhat complex mathematical summing series created with many divisions needed. It is also of note that this formula does not explicitly or directly use the variable (e) = eccentricity, however, the axis variables (a) and (b) are used which do actually define the value of (e):

$$Pe = (pi)(a + b)\left(1 + \frac{3h}{10 + \sqrt{4 - 3h}}\right)$$

: **Perimeter Of An Ellipse** , credited to **Ramanujan** from India
h = (a - b)^2 / (a + b)^2
Note here: a = semi-major axis , b = semi-minor axis ,
For a circle: a=b=r , h=0 , P = (pi)(r + r) = (pi)(2r) = 2(pi)(r)

It is conceivable that the distance between every two successive, very close points on the ellipse can be summed together so as to find the perimeter. This is can be done with a computer using the ellipse equation and the distance between two points equation. Since the ellipse is symmetrical about both axes, only one quarter of its perimeter, such as from x=0 to x=semi-major axis, needs to be found and then multiplied by 4 to find the entire perimeter value.

The author has found a very slight correction or adjustment value for (h), and which will improve the calculated perimeter result slightly, and particularly for when the eccentricity is high, and that is: h = h + (h)(0.0016523164869) =
= h (1 + 0.0016523164869) = h (1.0016523164869)

For the **area of an ellipse**, first consider the area of a circle being: A = (pi)r^2 = (pi)(r)(r) , and that we can find the area of an ellipse by letting one variable r=a=semi-major axis, and the other variable r=b = semi-minor axis::

The area of an ellipse is: **Ae = (pi) (semi-major axis)(semi-minor axis) = (pi) a b**

: **Area Of An Ellipse** , and here:
a = semi-major axis
b = semi-minor axis
For a circle: a=b=r , A = (pi) a b = (pi) r^2

There is a constant ratio value of the area of an ellipse or circle to that of the surrounding rectangular area with the same dimensions as the major and minor axes, and this value is: **ka = 0.785398163397448** , and this value happens to be the corresponding radian angle of a 45 degree angle, and it is also equal to: **(pi) / 4**. **Area of corresponding ellipse = (ka) (Area of corresponding rectangular area).** 1 / 0.785398163397448 = 1.273239545

The ratio of perimeters is not a constant but has a range from about 1.57$\underline{1}$ = (pi/2), to 2.0 as mentioned above, and the ratio of the two extreme values of this range is also k = 0.785398163397448. The perimeter of the ellipse within the rectangle will always be larger than the perimeter of the surrounding, corresponding rectangle. The area of the ellipse within the rectangle will always be less than that of the area of the rectangle.

One might ask, what are the dimensions of the axes and-or corresponding rectangle when **e=0.5** (ie., half of the maximum value of 1)? The answer to this is interesting, and it is when the ratio of **(b/a)** is nearly equal to: (epsilon / (pi)) = (2.718281828 / 3.141592654) = 0.865255979, and this is =~ **0.866025403** = sin 60°, and is nearly equal to the (square root of k) = 0.8662269254527578. Here, the ratio of the perimeter of the ellipse to that of the circumscribing or corresponding rectangle is about 1.5728246008$\underline{1}$ ~= (pi/2).

When the ratio of **(a/b =2)** and-or **(b/a = 0.5)**, e = 0.866025403 = sin 60° = square-root of (0.75). When **a/b = 2** and-or **b / a = 0.5** and-or **b/a=2,** that is, one axis is twice as long as the other, the ratio of the perimeters is a constant of: **1.61481450996017**. Another observation is that epsilon (e) is about equal to (pi) (sin 60°). When (b/a = 0.25) and-or (a / b = 4), the area is equal to (pi)(b^2).

When a=b, the ellipse is a circle and has the smallest perimeter for that value of: 2(pi)(r) = 2(pi)(a) = 6.283185307a. As (b) gets smaller for a given value of (a), the perimeter of the ellipse will decrease to its minimum value of 4a where (a) is the semi-major axis, and (b) will be equal to 0. When **a=b**, the ratio of the perimeters is a constant of: Pe/Pr = **1.570796325** = (pi)/2. The above ratio leads to the conclusion that when the ratio of (a/b) and-or (b/a) is a certain constant value, the ratio of the perimeters also has a specific constant ratio value.

When **a=b**, the ellipse will have an **e=0**, and it will be a circle shape and have the maximum area for a given value of (a). A = (pi)(r^2) = (pi) (a^2) where here, (a) = (radius = (r) of the circle) =semi-major axis. As (b) gets smaller, approaching 0, the area of the ellipse will also approach 0 and **e=1**, as for a line.

When **(b/a)** is about 0.66, and-or (a/b) is about 1.5, **(e) =** about **0.75**. A more precise ratio value is (b/a) = **0.661437827**.

When **(b/a)** = **($\sqrt{2}$ / 2) = 0.7071067811865475 , (e) = 0.7071067811865475 ,** and the **focus = b** , (a/b) = 1.414213562

Extra, from: Ae = (pi) (semi-major axis)(semi-minor axis) = (pi) a b , the ratio of the ellipse area Ae to that of the semi-minor circle area is: (pi) (semi-major axis) (semi-minor axis) / (pi) (semi-minor axis)^2 =
= (semi-major axis) / (semi-minor axis) , ex: a / b , 10 / 2 = 5 , hence the ellipse area is 5 times more.
Likewise: (semi-major axis circle area) / Ae = (pi) (semi-major axis)^2 / (pi) (semi-major axis) (semi-minor axis) =
(semi-major axis) / (semi-minor axis), ex: a / b , 10 / 2 = 5 , hence the circular area is 5 times more.
For circles, when r=radius changes by a factor of (n), the circumference (C) will also change by that same factor of (n), and the area (A) will change by the square of that factor of (n), and which is (n^2).

According to Kepler's Law about equal areas (and not equal angles) of an ellipse being traversed during equal time of an orbit about the focus (such as the Sun), this total area can be divided by the (average) time of orbit so as to find out the area segment of the ellipse traversed per unit of time:

$$\frac{\textbf{(ellipse segment area)}}{\textbf{time}} = \frac{\textbf{(total Area of elliptical orbit)}}{\textbf{(Period of orbit)}} = \frac{\textbf{ellipse segment area}}{\textbf{unit of time}} = \textbf{a constant for this ellipse}$$

As for finding the **average velocity** of an orbiting body such as a planet, and since the velocity is always changing due to gravity and especially when it is near the focus of the orbit such as the Sun where the gravity force is higher:

$$\text{From distance = velocity x time ,} \quad \textbf{v av.} = \frac{d}{t} = \textbf{v av.} = \frac{\textbf{Perimeter of ellipse orbit}}{\textbf{Period of elliptical orbit}} = \frac{\textbf{average distance traveled}}{\textbf{unit of time}}$$

Extra: Of possible use: Area / time = A / (d / v) = Av / d = d^2 v / d = dv = (vt)v = v^2 t

Extra: For some computer program which require quick graphics or image displays, there is fast algorithms (steps or sequence of computer instructions or program code) developed to display many common geometric shapes such as a line, circle and ellipse. These algorithms are based on integers values, rather than the slower floating point (true or "real" [in reality, possibility], decimal values with a fractional part) values. These algorithms work because the pixels or single dots on the screen have coordinates (ie., like address locations) that are numbered and accessed as successive integers. **Jack Bresenham** from the IBM (International Business Machines) company is credited in 1962 to the initial (Bresenham's) **line algorithm** for drawing-printers and-or for computer graphics today. This algorithm is "fast" so as to facility graphics (computer drawings, typically shown on a viewing screen or "TV") appearing more quickly and realistically when needed. It is of note that some computer languages, such as C, as standardized by an ANSI standard, do not include graphics functions (ie., to set pixels and-or colors, draw lines and curves such as circles, etc.), and it is up to the compiler to do so, such as by including functions to draw graphics on the computers viewing screen if the computer is capable of displaying graphics, such as when it has a graphics card (ie., circuit). An example of a function to set a single pixel on the screen would be something similar to: setpixel(horizontal position, vertical position, color)

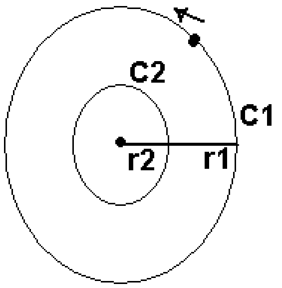
A note and example about angular momentum.

Angular momentum can be considered as a measure circular or orbital momentum, and-or circular or angular motion in general. Consider an object having a momentum of p = mv, and it is orbiting about a planet at a far away distance. If that object were to then be placed closer to the center of its orbit, its momentum is still the same if it has not gained any more energy or momentum along the way. Its momentum is still p = mv, and this is generally called an example of the concept of **the conservation of momentum**. Its velocity will remain the same, but its angular velocity will increase and it will make a complete orbit much faster now. An example of this would be where a ball is attached via a thin string to a rod or pole in the ground. The ball is then thrown so as to orbit about this pole. Meanwhile it is orbiting this pole, it is also getting closer to the pole because the string is getting shorter as it wraps around that pole. The ball will orbit much faster and give the appearance that it is actually going faster in terms of effective linear velocity = d/t, but it is rather the angular, circular or orbital velocity = (angle / second) and-or (rotations or orbits) / time that has increased, and it is still going the same linear velocity as that in its far away orbit.

For an orbiting object, if (r) decreases by (n), the circumference or distance of that orbit decreases by (n).

$$C = 2(pi)r \quad , \qquad \frac{C}{n} = \frac{2(pi)r}{n} = 2(pi)\left(\frac{r}{n}\right)$$

Given a constant velocity for an orbiting object with momentum = p=mv, if the orbit distance or radius of orbit is now (n) times less, the orbit distance (ie., C) is now (n) times less, and the orbiting time is also (n) times as less, and the angular velocity (ie., angle / time and-or rotations / time) is now (n) times more. If the orbiting object has not gained or lost any kinetic energy, its velocity will still be the same as that of the distant orbit, and its momentum will still be the same value. The following analysis may also be helpful to this subject: [FIG 259]



In the above figure, an object is in a circular orbit with a circumference of C1. It takes 1hour = 1h for the object to make an orbit. From d=vt ,its velocity is:

$$V1 = d / t - C1 / 1hr = 2(pi)(r1) / 1hr$$

In terms of rotations (rots), revolutions (revs) or full-orbit velocity (Vo):

$$Vo = 1 \text{ orbit} / hr = 1 \text{ rot} / 1 hr = 1 \text{ rev} / 1 hr = 1 \text{ cycles} / hr = 360° / 1 hr = 2(pi) \text{ radians} / 1 \text{ hour} = 1 \text{ wave} / 1 hr =$$
$$= 1 \text{ repetition} / 1 hr = w = \text{angular or circular velocity}$$

If (r) is changed by (n), either as a numerical co-efficient factor or divisor, C1 is then changed in the same way by this value of (n). If (r) is decreased by a factor of 2, hence (r/2), then C1 will also decrease by 2 to be a value of say C1/n = C1/2 = C2 in the above figure. Given the same velocity (V1) and time of 1 hour, the number of orbits with each being equal in length to C2 will also increase by the same value of (n):

$$\text{From } C1/n = C2 \quad , \quad C1 / C2 = n \quad , \quad \text{checking: } \frac{C1}{C2} = \frac{2(pi)(r)}{2(p)\left(\frac{r}{n}\right)} = n$$

$$C1 = n\,C2$$

same distance = same distance

And this implies that during the same time (t) necessary to orbit C1 , there would be many (ie., n) orbits of C2.

From $d = vt$ and $\frac{d}{t} = v$, Since a circumference is a distance: $C = vt$ and mathematically: $\frac{C}{t} = v$

From $C1 = n\,C2$ and dividing each side by t, we have:

$\frac{C1}{t} = \frac{n\,C2}{t} = v$: same velocity if no forces have act upon the object, and which would then change its speed or direction. This is mathematically equal to:

$V1 = V2$

same velocity = same velocity = v : linear or distance related velocity

Though the linear velocity is the same, the angular velocity = w/t is not the same. In the same amount of time, there will be (n) orbits associated with the object and C2, and its angular velocity will be (n) times greater:

$$w = \text{angular velocity} = \frac{\text{amount of rotation}}{\text{time}} = \frac{\text{orbits}}{t}$$

For the object in the orbit of C2, in the same time it takes to orbit at C1, it will make (n=2) complete orbits, hence it will go a total amount of rotation measured in degrees for (n) = 2 rotations.
Total Degrees = orbit1 + orbit 2 = 360° + 360° = (n orbits) 360° = (2)(360°) = 720°

$\frac{2 \text{ rotations}}{1 \text{ rotation}} = \frac{2 \text{ orbits}}{1 \text{ orbit}} = \frac{720°}{360°} = 2 = (n)$: after the same time duration or period
For the expressed ratio of angular velocities:

$$\frac{w2}{w1} = \frac{\frac{2 \text{ orbits}}{t}}{\frac{1 \text{ orbit}}{t}} \text{ or } = \frac{\frac{720°}{t}}{\frac{360°}{t}} = 2 = (n)$$: ratio of angular velocities

If (r) decreases by a factor of (n), the angular velocity increases by (n): $w2 = (n)\,w1$

A COMPUTER PROGRAM FOR THE PERIMETER AND AREA OF AN ELLIPSE

```
/*----------------------------------------------------------------------------------------------------
EllipsePerimeterAndArea.c

        A program to input the major and minor axis lengths of an ellipse, and
        the perimeter of that ellipse will be calculated using Ramanujan's
        practical formula, that is perhaps easier than using the summation
        method (by hand and pen) with more mathematical divisions needed
        to make that method of calculation.  The area of the ellipse is also
        calculated.  Other values are also calculated.   You may wish to modify
        the program to reduce input errors, and also to display the perimeter
        values when the value of (h) in the perimeter algorithm is not used, and
        then when used.

Corresponding Rectangular Perimeter = 6

Ellipse Area = 1.5707963267949
Corresponding Rectangle Area = 2

Ratio Of Ellipse Area To The Rectangle Area = 0.785398163397448
Ratio of Ellipse Perimeter To The Rectangle Perimeter = 0.807407255798853

Press A Key To Continue, or ESC to exit:
```

Extra: If both the axis (a and b) of the ellipse increase by the same factor value of (**n**), it essentially results in a magnification of that ellipse, and both the perimeter and focus (c) of it will be magnified or increased by that same value of (n). The area of the ellipse will increase by (n^2). **Both ellipses will have the same eccentricity = (e)** because the ratio of the axes (a/b) is still the same value. The outer rectangular perimeter will increase by (n) and its area will increase by (n^2).

ACID AND BASE

This discussion here about "acid and base" is only intended to be a simple and practical one for most people, yet it is still enough for most people to consider so as to have enough basic knowledge about it, and to then consider if they need to learn more about it elsewhere.

SEVER DANGER AND HEALTH WARNING: When working or using chemicals such as acids and bases, **wear proper and-or expendable clothing**, **gloves, breathing and eye protection**. Some chemical reactions or processes are very fast and can produce a lot of heat and gas when energy is released in a short amount of time, and hence they can be explosive (ie., rapidly expanding) and-or combustible, and cause injury, damage, and-or a fire. Rinse protective gear (clothing, eye protection, hand protection, etc.) them off thoroughly in water if it is permitted to reuse them again. Inspect them for tears, loose seams and holes, and are good working order. It is recommended to keep all chemicals and cleaning products hidden and out of reach of curious children and pets. If an accident happens, seek medical attention immediately; dial **911** (in U.S.A.) on a phone (unpaid phones still allow 911) for the emergency and so as to receive help. **A common and fast treatment for many chemical burns of the skin and-or eyes is to gently rinse (do not scrub) the area for up to 20 minutes using cool uncontaminated water poured over the area and-or shower in cool to warm water.** A fire extinguisher and-or a water-hose needs to be considered for some experiments involving heat and-or fire. Also, keep curious people and pets away from the experiment and-or work areas, have signs indicating the danger and to keep out, and properly clean up and dispose of any debris. **Properly label each chemical and-or mixture, usage, and potential dangers.**

The concepts of electric charges, acids and bases are widely used in the field or study of chemistry. An acid or base are general classifications given to substances, often in liquid (aqueous [aq], water) or dissolved form, which can help a chemical reaction take place due to a transport medium such as water. A common and rechargeable lead-acid (lead metal in an acid electrolyte) battery in an automobile has an electrolyte solution between its internal metal plates of each cell, and it is an acid solution, usually (dangerous) sulfuric acid (H2S1O4, hydrogen, sulfur and oxygen, avoid contact and-or inhalation, wear protection). The fluid substance or medium helps the distribution and mobility (ie., travel, movement) of all the atomic parts (molecules, protons, electrons) of the acid or base solution and substance(s) in it. The **pH scale** is a measurement of the strength (ie., "chemical power" (p) or "chemical potential ability", particularly of the hydrogen ions which are only protons, and without any [electrically balancing or neutralizing] electrons) of an acid or base aqueous substance. In short, the pH scale could be described is a measure how how acidic a substance is due to each substance having some level of hydrogen proton activity..

A neutral ("neutrally charged", or "balanced") atom has the same number of protons and electrons, and is said to be electrically neutral or chemically stable. When the number of electrons and protons are not the same in an atom, that atom is called an **ion**. Often an ion is positively charged since the atom is missing an electron in its orbit. An atom is said to be an **isotope** if the number of its neutrons has changed and this will also change the physical properties of that atom(s), material, substance, but the chemical and-or electrical properties of isotopes of the same atom are fairly similar.

An **acid** substance has or causes an abundance (ie., extra) of protons (ie., hydrogen ions) and can effectively release or "donate" them when that acid is put in a water solution, and so as to then have "balanced" or neutral atoms that have no net electrical charge. The abundance of protons is due to positive hydrogen ions (H+) that lack an electron because it has moved elsewhere, and what remains is a proton with a positive (+) charge. A free moving proton has much more mass than an electron and therefore, it has a higher kinetic energy than an electron, and can do more damage (via collisions, and freeing some electrons) and dissolve things. A proton also attracts electrons, and this can **dissolve** and-or break apart atomic structures, such as crystal bonds and-or molecular bonds at the boundary or surface layer of the acid and material, and then continue to dissolve the material. To make an acid solution, electrons need to be removed from it so as to have an abundance of protons. When an acid molecule disassociates (breaks apart) in water, it creates protons (+ , positive charge) particles, and anions (- , negative charge) particles from that acid molecule.

A **base** substance has a lack of protons and can "accept" them so as to become neutral atoms. A base substance has an abundance of electrons, and can release hydroxyle (hydroxide, OH^-) ions. As indicated by the sign, this molecule has a negative electrical charge, hence has more electrons than protons.

To determine how acidic or basic a substance is, a certain amount of it is dissolved in an aqueous (ie. aqua, "watery", liquid) solution such as a certain amount of pure water, and a pH measurement is then taken. This measurement is called a pH measurement and means: **pH** = **p**otential (strength) **H**ydrogen, and which for here, it is the hydrogen positive ion level in a substance, hence the proton and-or acid level. A positive hydrogen ion atom is indicated as: H^+, and which is actually just a single proton that has lost its electron, but can electrically attract one back into orbit around it. The pH scale of values is a "relative" (roughly, non-exact) type of logarithmic scale with a numeric base of 10. **Each integer increase or decrease in this scale means that the substance is now considered 10 times more or less of an acid or base than the previous value, hence the hydrogen ion concentration will change by a factor of 10.** This "small" logarithmic scale is needed due to the potentially high number (up to trillions) or concentration (ex. mol units) of atomic particles (H^+ protons from an acid, or OH^- from a base) involved. **OH^- is a hydroxyl ion** that consists of a bonded hydrogen and oxygen molecule, somewhat like a water molecule (H20) but having just one hydrogen atom, and is (net) negatively charged and is the main component of a base substance. A proton, being positively charged electrically, can attract electrons or molecules that are (net) negatively charged. These attractive or repulsive forces are very strong when the distances are small, and an acid can then (atomically, electrically) dissolve or separate objects such as molecules of a substance, and back into the atoms that composed it. A single proton when unbound to a neutron, nucleus, rigid crystal or molecule structure, is then able to easily travel about due to electric charges and-or forces influencing it to move.

The pH scale is currently defined as from 0 to 14 only. The pH scale was invented in 1909 by chemist **Soren Sorensen**. The formula for pH was made so that all the values (0 to 14) are simply positive in value and that water being nearly neutral (here, being a very weak acid, and very weak base) is in the middle of this range with a pH of 7, but it is still able to dissolve (ie., "corrosive") some materials over a length of time due to hydrogen ions (H^+, which are protons, and which have a positive electrical charged). Warmer water also has more hydrogen ions, and which will then also dissolve or loosen some materials faster. To help rationalize this strange valued scale, this scale can be somewhat thought of as the relative value or concentration of $[OH^-]$ in the substance. A pH of 0 means no concentration of $[OH^-]$ as expected for an strong acid substance which has plenty of protons. A pH of 14 means an incredibly high, maximum concentration or count of $[OH^-]$ as expect for a strong base substance that has plenty of electrons.

A pH value (the "**p**otential" of hydrogen, and-or its protons) to dissolve things for an acid is low because its ability or activeness to dissolve itself is low. A base substance, or even other acids rated with a higher pH, will have a higher pH rating because the ability of the (hydrogen, proton) acids ability to affect (chemically, electrically) it is higher.

Technically, a pH value is calculated as the negative of the logarithm (ie., an exponent value) of the hydrogen ion concentration amount. This concentration amount is measured in gram-moles per liter. The actual volume or amount of an acid substance in a solution will also determine the number of hydrogen ions (ie., protons) available and how active (dissolve-ability) that acidic solution is. In a way, the pH value indicated on the scale can be thought of as an inverse relative value or indication of the dissolving-ability of that specific acidic substance when it attracts electrons to it and pulls apart (ie., "dissolves") molecules. The pH scale is generally considered as an indication, ability or potential of a (aqueous, watery mix of) substance to attract protons and-or release electrons. Bases have a high pH, and the higher base pH, the more that the substance is affected by an acid and-or any substance with a lower pH including water with a pH of 7.

Hydrogen ion or proton concentration has units of: (moles of the mass of the ions in grams) / Liter

pH = - log (hydrogen ion or proton concentration in the solution) = $-\log[H^+] = -1\log[H^+] = \log[H^+]^{-1} = \log[1/H^+]$

Mathematically: (hydrogen proton or ion concentration in a liquid solution) = $10^{(-pH)} = \dfrac{1}{10^{pH}}$

> From the above formula , note that pH is a logarithmic value, and we see that the lower the pH, the higher the hydrogen ion or proton concentration.

Adding water to an acid will decrease the hydrogen ion concentration or amount of ions in the solution, and the pH of that solution will increase. As more and more water is added, the pH of that solution will become close in value to that of water which is 7.

A base has a pH greater than 7, ex: calcium carbonate, baking soda (sodium bicarbonate, pH=8), bleach, etc. Plain or pure water is said to have a pH of 7, since it does have some equal (neutral) amount of both hydrogen ions (ie., protons) and hydroxyl ions, and hence having a low dissolving ability with the relatively few positive hydrogen ions available, and the pH is considered as 7 (ie., in the middle) on the pH scale.

Pure water is said to have a "self ionization" process, and even has a very low electron (-) conductivity. In a volume of 1 liter of water, there is a concentration of about 10^-7 mols of hydrogen ions (H+):

pH water = - log 10^-7 = (-1)(-7) log 10 = +7 (1) = +7 : the log exponent rule was utilized here for simplification

An acid has a pH of 6 or lower. ex: vinegar and lemon juice. Vinegar, such as clear white "5%" acetic acid and the remainder being water. Common household food vinegar is sometimes called a weak acid and has a pH of about 2.4

min. pH				max. pH
0	**pH < 7**	**pH = 7**	**pH > 7**	**14**
	acid	**neutral**	**base**	

Pure hydrochloric acid (HCL, hydrogen and chlorine atoms combined into molecules, and creating a very strong or active acid) is rated and standardized as having the lowest pH of 0. Most soaps for household cleaning have a high pH, and are therefore a base substance.

If the hydrogen ion or proton activity in a solution is less than that of pure water, the solution is a base solution and its pH is actually greater than 7 according to the pH formula.

Acid substances can release or "donate" hydrogen ions (H+, protons) into a water solution. Base substances can release or "donate" hydroxide ions (OH-) into a solution. Acid solutions are highly chemically "active", and can atomically, electrically attract and break apart atomic bonds and therefore dissolve other substances such as molecules of compounds and crystallized elements (such has metals) into smaller particles and-or atoms or ions. Consider that a hydrogen ion (H+) is electrically positive and can attract loosely bound electrons (electrically negative, -e) of other substances, and this leads to molecules, and crystals of even a single elements having their atomic bonds broken apart, and that material or substance will then dissolve by and into in the acid solution.

Note that hydrogen atoms are also the smallest atoms and they can more easily "go through" other substances and materials than the atoms of any other type of element. This makes confining hydrogen gas a problem that needs to be resolved, such as for potential spaceflight use.

For some plants to grow well, they may need or favor a particular soil pH, climate, water availability, etc. Litmus paper "(pH) test strips" can measure, indicate and help determine the pH (via color of the red and blue dye-chemical coated wood cellulose papers) of a uniform or consistent (well mixed - "homogeneous", sometimes with a measured dilution of the solution, average) substance. A blue colored test strip will turn a shade of red in an acid solution. It is even possible to make these test strips at home with fairly common substances. Electronic pH meters are also available. Some of these have metal probe(s) made of non-reactive (ie., chemically stable) platinum metal, and less inexpensive pH meters may use some other inexpensive metal with similar characteristics. Acids and bases can dilute (ie., weaken by reducing the amount of a substance in a mixture) and even neutralize each other to a pH of 7 and actually produce some water (H20) if the cation (see the text below) is from an acid, and if their relative strengths are the same and-or the amount of each substance used is enough to essentially create the neutral state or a certain pH value desired. If the cation is from a base element such as a metal, a solution of an acid (such as having hydrogen protons) and that base metal will produce a (electrically neutral, "neutralization reaction") **salt which is formally defined in chemistry as a molecule composed**

of both a positive ion and a negative ion. This molecule is an ionic compound. Also produced is hydrogen gas, rather than water molecules. **Sodium-chloride (NaCl)** is a salt commonly known or called as table salt or food salt, and it is composed of both (metallic) sodium ions which are positive, and (non-metallic) chloride ions which are negative. Each sodium chloride molecule has one atom of sodium and one atom of chloride, hence a 1 to 1 ratio. Table salt is a hard and clear (stone, mineral) crystal if it is pure.

Cleaning **soap** is a (chemical, not specifically table-salt) salt substance made from sodium or potassium hydroxide as the (pH) base metal, and biological (organic, usually from plants, and therefore it containing some carbon) fats and-or oils which are also called "fatty (pH) acids". To clean things, a soap essentially weakens the bonds of oil molecules, and this will allows oil debris to be more easily removed from things, and then clean water is typically used to flush away the loosened oil and debris which also get partially dissolved by water itself. Dampening or soaking items in water for an amount of time is a helpful measure to soften debris before removal and-or cleaning.

An ion that is positive in charge is called a cation. An atom that looses an electron(s) is a positive ion, such as a hydrogen ion (H+) and of which is actually a single proton. Cation (ie., cathode metal ion) is a word similar to the word cathode which is an electric terminal point such as on a battery or wire. A cation can be created from a metal atom. **An ion that is negative in charge is called an anion** (ie., anode metal ion). An atom that has gained an extra electron(s) is called a negative ion. Anion is a word that is similar to the word anode which is an electric terminal point such as on a battery or wire. An anion can be created from a non-metal atom. Hydrogen is an atom that can be a cation or anion.

Both acids and bases are often dangerous because they can chemically "burn" and-or dissolve things and release large amounts of energy in a short amount of time (ie., high power, watts = joules/second), often in the form of heat, during the fast chemical reaction(s) taking place. This is also called a "chemical burn" or "caustic burn" such as when it injures someone.

The small amounts of acids and bases that humans do consume in foods is relatively weak and near the pH of water at 7. The pH of lemon juice that is generally known as a "weak acid" is about 2.5. A lemon or other citrus fruits have a "sharp", "tangy" or "sour" taste due to the citric acid in them, and the Latin word "acid" basically means "sharp" and-or "sour" tasting. Consuming some foods can cause and-or aggravate (painful, burning) heartburn and-or other digestive issues and teeth erosion. If you have this, a quick remedy is to drink something that does not have any acid in it and so as to reduce and-or "neutralize" the level of acidity in you. There are medications (prescribed by your doctor, and-or "over the counter" types without a doctors prescription needed) available so as to occasionally (when absolutely needed) prevent excessive acid from even being produced by the body for digestion, and so as to have much more control of the problem and possibly prevent it or reduce its severity. The pH of the human stomach, is about 2.5 on average, and it is a moderate level of acid so as to aid digestion by reducing all types of possible germs, and for pre-processing or preparing the nutrients in the food for absorption into the body through the walls of the intestines.

Bases, such as sodium hydroxide (ie. "lye" = "caustic soda"), can be used to break down fat molecules in a process called saponification **(**non-formally: that which produces a sap-like textured substance like feel of the semi-solid sap from a tree, and another similar definition is the "hardening" or "firming" of a substance**)** and is used to make soaps and with **glycerol** (C3O3H8, or "**glycerin**", a thick sugar-alcohol substance, and can be used as a moisturizer, used in some foods, etc.) as a byproduct. Hard **Soaps** are made of mostly oil and some sodium hydroxide placed into a water solution and heated or allowed to dry out or "cure" naturally. Soaps have a slippery feel to them. Soaps can mix into water, unlike insoluble oils. Base solutions are often called **alkaline** solutions and their pH is said to be of an alkaline value greater than 7.

Clean drinking water with a pH within the range of 6.0 to 8.5 is considered safe to drink. The pH of human blood is typically about 7.4, hence it is and-or should be a mild base solution. Blood is typically 9g of salt / liter = 9g/1000mL = 9g/1000g = 0.009 = 0.9% vital salt, and this is just slightly less than 1% salt. Salt is generally needed by the body for various electro-chemical reactions and processes such as for digestion which is the breakdown or dissolving of food so as to extract the nutrients (nutrition - minerals [elements] and vitamins [A, B, C D, etc]) to then be more available to and absorbed by the body.

Water is a mild solvent when the pH is less than 7. If you put a substance such as a hard candy, salt, sugar, or maybe a hard vitamin into a glass of water, it will slowly dissolve (break apart to smaller pieces), but for a given volume of water, there is a maximum amount for each specific substance that can be dissolved by and into that amount of water. Solubility is a measure of how well a certain substance or material can be dissolved (dissociates, "breaks off or apart from") in a specific substance. The units of solubility is grams of the substance per milliLiter = g/mL at room temperature. 1mL = 1cc. The maximum solubility of sugar at room temperature water is:

(180g sugar/100cc water) = (180g/100mL), and from this, dividing both the numerator and denominator by 100, we get: (1.8g sugar) / (1 cc water) = 1.8g sugar / 1 mL water = the solubility of table sugar in water

How much salt can dissolve in water? , How much salt is in sea water? , How much sugar can dissolve in water?

When a solution can no longer dissolve any more of a certain substance placed into it, that solution is called a **saturated** ("fully filled") solution, and this determines the (max.) solubility of that specific substance in a specific liquid. Solubility (ie., dissolvability, reduce to very small particle size) can also be expressed as the number of mols per liter (L). The **solubility of salt** (NaCl, sodium chloride, "table salt", crystals) in fresh, pure water is 35g/1kg = 35g/liter = 35g / 1000cc = = 35g/1000mL = 3.5g/100 mL = 0.35g / 10 mL = 0.35g / 1cc of pure water. 35g/1000g = 0.035 = is a relative value of **3.5%, by weight ratio, maximum** in any volume of water. For conversions: 35g salt / 1000g water = 1.235 oz salt / 35.274 oz water = 0.035 oz salt / 1 oz water. Sea or ocean water has this value on average, and is therefore already (salt) saturated. Adding more salt into this solution will not dissolve it, but rather the salt will be a **precipitate** (ie., "precipitation", "fall out from", "come out of solution") because it can not dissolve further, and any additional salt is then said as being insoluble. Rain coming from or falling out of the moist saturated clouds is also called precipitation. Precipitation is due to that there is not enough chemical energy left in the solution to dissolve any more of the substance such as salt. Perhaps this is how large salt deposits were made, and of which are sometimes mined for "table" or "food" salt and-or for industrial usage.

Granulated ("table") **sugar** has a solubility of about 1.8g / mL = 1.8g / cc =~ 54g sugar / 30 cc water =
54g sugar / 1 fl-oz water =~ 1.9 oz sugar / 1 fl-oz water. 1 fl. oz is actually defined as about =~ 29.5735$\underline{3}$ cc =~
30 cc. 30 grams of mass is often said as being a "food ounce".

Diluting and-or lessening an acid or base

If you add plain water into an acidic or base solution, you will dilute and weaken the concentration and ability of that acid or base solution. The pH of that solution will then change so that it is less of an acid or base and the pH of it will approach a value of 7 if enough water is added into the solution.

As the temperature of an acidic solution increases, it (ie., the atoms, ions, molecules) and any substance in that acid becomes more energized by the heat and become more chemically and-or electrically active. The protons and electrons become more mobile and potent with the higher kinetic energy, and can then dissolve things easier and faster as if more or a stronger acid was added into the solution. The heat energy can cause electrons to have enough kinetic energy to become free electrons, and or weaken the bonds of molecules so as the acid is more effective to dissolving them.

Adding **table salt** (Sodium-Chloride molecules, with the chemical name of NaCl) is a hard crystalline structure that is a compound or combination of sodium and chloride molecules) into a water solution is not known to change the pH of that water solution. Water will dissolve (here have enough electric forces to break apart the salt molecules ionic bonds) the salt into sodium ions (Na +) with a net positive electric charge, and chloride ions (Cl -) with a net negative electric charge. The (H2O) molecules of water will cause the sodium-chloride molecule to break apart (dissociate) into separate ions. The net positive hydrogen atoms or protons on the water molecule will be attracted to the net negative Cl ions. The net negative oxygen atoms on the water molecule will be attracted to the net positive Na ions.

A health tip about pH and acidic foods:

Some foods we intake (ie., eat) are slightly acidic (acid-like, having a low pH) foods, and in order to obtain the healthy nutrition in them, we need to eat those foods and-or use nutritional (vitamins, minerals = elements) supplements. In general, most naturally acidic foods usually have a pH just below that of water, which has a pH of 7. These acidic foods might have a pH rating between 5 to 7. Try not to eat and drink too much of foods that have high acidity. Some foods such as lemons, limes and many spices are known to be acidic, however, science has shown that some acidic foods effectively become as an alkaline foods in the bod after some digestion and-or processing by the body has taken place.

Bacteria are said to thrive (ie., grow, multiply) in an acidic environment, and also like to eat sugars of various types. High amounts of bacteria and sugar can be detrimental to health, such as causing tooth decay (ie., cavities or holes in our teeth). High amounts of sugar can also cause health problems due to an imbalance (often to much) of sugar in our bodies which is usually known as diabetes. The amount of sodium level in our blood can also become in balanced (often too much). We need salt to function properly, but either too little or too much can cause a health problems.

Acidic foods can also cause a chemical reaction on your teeth surface and cause them to decay and-or discolor.

Due to the above knowledge, a health tip or advice would be to rinse your mouth and teeth with plain, common water after eating a meal or snack. This will help remove debris or particles of food, and reduce the concentration and-or pH of any acids in your mouth which can damage the surface of your teeth and-or aggravate mouth ulcers. Brushing teeth and flossing (with a thin cord of material specifically made for that purpose) between them is also recommended. Many dentists also **recommend not rinsing your mouth out immediately after brushing with fluoride enhanced toothpaste** because it takes some amount of time for the fluoride substance to more fully interact with your teeth and obtain the most amount of health benefit. After brushing your teeth properly, let most of the matter in your mouth go down the drain, and then rinse your mouth and teeth after a few minutes, and then try not to eat or drink for 1 hour of elapsed time. There are various mouth and-or teeth rinses available at a relatively low cost, and only a small amount is needed at a time, and these are used as an additional supplement to brushing and cleaning your teeth.

Low pH mouth washes or rinses are also available, and if it not available, a small amount, perhaps a gram, of baking soda (sodium bicarbonate) in a cup of water will create a water solution with a high pH, hence a base solution. Do not drink this solution either because it does have some sodium in it due to the sodium bicarbonate in the baking soda. It is best not to use baking powder for this use purpose because it has some additional materials in its mixture, such as a trace amount of aluminum, and this type of powder is usually used to help bake some foods such as cakes, and if yeast was not being used, however, baking soda can be used, and of which already comes included with an acidic ingredient that will help release carbon dioxide bubbles from the baking soda (a base) when it is activated by the wet ingredients and acid. How much sodium is baking soda? Baking soda will have about 1280mg = 1.280g of sodium per 5cc or 1 teaspoon of volume. The RDA (Recommended Daily Allowance) of sodium or general guide is about **2300 mg = 2.3g total throughout the day** for an average working adult, and unless a doctor and-or nutritionist recommends otherwise. For some reference, a volume of about 5cc volume if water =~ **1 teaspoon of table salt** has about 2300 mg of sodium. 1280g / 2300g = 0.56, and this is over 50% of the RDA of sodium, and in just 1 teaspoon of baking soda. Because baking powder also includes a large amount of corn starch, the sodium content in it is 520 mg per teaspoon, and this amount is (1280mg - 520mg) = 760 mg less per teaspoon of volume. In terms of percentages, it could be said that the amount of sodium in baking powder is (520 / 1280) = 0.41 = 41% that of the sodium in baking soda, and-or that the amount of sodium in baking powder is (100% - 41%) = 59% less than the amount of sodium in baking soda. Be aware that other foods you eat may have sodium and you do not want to continue exceeding 2300 mg per day as an adult. People less than adult age, and smaller in size will obviously not usually need the mentioned adult RDA of sodium mentioned. 1 teaspoon of **table salt (NaCl)** will also contain the adult working male, RDA of **chlorine** which is about **2300 mg**. A level teaspoon of water weighs 5g, and a level teaspoon of fine salt weights about 6g. **With these numbers, a total of 4600 mg / 6000 mg = 0.77 = 77% =~ 75% or (3/4) of a teaspoon of level table salt will provide the necessary RDA of table salt for an adult working male.**

Some dentists can prescribe a tooth paste having a high amount of **fluoride** in it if your teeth could use an extra amount of it. They can also prescribe a special dental rinse and may contain **chlorhexidine** to help eliminated bacteria that can cause problems, either before or after a dental procedure. A dentist may also prescribe a 10 day round (ie., supply and procedure) of antibiotics of some type of Penicillin anti-bacterial such as Amoxicillin. It is difficult to avoid all cavities, but preventing most of them is possible. Try to have a regular dental checkup. Modern dental work is usually pain free with new forms of pain reliever available, and if requested by you, even your gums can be ("topical") numbed before any teeth "scraping" and-or flossing between teeth to remove plaque is performed.

Here are come common substances and their pH:

Substance pH (typical , average)

gastric acid , stomach acid , 2.0 on average
vinegar , white household , 5% acetic acid , 2.5 typical
lemon 2.5 : due to citric acid often found in citrus fruits
lime 2.5
soda 3.2 typ , the acidity is usually due to the added carbonic-acid to make the "bubbles", and the phosphoric acid. Your body will try to neutralize this with alkaline molecules if its able to, but otherwise it still is a significant acid, and it is recommended to not drink too much soda with a low pH which can cause **tooth erosion** and potential gastric issues like "acid reflux (gerd), "heartburn" or aggravate an ulcer. Regular Coca-Cola (R) soda has a low pH for soda, and is between 2.52. Pepsi (R) soda has a pH of about 2.53 Dr. Pepper (R) has a pH of about 2.89. A few of these sodas throughout a day of time is generally not a significant health issue.
tequila 3.2
white wine 3.3
grapefruit 3.4
apple 3.6
red wine 3.7 (typical)
grapes 4
beer 4.5 (typical) , (3 to 5) , hence acidic
coffee , no milk added 5
coffee , with milk added 6
tea , black no milk added 5.2
green tea , 7 before digestion, and 8.5 after digestion , and this is then said as being "alkalizing".
milk , 6.5 , slightly acidic
cheese 5 (typical)
white flour 5.5
various pepper plants are 5 to 6 before digesting, and can be 8 after digestion in the body
whole wheat flour 6
potatoes 5.5
garlic 6
carrots 6.2
cinnamon , before digestion 5

isopropyl alcohol 6 , "rubbing alcohol" , for household use such as a solvent and disinfectant , hence slightly acidic , and this is not for consumption like ethyl alcohol is. Avoid breathing its vapor, and contact with skin other than for short duration - war gloves if needed for longer duration of use. Alcohol can be flammable in high enough concentrations. It can be diluted with water, but this may reduce or negate its disinfectant ability. Chemical formula is: $C3H8O$, **Do not drink this type of alcohol**.

vodka , 6.5 (typical) when at 40% (edible in moderation or small amounts, **ethanol**) alcohol per volume, and with the remainder 60% usually being water. Do not drink this when concentration and focus is important, such as driving a car, operating machinery, taking care of others, etc, due to its sedative effect that can dull senses, lower awareness, and may produce a type of calming effect and-or bad behavior. In general, alcohol is not prescribed by health care as a medicine of any sort.

water 7 , distilled, pure water with no trace of other elements , makes a good pH reference calibration for a meter
When pH is 7 in a substance, the amount or concentration of hydrogen ions or protons (H+) is equal to the amount or concentration of hydroxide ions (-OH), and therefore, the number of these two different types of ions are equal and are then said to be in balance with no net amount of either type. The solution containing these ions is then said to be neutral, and the substance has no net or significant acid or base activity, and-or that their activities are equal in value. Consider that water can soften and-or dissolve many organic substances.
(number of hydrogen ions) - (number of hydroxide ions) = 0 in a neutral solution or substance.
Note that a neutral solution such as water still contains these two different types of ions.
Water is a common substance to dilute another substance so as to change the pH of that substance, either an acid or base substance, so as to have a pH closer to 7, but not necessarily 7, and this dilution by water process can not convert an acid into a base, or a base into acid.

table salt 7.0 , sodium-chloride molecules , a necessary nutrient , such as for digestion and body processes, however too much can cause or aggravate health issues such as hypertension, and some kidney problems

cocoa powder 7.3 , after it is reduced in acidity during its manufacture
human body internally , blood, 7.4 (common, average, typical) , hence **slightly alkaline**

cinnamon 5 ,after digestion 8.5
honey 5
spaghetti sauce or pizza sauce 5.75
salt 7
salt with iodine , manufactured to be about 7.5 before digestion, so as to stabilize the volatile iodine atoms from "gassing off" (evaporating).
salt water 7
table sugar 7
sugar water 7
rain 5.3 (typical, average)

soda pop soft drink 3 (typical, average) , it is **acidic** , many soda pop drinks contain phosphoric acid
apple cider vinegar 2.5 ,vinegars contain acetic acid that is made from a certain bacteria (acetic acid bacteria) added to alcohol during the fermentation process to make and-or convert it to the vinegar. Obviously then, this bacteria can thrive in the **acetic acid** of vinegar. "Mother of vinegar" is a safe cellulose substance often seen at the bottom of some unfiltered apple vinegar bottles, and is infused with the bacteria which if uncontaminated, it is often deemed as a healthy "gut bacteria".
hydrochloric acid 0

toothpaste 8 , typical, can be 7 or higher (less acidic), and this high pH means less acidic and so as to protect the (protective) tooth enamel coating from dissolving or eroding such as an acid would cause. The same can also be said for **mouthwash**. In general, avoid using toothpaste and-or mouthwash (or mouth-rinse) with a pH less than 7.0, hence avoid acids from damaging your teeth. If you do not have toothpaste available, you can rinse your mouth out with water so as to help neutralize any remaining acid or base in your mouth, especially after eating .

baking soda 8.5 , and this is measured when a specific amount of it is dissolved in a specific amount of water, and at a specific temperature of say 25°C for example. Temperature changes will affect the energy and-or chemical reactions, and the result of the pH measurement.

A pinch of baking soda added into a cup (8 fl-oz = 0.247L =~ 0.250 L = (1/4) L) of coffee is enough to neutralize (make it ineffective as an acid) the amount of acid in that amount of coffee so as it will have a pH of 7. This will also add a few (about 10) milligrams of sodium into your diet. If some extra water was then added into the coffee, it would also change its pH , but then it may not taste as good, but it is a solution to reduce the amount of acid in that cup of coffee. **Since the reference pH measurement for coffee was taken with these specific conditions (amounts, measurements, sizes, temperature, etc), pH measurements of cups of coffee should then be taken using those specific reference of measurement conditions, and this needs to be considered for other substances other than coffee.**

antacid , 9 typical, (8 to 9) , often used to neutralize excessive stomach gastric acid, but note that stomach acid is necessary for proper digestion of food. Some table salt (sodium-chloride) in the diet is also necessary so as to make that stomach acid and for other vital biological functions. There are some medicines which can also prevent excessive stomach acid production so as to then prevent excessive "hear-burn", "acid reflux" or "gurd". Some of these can be bought at a common store, and some others may require a prescription from a healthcare worker.

ammonia 12 , as a household cleaner

bleach 12 , chlorine bleach, stain dissolver/remover , common household cleaner and disinfectant that usually has a 6% to 8% concentration of sodium-hypochlorite in water. This high concentration of sodium-hypochlorite solution in "concentrated household bleach" is then often further diluted with water so as to make a less caustic and or corrosive cleaning and-or disinfecting ("germ fighting") solution, and a typical solution of this has 3% being bleach, and 97% being cool water. Do not add any other substances into a bleach solution. Use proper cleaning gloves and adequate ventilation when using bleach so as to help remove any dangerous chlorine gas it produced.

lime 12.5 , calcium carbonate , limestone , a strong base substance, can cause caustic (chemical reaction, releasing heat) **burns**

lye 13 , sodium hydroxide 14, **caustic** , a strong base substance , often used to make soap , also used as a drain pipe cleaner/unclogger/dissolver.

Although **soap** is often made using sodium hydroxide as one of its ingredients, the desired and safe pH of the hard soap is less than 10 and greater than 8, and with 9 as the average, and this is achieved by adding in the lesser pH of the oil and water ingredients when making that soap. Liquid soap usually has even a lesser pH at about 7.5 due to the higher amount of water in it. If you make soap, please obtain a pH meter and-or litmus paper strips to determine the pH of your soap so as to not be caustic to the skin. Ivory (R) soap has a pH of 9.5. Although the pH of a persons skin varies slightly from region to region, The average pH of human **skin** is 5.0, hence it is slightly acidic, and this helps reduce bacterial growth on it. When the pH of the skin is lower and-or more acidic, the skin can dry out when its natural oils are removed. A soap having a high pH can also dry the skin out, and hence it is recommended to use it quickly and-or use a soap with pH not much different than the pH of our skin. Certain skin diseases may require a special soap and-or pH so as to not irritate your skin.

pH and associated knowledge is very important in modern and-or advanced farming (many fruits and vegetables grow well in soil with an average pH of 6), chemistry, medicine, and many other sciences. pH measurements of each ingredient and result of a chemical reaction can help ensure it was done properly and-or obtained the desired and-or standard result expected.

Please read the following cautionary note about chemicals:

Many chemicals are potentially, in dangerous in some way, either by themselves and-or when mixed with another chemical, and they can very rapidly cause intense heat and-or an explosion during a chemical reaction of some sort: either expected or usually unsuspected. Please take the time to acquire and use eye protection and accurately follow the recipe and-or steps that scientists have previously developed so as to avoid injury and other problems. Scientists and chemists have much proper equipment available, knowledge and training so as

to make and do experiments more safely and avoid injuries and-or damages. Please label and store chemicals and other dangerous products in a safe and secure location. Do not touch, inhale, eat or breath unknown and-or potentially dangerous chemical substance, for even small amounts of some can cause health problems. Research each chemical and-or mixture to know what procedure(s) to do if an accident happens and-or how to dispose of any waste materials. If you have an issue, please seek medical help as soon as possible.

[This space for edits.]

SOME HELPFUL ELECTRONIC DEVICES AND FORMULAS

In 1799, at the dawn of the 19th century A.D., **Alessandro Volta** (1745-1827), from Italy, invented the first electrochemical device to produce electricity. He called this fundamental structure and unit of his device a **cell** (ie., container, compartment). A cell consisted of two different types (elements) of metals, such as copper and zinc discs, perhaps 1 inch (= 2.54 cm) or more in diameter, separated by a thin (liquid of which) **electrolyte** (such as for example: salt water, lemon juice, vinegar or other acid, for a liquid "wet cell") which is somewhat electrically conductive and allows the flow or transfer of charged particles (negative electrons, and positive ions) from and between the two pieces of metal. More technically, his cell is also known as "galvanic cell" found at about the same time by Luigi Galvani. This cell undergoes a process or chemical reaction called redox which is an oxidation (electron loss, oxidized, ex. iron oxide = "rust") and reduction (electron gain, or less oxidation, reduction in total positive charge) of the electrons in the two types of metals used, and of which are at two different electric states or potentials naturally due to the number of free electrons and-or weak electron bonds in their atoms. Even if an atom looses an electron, and not due to an oxygen atoms(s), it is still generally called **oxidation** so as to convey what has happened much like steel or iron rusting due to moisture (ie., water) and-or air (ie., oxygen).

By placing or stacking (piling) these cells in series or "pile" ("voltaic-pile") with each other, Volta invented the first **battery** (a multitude, or array of individual cells) that produced a higher voltage equal to the sum of voltages of each voltaic cell in the pile or series of cells. Many years after the discovery of the cell, it was found that electrons in the cell are essentially placed in and will pass through a higher electromotive field and will gain more kinetic energy called electric potential energy or "voltage". A battery also creates a more practical, controllable, reliable, and a reasonably constant amount of current ("electricity") which was very practical and useful for the many new discoveries and inventions that used electricity.

Unlike a "primary cell", a "secondary cell", such as a common lead-plate in acid ("lead-acid") battery in an automobile, can be recharged in a reverse type of manner to how it is allowed to generate electricity (electrons) and discharge it through an external electrical path or circuit. **In general, a battery is commonly known as a device to store electrical energy.**

A "chemical" battery, such as an alkaline battery uses the chemical energy of a paste placed between the electrodes so as to create current. An alkaline battery is a (sealed) "dry cell", and the electrolyte is a (chemical) paste consistency and where the electrolyte is not an acid pH and water mix, but a base pH chemical substance. One electrode in common alkaline batteries is zinc metal, such as used for the outer can or container structure.

In about 1827, after a few years of experimenting with the recently developed (voltaic) battery, **Georg Ohm,** in Germany**,** realized that when a voltage (V) was doubled, the resulting current (I) doubled, hence a direct and linear or proportional (ie., at the same rate of increase) relationship, which is sometimes called as having a "direct proportionality" between current and voltage. Ohm also noticed that when a resistance (R) doubled (by 2), the current was divided in half (by 2), hence there also a real physical and logical mathematical relationship between current and resistance, but it's an inverse linear relationship. As resistance increased, the current decreased by the same factor. These facts or relationships were summarized and expressed with a simple and most useful mathematical equation known as Ohm's Law:

$$\textbf{Current} = \frac{\textbf{Voltage}}{\textbf{Resistance}} \quad \text{or} = \quad \mathbf{I} = \frac{\mathbf{V}}{\mathbf{R}}$$

: Ohm's Law **Units: current = amps , voltage = volts , resistance = ohms**

Hence mathematically: **V = I R** **and** **R = V / I**

Resistance (R) is that which impedes (reduces) or prevents the flow of current. According to Ohm's law, current (I) is inversely related to resistance: I = V / R. For the total resistance of **resistors (R) in series**:

Two or more resistors in series essentially creates a greater resistance equivalent to a singer larger valued resistor:

Rt = R1 + R2 + **. . .** **:** series resistors or resistance

For the total resistance of **resistor in parallel**:

$1 / Rt = 1 / [(1/R1) + (1/R2) + . . .]$: parallel resistors : this was derived previously in this book

For just 2 resistors in parallel, the formula simplifies to:

$Rt = \dfrac{R1R2}{R1 + R2}$: Total resistance of 2 resistances in parallel. The net or total resistance is always lower than the least valued resistance. Two resistances in parallel reduces the total resistance of the circuit path because there is more conduction area or "room" for current to flow. There is a similar formula for two capacitors in series or two inductors in parallel.

A resistor can be thought of as having the qualities of an insulator and conductor, and which results in a low conductivity material that has a lower number of "free", "loose" or "unbound" electrons to help conduct current than a typical metal conductor has. Electrons passing through a resistor also have a higher chance of colliding with atoms and will then loose kinetic energy as heat energy. This wasted energy is therefore a power loss (joules/time = watts). In a certain way, a resistor is a type of semi-conductor. Given a resistance with a certain voltage across it and current through it, to effectively force the same amount of current though a higher valued resistance will take a higher amount of energy, and that is a higher electric potential energy, potential energy difference or electromotive force called voltage.

For the **capacitance of a capacitor (C)**

A **capacitor** is a relatively simple electronic device that can store an amount or capacity of electric charges, and that is why it is called a capacitor. Basically, the amount of charge it can store is mainly determined by the size of its two plates of metal or metallic-like substance. **DANGER**: A capacitor may already have energy stored in it which needs to be released, transferred or discharged through a relatively low resistance (ex. a 1ohm to 5 ohm power resistor) across its terminals before handling it.

A capacitor can store charge (ie., electrons and positive ions) on two parallel and separated metal plates (such as two pieces of aluminum foil separated by a sheet of thin paper, which could then be rolled up), much like a rechargeable battery. One plate will hold electrons, and the other plate will hold positive ions. The charges are held in position by the applied voltage across those plates and-or electrostatic forces when the voltage is removed. Since the charges are stored, they will have electric potential energy and have a voltage across the plates. Capacitors therefore can accumulate and store energy much like a battery stores energy.

Charge is essentially forced or driven onto the plates with a voltage (electric, electromotive force, emf, applied to the charges giving them kinetic energy to move or flow). The energy of the charge will be stored or maintained in position by an electric field potential (emf), and capacitance is a measure of its storage ability and will have units called Farads. The stored charge will then have a voltage (emf = electromotive force, potential ability) between them, and this internal voltage can then send those charges (ie. electrons) as an electric current through an electric circuit so as to balance those charges to 0.

As a capacitor is charging up (with current, electrons) due to a supplied voltage source, the internal emf across its two plates will be equal to that supply voltage and will essentially prevent any more charges from accumulating on its plates. This is sometimes called a "back-emf" or "(opposite measured polarity) reverse voltage". As this reverse voltage increases, it effectively decreases the net voltage applied to the capacitor, and therefore the current or charge to the capacitor will decrease. During charging, the repelling force due to the charge already on the capacitor is preventing more charge from being stored.

The time it takes a capacitor to charge up to the supply voltage is determined by the resistance in series with it, and which will essentially reduce the charging current or slow the rate of charge. As a "rule of thumb" or very close approximation, a capacitor is considered as charged or discharged in 5 "time constants", where 1 **time constant** is equal to: (Rohms series resistance between the charging voltage and the capacitor) (Cfarads) with units of seconds of time. Time of complete charge or discharge = **Ts = RoCf**

In about 1745 a crude type of capacitor with charge storage ability was discovered by **Ewald von Kleist** in Germany. Not long afterwards, capacitors were called "**Leyden Jars**" (named after the Leyden university where some initial experiments took place) and were very helpful as part of the initial discoveries about electric charges. Since the battery had a few years yet to be invented in about 1799, charges were usually created using various types of hand powered friction (of two surfaces) machines, and then those charges were stored in a Leyden Jar. These machines could produce a very high voltage, but little current, unlike a battery. In just a short time later, these jars were being connected in parallel so as to be able to hold more charge because the (foil) plate area was now essentially larger as the sum of the plate areas. In about 1750, the famous U.S. statesman **Benjamin Franklin** took interest in electricity and Leyden Jars. Franklin called the arrangement of parallel Leyden Jars a "battery" which could possibly be interpreted as: "an array with increased power". and soon created a type of relatively **simple electrostatic motor** which had only a low power ability, but it still rotated and showed that electricity could be useful and needs to be studied more. Franklin discovered that objects are always charged up or discharged with the same electric or charge "fluid" or substance (ie., called electrons today) transmitted through or along the wires to other objects. In short, it was this substance that gives charged objects their charge because that substance itself is the charge, or lack of it, and that the state of an object being charged is due to that (charged) substance. Franklin also expressed a controversial thought that charge is stored in the dielectric material of a capacitor. Since the plates of these Leyden Jars were relatively far apart, these capacitors could store a high voltage before dielectric breakdown and self-shorting out and-or discharging, but only a low amount of charge or current.

Since electrons have the same charge type, they repel each other, and it will then take a stronger force to essentially increase the electron particle density or number of them in the same given area and-or volume, and this will mean a stronger electric force, hence a higher voltage will be needed. An analogy would be that since a spring will have an equal and opposite force, it will take more force to squeeze that spring closer together, and in return, more energy is stored by that spring. As a capacitor charges, the capacitor charges up to the supply voltage, and then stops because there is no effective voltage difference for the current to flow, but is rather repelled due having the same electric polarity and net (emf) force.

Capacitance in terms of its electrical characteristics:

$Cf = Qc / Vv$: Q = charges measured in Coulomb (c) units, Qc = stored charge in the capacitor
V = voltage across the capacitor's two plates
f = Farads, the units of measurement for capacitance which means its capacity (ie., room, ability) to store charge or electrons per applied volt ($V = J / Qc$).

The unit of farad (f or F) is named after Michael Faraday who discovered that various dielectric materials between the plates of a capacitor increased or decreased its capacitance.

By observing the formula, capacitance can then be thought of as the amount of charge stored per applied volt across its place.

Extra: $Cf = Qc / Vv = Q / (J / Q) = Q^2 / J$, also :
$Vv = Qc / Cf = J / Qc$
$Qc = Vv\, Cf$

Capacitance in terms of its physical characteristics:

$Cf = k$ (plate area / distance between the plates) $= k (Am^2 / Dm)$ $:= Qc / Vv$: this fraction resolves or reduces to: $Cf =$ (charge / 1 volt)

A is the area of a plate in unitsof square meters.
. **D** is the distance in meters between the plates.
k = **e** = (electric) permittivity or= dielectric constant of the dielectric material placed between the plates of the capacitor.

permittivity is a measure of how much the dielectric material can permit or be electrically polarized by the presence of an electric (force) field such as that extending between the charged plates. For this formula, (e) is an absolute, true or specific value, and not any relative (r) or "comparison" (ratio, magnification) value to that of a vacuum (eo) that has a permittivity of about: $eo = k = (Qc/Vv)(d/d^2) = Cf / m =$ about $8.8541\underline{9} (10^{-12})$ F / m
If a dielectric material has an (e) value that is twice as much, C will be twice as much. $er =$ (e of material) / eo : er = relative permittivity

A **dielectric** is also an insulator material so as not to "short out" (ie., effectively, electrically connect, low resistance path) the plates, and allows charge flowing from plate to plate, and the capacitor no longer has charge storage ability. .

Some **r**elative permittivity (E**r**) values of some various dielectric materials in a capacitor that have a temperature of the "room" or "comfortable living" temperature of 72°F = 20°C :

Here is a table of relative perrmmittivity:

material	**relative permittivity = er = (permittivity of material) / (permittivity of vacuum) = e / eo**	
vacuum	1	
air	1.00054 = ~ 1	: at standard pressure of 14.7lbs/in^2, value is slightly greater than a vacuum. Though an air capacitor does not generally store much charge and has a low capacitance, it offers fine tuning of oscillators and radio receivers.
mineral oil	~2	
wax paper	2.5	
vegetable oil	2.5	
mylar	~3	
paper	~3.5 av	
nylon	4.5 av	
mica	4.75 av	: good
glass	7 av.	
diamond	8 av.	
aluminum oxide	~9	: very good
zinc oxide	~10	: high
tantalum-oxide	~26	: high
ceramic	30 av	: very high
niobium-oxide	45 av	: very high
glycerin	57 av.	: very high
water	85	: extremely high , this will get lower in value as the temperature lowers
titanium dioxide	115 av	: extremely high : sometimes used in the dielectric of "super capacitors". : some other alloys of titanium can have much higher values

The permittivity of water has a wide range and varies much with temperature, hence it is possible to use this type of capacitor as a thermometer sensor so as to measure a temperature such as air, and comparing its measured capacitance to that capacitors corresponding temperature scale that was pre-made, calibrated and known.

The energy stored in a capacitor and-or equivalent amount of work (W) needed to charge it up to that amount is:

W = (Cf)(V^2) / 2 : with units of joules : this is similar to the kinetic energy formula KE = mv^2 / 2 , but here mass has been replaced with capacitance and velocity (v) has been replaced with voltage (V). Note: joules of work = joules of energy

The Cf or farad rating of a capacitor is an indication of that capacitors charge holding ability or capacity, and not specifically the amount of charge on its plates at any moment. The energy stored within a capacitor also depends on the voltage applied across that capacitor. The maximum safe voltage rating of a capacitor is the dielectric breakdown rating of a capacitor, and it will therefore determine the maximum safe energy storage in that capacitor.

Some other formulas for the energy in a capacitor are:

Since: Capacitance = Cf = amount of charge held on the plates per volt (emf) across the plates = Q / V:

$$W = \frac{CV^2}{2} = \frac{(Q)}{(V)}\frac{V^2}{2} = \frac{QV}{2} \text{ , joules}$$

Since: V = Q/Cf ,

$$W = \frac{QV}{2} = \frac{Q\,(Q)}{2\,(Cf)} = \frac{Q^2}{2Cf} \text{ , joules}$$

For the total capacitance of **parallel capacitors**:

$Ct = C1 + C2 + . . .$ **:** parallel capacitors, this formula is similar to that for series resistors

Capacitors in parallel is essentially creating a larger capacitor with larger plates.

For the total capacitance of **capacitors in series**:

$1 / Ct = 1 / [(1/C1) + (1/C2) + . . .]$: this formula is similar to that for parallel resistors

When capacitors are placed in series, we see that their total capacitance is less than any one capacitor, and this is due to the effective larger amount of dielectric material involved, and when the dielectric material has a larger width between the plates, the plates are farther apart, and the resulting capacitance is less. If the capacitors are identical, the total capacitance will be half that of any one, and the breakdown voltage will be twice that of any one.

.

Capacitors in series will create a voltage divider. For an AC voltage and-or signal applied to these capacitors, the voltage across each capacitor depends on the reactance (Xc) of each capacitor to that AC signal, and of which depends upon the frequency of the signal. Vc = Ic Xc Smaller capacitors will have a higher reactance (ie., impedance, , AC resistance) to the AC signal, and therefore a larger voltage across it.

First, a voltage source will cause current to flow into and be stored by electrostatic (or "Coulomb") force in an "empty" or uncharged capacitor. The rate of this charging (Coulombs per Second = Amps) depends on the circuit resistance to the flow of the charging current. The lower this rate, the longer it will take the capacitor to charge up. The capacitor will stop charging when the voltage of the capacitor equals the source or supply voltage because there is no difference in voltage for the charge (current, electrons) to be electromotively forced to due so. Vc grows while charging and is essentially a "back-emf" that will begin to limit the flow of current (as if it was repelling it due to electrostatic forces) because the effective supply voltage or emf is reduced even though Vs usually remains a constant voltage source.

When Vc = Vs, their difference or (electrical or voltage) potential difference is 0v: (Vs - Vc) = 0v, and there is no net voltage potential or available electromotive force condition to cause current to flow and the capacitor is done charging.

The effective (Ve) supply voltage = voltage potential difference, "emf" or "pressure" = (Vs - Vc).
Since Vc = 0v at t=0s of charging, Ve = (Vs - 0v) = Vs

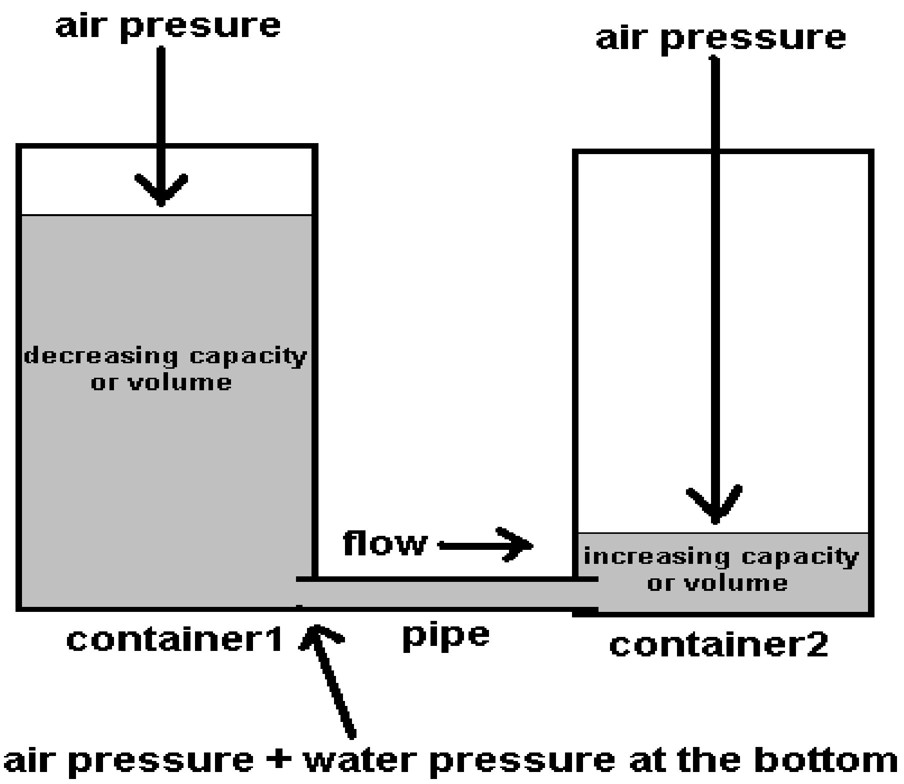
While the capacitor is charging, Vc will increase and Ve = (Vs - Vc) = effective potential difference, will decrease.

When Vc = Vs , Ve = (Vs - Vc) = (Vs - Vs) = 0v and current will cease to flow, and the capacitor is done charging.

The capacitance (Cf) rating of a capacitor is due to how much charge (Qc) it can hold on its plates due to the voltage across those plates. If the plates are small, then the amount of charge that it can hold will be reduced since like charges (ie., such as electrons) on the plate will repel each other, and it becomes difficult to place more charge onto smaller plates. Qf = Qc / V. Given an applied or supply voltage of Vs, the amount of stored charge in a capacitor is: Qc = Cf Vs . In the analogy below, an empty capacitor is charged up from a charged capacitor and its voltage will be half of that capacitors voltage, hence (Vs/2). The charge in that empty capacitor will become: Q = (Cf)(Vs/2). The maximum possible rated charge before a dangerous situation of the capacitor having "voltage breakdown" or conduction across its plates is: Qmax = (Cf)(Vmax rating).

Capacitor-water analogy for charging and discharging

Initial considerations for this analogy come from the water analogy of electric current flow being like that of water flowing like a current in a pipe. The water movement is influenced by a force and pressure at one end, and this is analogous to the voltage applied to a conductor (wire). The pipe diameter also determines the volume or the amount of the flowing water, and is analogous to the resistance between the two capacitors. This analysis below for a capacitor is mainly to understand the shape of the curve of how it charges, and the full analysis may not be perfect since the final water pressure and-or height of it is only half as that of the source. That is, when a capacitor charges, it charges up to that of the constant voltage source (emf, or pressure) applied to its input terminals, and not half of that voltage source. Still, the analogy described below is useful in several ways, and when considering two capacitors in parallel to each other, with one charged, and the other empty. [FIG 260]



In the above figure, each tank (with any maximum volume, size, shape or "capacity") represents a capacitor with a certain maximum capacity or volume. In this figure, container1 was filled up and container2 was initially empty. The amount or the volume of water present in each tank represent the total amount of electric charge in each capacitor. Note that a greater volume of water does not necessarily mean an increase in water pressure unless the height (ie., the depth of it) of that amount of water is also increased. Also, any surface of water on Earth will have the standard air pressure of 14.7psi applied to it, but if this is applied to both tanks of fluid in this system, these pressure values negate each other, adding to 0 net pressure to the actual fluid flow.

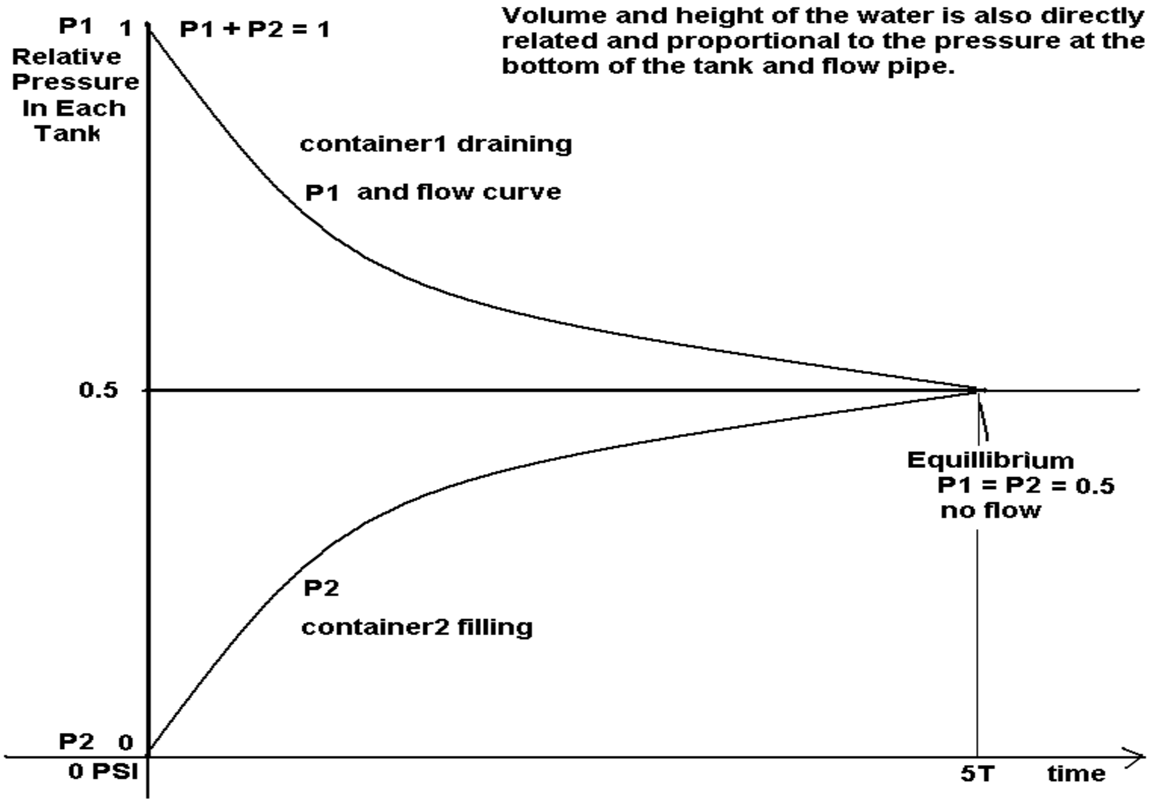
Initially, and when charging, at the bottom of container1, there is an higher pressure than at the bottom of container2 since the weight of the water also applies pressure to the bottom of the tank where the pipe is. There is a negligible difference in the water pressures of each tank due to the air pressure above, and it will not be considered further in this analysis, and in fact the two air pressures are of the same value and effectively cancel each other out mathematically in terms of net pressure and-or difference in pressure. Due to the volume and weight of the water in each tank, there is a difference in water pressure or force at each end and opening of the pipe. Here, the pressures corresponds to voltage and the difference in pressure or net effective pressure corresponds to a net or effective voltage difference. If there is a path to flow, the higher pressure (ie., a force) water will flow to a lower pressure region such as in container 2.

The volume of the tank represents the maximum amount of water that it can hold before overflowing and-or not allowing any more equal or lower pressure water into it if it was sealed with the filling pipe going into it, and this is analogous to the maximum amount of charge that a capacitor can hold or store before being damaged.

Water pressure and voltage pressure are analogous since they induce the flow of current, such as water and electrons.

During the discharging of container1 into container2, the water pressure is decreasing in container1 and increasing in container2. The pressure of the water in container2 is increasing and the difference in pressure is getting smaller and smaller till there is no pressure difference at the pipe openings, and the flow will cease. It could be said that the pressures are at equilibrium and have the same value.

Initially the flow is high but decreased to 0 due to the lack of a pressure difference. Initially the amount of water in container2 was 0, but increased till the pressure of the water in each tank was equal. It is not too difficult to imagine that when the pressure of container2 is half that of container1, that the flow is then half. Pressure against a flow is like a resistance to that flow, and the net effective or difference in pressure causing that flow is then reduced. [FIG 261]



When (e) is used for these equations, the formulas could probably be written to be somewhat similar to that of the catenary curve. The flow-rate (ex., gallons / hour) depends on the pressures involved which depends on the volume of water. The maximum flow-rate is at maximum effective pressure or "pressure difference" when t=0. The time till the pressures are the same or at equilibrium depends on the flow-rate and the specific volume of water available in container1 at t=0, and this is why non-specific or "relative values" (ie., percents, fractional values) were used in the above figure and analysis.

It was indicated that the pressure at the bottom of a tank is directly and proportionately related to the volume or height of the water in a container or tank. With two containers and a pipe system, the effective pressure at the bottom of the tank is due to what water remains in both tanks. Effective pressure is the water pressure difference of the two containers. **Because of P2 affecting and reducing the flow more and more as it grows, there is no linear-like relationship to the water height, volume and pressure of both P1 and P2.** In general if, container1 just drained out, there would be no back pressure and the flow would have a constant reduction with respect to time. In an electrical circuit and-or capacitor, this back pressure is analogous to a "back-emf" or emf of a reverse polarity, reducing the net voltage available to the sum of those two voltages.

The total time it takes till the flow stops could be set equal to 5 time constants = 5T. During the first time constant, the flow rate (= volume or amount **/** time) is relatively high, and then it decreases for each unit of time.
Ex. Below is a figure to verify this discussion. Two empty plastic bottles were hot-glued together along their height side and with some extra supporting pieces of wood. The actual volume does not matter for this initial experiment, but it can be used later so as to have some actual (rather than relative, portion or percent) values if needed. The bottles had a volume of about 2 liters each. Between the plastic bottles is a plastic tube with nearly 1/8" inside diameter. This tube was from a used spray bottle. The tube ends were place close to the center of the bottom of each bottle, and also hot-glued into position between the bottles and to prevent water leakage. A bottle cap is initially needed on the second bottle so as to help keep the water in the first bottle from entering into the second bottle. [FIG 262]

Initially, as a construction test, the cap was removed from the second bottle and it would fill up so as to be at pressure equilibrium (ie., the same pressure) with the first bottle. A line was drawn on each bottle at this height. With a ruler, also measure half this height and mark that line on each bottle. Use a timer and-or calculate the number of seconds until equilibrium is reach. Be patient and try to wait till they are exactly equal for it will help in the accuracy of the calculation. Due to a theorized natural flow, increment, decrement of the values in this type of system being analyzed, let's set this number of seconds till equilibrium is reached equal to 5T = five time constants, and after this amount of time and changes become negligible and are practically 0, and e^(-t/T) = 1/e^(t/T) = 1/e^(5T/1T) = 1/e^5) = 0.00674. Dividing this 5T value by 5 we will have the time value of one time constant (T) for this particular system of natural forces or pressure, and whose formula for analysis will include the natural number (e).

During this experiment, equilibrium took 11minutes = 660seconds = 5T.   Ts = 1Ts = (660s / 5) = 132s

For the volume (V2) of the second bottle being filled from the water (Vt=total volume) in the first bottle:

$$V2 = Vt\, e^{(-t/T)} = \frac{Vt}{e^{(t/T)}}$$

Using relative values, we can assign V2 = 100% = 1 at equilibrium and the maximum value of V2 has been reached. We can set V2 equal to half of 1 = 1/2 = 0.5 so as to find the time it will take to reach half of the equilibrium volume or final value of V2.   This value should then match that of the actual experiment, and it will also bring some verification to the formula used. Note that the actual physical volume of V2 at half its maximum value is only 1/4 of the total volume of V1=Vt at the start of this system.

$$0.5 = \frac{1}{e^{(t/132s)}}$$ solving for the indicated power of e:

: or = $0.5 = 1e^{(-t / 132\ s)}$, though this seems like a decaying function for V2, the reciprocal of it is indicated, and which therefore indicates a growing or increasing value.

$$e^{(1t/132s)} = 1/0.5 = 2$$

$$e^{(0.007575758t)} = 2$$ taking the ln of both sides:

$$\ln e^{(0.007575758t)} = \ln 2$$
$$0.007575758t = \ln 2$$ solving for (t):

$$t = \frac{\ln 2}{0b007575758} = \frac{0.693147181}{0.007575758} \approx 91.\underline{5}s$$: this value was verified when the experiment was performed again 91.5s ~= 1minute and 31 seconds = 00:01:31 of time

If 1 time constant = T = 132s, how many time constants is 91.5s where half of the final volume of V2 has been filled? Setting up a proportion or equivalent fraction:

$$\frac{1T}{132s} = \frac{xT}{91.5s}$$ after solving for xT , xT =~ 0.693T =~ 69.3% of one constant (T).

t/5T =   91.5s/660s = 0.1387 = 13.87% of the total time of filling, hence (1 - 0.1387) = 86.13 = 86.13% of the total time of (5T= 660s) remains until the equilibrium condition. 5Ts - 91.5s = 660s - 91.5s = 568.5s = 9m and 28s

It will take about (5T - 0.693T) =~ 4.30T more for the remaining half of V2 to be filled and the equilibrium condition exists, and this amount of time is:

4.30 (T) = 4.30(132s) = 568s = 9 minutes and 28 seconds , and this is (568 / 91.5) = 6.2 times longer than the first half of the volume of V2 being filled.

From the above analysis, if a container is filling under similar pressure conditions, and if it is halfway filled, then that amount of time is 69.32% of 1 time constant.   If the time to reach this half (0.5) amount of the final volume was 91.5s, then one time constant is then: 0.6932T = 91.5s , and after solving for T = 91.5s/0.6932 = 132s. This type of analysis can also be done for other fractions of the final volume, such as for 10%, 1% of the final volume.

For relative amounts in each container: Vt = 1 = V1 + V2   and   V1 = 1 - V2 = 1 - $e^{(-t/T)}$ and:

At (pressure, and volume) equilibrium: V1 = V2 , Vt = V1 + V2,   1 = V1 + V2,   1 = V1 + V1 = 2V1 ,   therefore mathematically, solving for V1, we find V1 = 0.5 = V2 at equilibrium.

Note that the amount or volume of water removed from one bottle will be added to the volume of the other bottle. Likewise, since the bottles are similar, the height decrease in one bottle will be a height increase by the other bottle. It could also be said that with this system, the sum of volumes is constant, and the sum of heights is constant.

If it is impractical to make the above device shown in the figure, a simpler device for experimentation with volume, pressure and time would be a plastic container with a 1/8 inch hole near the bottom of it. With this system, there would not be any effective "reverse" or "back" pressure from another container and therefore, the flow rate does not decline as much. With this system, the water analogy of the capacitor is not present, but the flow rate still decreases from the reduced water pressure of the reduced volume of water as time increases. The water volume, pressure and size of the hole determines the output flow rate, and therefore the total time until the container is empty. Since there is no "back" pressure reducing the flow, the volume will drain faster as compared to the system noted above. For a reasonable, but technically incorrect, linear-like estimate for the remaining volume left in the container, you can take the total time and divide it by 7 [6.6 to 7 is close] so as to have the time of the first quarter (1/4 = 0.25 relative value = 25%) of the volume drained, then double [2 is ok, and 1.9 is a better value] that time to find the time of the next quarter (50% of the volume drained off) and so on. For example: The first or upper (highest) quarter of the volume took 18s to drain out , the second quarter will drain off after about (2)(18s) = 36s. The third quarter will drain off at about (2)(36s) = 72s, and the remaining fourth quarter will drain out at about (2)(72s) = 144s. If the first quarter of the total volume took N seconds to drain out, the estimated total time till that total volume has drained out is: total time = (7)(Ns). A basic formula for an estimation of the percent of the volume left after time past is: % of volume remaining = 1 / 6.6^((1.2) time / total time). The formula is more accurate for the higher percentages of the volume remaining, but it can be adjusted after more experimentation. Solving for total time: (total time) = ($2.264483\underline{6}$) (time) / Ln (1 / percent remaining).

Another similar formula is: % of volume remaining = 1 / 9^(time / total time) , or:
%Vremaining = 1 / e^((2.4) time / total time) , or: %Vremaining = 1 - ((1.56) time / total time) which is a good approximation for up to 65% of the total time.

With the knowledge presented in this overall discussion, we can apply it to the flow of charge or current in a charging or discharging capacitor: With the above water analogy, volume two, (V2) will fill up to half of the initial value of the total volume (Vt). For a capacitor, the voltage across it, (Vc), after "filling up" or charging is equal to the supply voltage (Vt).

When an empty (of charge and voltage) capacitor is first charging, the flow rate (ie., amperes) of current is high, but then decreases due to that the effective voltage or potential difference (like a difference in pressure) causing that flow is decreasing. This constantly decreasing flow rate will then effectively increase the time it will take to charge up that capacitor to a certain amount of charge and-or voltage, hence charge up to an energy storage value.

The formula for the decreasing flow or charge rate (ie., current) to the capacitor will be one that expresses a natural-like decay with respect to time, and will cease at some certain amount of time, and this time is determined by the capacitor's capacity and the maximum charge rate initially to it. A higher capacity or capacitance means that at a certain initial or maximum charge (ie., current) rate value, it will take longer to charge that capacitor to a certain voltage. The formula for the increasing voltage of a capacitor will be one that expresses a natural-like increase in voltage over time and (practically, at 5T) ceases at some certain amount of time when the current ceases to a value of 0A due to a lack of voltage or pressure difference, and the capacitor has charged it up to the supply voltage.

Since (e) =~ 2.71828 is a natural-like value, it is typically used to express natural events such as growths. (e) is used to express the natural-like gravitational forces on a freely hanging chain from two supports at the same height above the ground, and which shape is called a catenary curve as discussed in this book.

$$V_c = e^{(-t/T)} (V_s) = \frac{V_s}{e^{(t/T)}}$$

: formula for the increasing voltage across a charging capacitor. Even though the voltage increases over time, the rate of this increase actually decreases over time (t). T is related to the total time or period it will take to charge and-or discharge that capacitor charged up to a specific amount of voltage. T is discussed further below. The negative exponent of (e) indicates there will be a natural decay over time.

$Vo = e^{(-t/T)}\, Vc$:formula for the decreasing voltage across a discharging capacitor

$Ic = e^{(-t/T)}\, It = \dfrac{It}{e^{(t/T)}} = \dfrac{Ve}{R}$:formula for the decreasing charging or discharging current of a capacitor
It or Imax is the maximum current flow which is determined by the series resistance (R) to and-or from that capacitor. The higher the resistance, the less the flow rate to and-or from that capacitor, and the longer the time of charging and-or discharging. Imax = Vmax / R = Vs / R.
The specific current flow is Veffective / R when charging, or Vc / R when discharging.
When charging, It = Imax = Vs/R , when discharging, It = Imax = Vc / R

A capacitor will take a certain amount of time to charge or discharge which depends on the rate (ie., amperes of current, coulombs per second) of charge flow and the maximum voltage to reach. R will limit current flow and increase the time of charge and or discharge. Resistance is a factor to the time to charge to a specific value. We can let time = (t) with units of seconds. The larger the capacitor, the longer it will take to charge up to a certain value. The capacitance of the capacitor (Cf) and R are factors of the (R)(C) time constant for a certain capacitor and resistance in series with it. It is of note that any resistance will reduce the power available at the output.

(t) = time in seconds, Ts = RoCf time constant or Period.

A capacitor is usually considered fully charged after 5 time constants = 5T = 5(RC)

When t = 5T, $e^{(-t/T)} = 1 / e^{(t/T)} = 1 / e^{(5T/T)} = 1/e^5 \approx 0.00674$, $Vc \approx Vs$

In a battery, the positive terminal is usually considered the higher potential where electrons are coming (repelled) out from, and they will travel through the circuit to the lower potential or pressure (attracted to the positive ions) in the battery.

When there is a thermal (ie., heat) energy difference between two items, say cubes of metal, the higher temperature metal will naturally transfer heat energy to the cooler metal and its temperature will rise. The temperature of the hot metal cube will decrease. This process will continue until both objects are at the same temperature, hence at thermal or temperature equilibrium. If the cubes are of the same metal they will have the same thermal conductivity, and if they are also of the same size they will have the same "**thermal mass**" (amount of stored thermal energy in its mass, some may might also call this "thermal inertia") and the concepts and curves will be similar to those shown above in this article for when there is a difference in pressure and one is decreasing as the other is increasing.

Also consider that since Cf = Q/V , and if two capacitors have the same farad or capacitance rating, and one is charged and the other is not, and if they are connected in parallel, we know that the total capacitance is twice that of a single capacitor, and this is so since the plate area is effectively doubled. The charged capacitor will charge up the empty capacitor. Each capacitor will receive half of the total charge (Q) in the first capacitor, and the voltage of each capacitor will be half of the total voltage on the first capacitor. A resistor can be used to increase the charging time and-or discharging time, and there will also be a power loss due to that resistance when current is flowing through it.

$$Ct = 2Cf = 2\,(Q/V) = [\,(Q/2) / (V/2) + (Q/2) / (V/2)\,] = 2\,[\,(Q/2) / (V/2)\,] = 2\,(Q/V) = 2Cf$$

In relationship to the water tank analogy, the water (ie., charge) level in each (similar) tank will be half as that of the full tank, and the water (ie., emf, voltage) pressure will also be half as that of the full tank. If a capacitor is being charged by a constant (non-reducing) voltage source, it will charge up to the same value of that voltage source. In the water analogy, a capacitor of a different value, say half = Cf/2, would have a lesser width, but still have the same physical height (as Cf, or container) so as to reach the same water pressure (ie., voltage) and then be at equilibrium. This smaller capacitor and-or tank will hold less water (ie., amount of charge) at equilibrium.

For the reactance (ie., impedance = Z, or effective resistance to ac signals) of a capacitor to AC signals:

As a reminder: **Resistance** will reduce the flow of current. **Impedance** (ie., to resist, to impede, an interruption, a blockage, a reduction) is the total effective resistance for AC current, and may include resistors and-or reactance. **Reactance** is how a device (such as an inductor and-or a capacitor) behaves or reacts when a particular frequency of AC is applied to it. It will behave as a certain value of equivalent resistance depending on both the device, its value, and the AC frequency applied. The units of resistance, impedance, and reactance are **ohms**. For a capacitor, the higher the applied AC frequency signal, the lower its effective resistance or impedance to current. A capacitor is said to more easily pass or allow higher frequency ac signals, hence it also rejects or does not easily pass lower frequency signals. For an inductor, the higher the applied AC frequency signal, the higher its effective resistance or impedance to current.

The **reactance of a capacitor** is how it reacts to an applied AC signal and is essentially a measure of its (perhaps unwanted, like a resistance) ability to impede (ie., resist) an AC (alternating current) signal. The specific value of its reactance is determined by both the capacity of the capacitor and the frequency of the applied AC signal. For example, consider that besides for an initial pulse of current to charge up a an empty (no charge on its plates) capacitor up to the input voltage, a capacitor will then block any direct current flow which has a frequency of 0hz. It becomes like an open circuit or very high resistance to low frequency AC signals trying to pass through it electrostaticly. This certain function of a capacitor is often used to isolate an AC input and signal from a connected devices DC (ie., a battery, etc.) power supply which may cause problems for both the input device and-or the signal efficiency. High frequency signals will pass through a capacitor with ease since it will have a low impedance to high frequency AC signals, and the capacitor will be practically like a low resistance piece of wire, hence like a short-circuit, or closed switch. Because of this frequency dependent value of reactance to ac signals, a capacitor can be used as a frequency dependent filter to block and-or allow desired and-or undesired frequencies. For example, unwanted high frequency signals can be "grounded" or sent to the ground connection and away from another circuit. Unwanted bass or low frequency signals can be greatly reduced and-or blocked from entering a circuit. Basically, reactance is how the device (a capacitor or inductor) reacts to an applied AC signal (here, in particular its frequency), and reduces that signal like a resistance would.

Xc = 1 / [2(pi)(Fhz)(Cf)] : **reactance of a capaacitor** in ohms units

Note for ex.: 1pF = 1 (10^-12)F , 120pF = 120 (10^-12)F =
120pF = 1.2 (10^2) (10^-12)F = 1.2 (10^-10)F

Cf = 1 / [2(pi)(Fhz)(Xc)]

As the input frequency to a capacitor increases, the charging and discharging time needed to reach or "follow" that input AC frequency and voltage signal is less, and the capacitor itself essentially reacts less with that signal and behaves more like a lower resistance to the signal. Remember that time=/frequency, so if the frequency is higher, the less time for each cycle of its wave. A smaller capacitor has a lower RC time constant and can quickly charge and discharge. A capacitor can be thought of as passing higher frequency signals easier with less reactance or impedance, and reducing lower frequency signals due to more reactance or impedance.

In general, the smaller the capacitor, the higher the frequency of the ac signals it will easily pass, and signals with frequencies below that high frequency will have more reactance and will be reduced as if a resistor was in series with that signal. To pass a low ac frequency signal with least impedance, a large capacitor (ie., a higher farad rating) should be used, and these types of capacitors are often found in audio equipment so as to pass low frequency ("bass") signals or audio. Large capacitors are often used to temporarily store energy (electrons and their voltage) so as to maintain a steady voltage value such as needed in a DC power supply to a circuit.

Using the above derived formula for Cf, the capacity or Farad value of a capacitor can be calculated after taking some measurements in a test circuit. This test circuit will consist of a voltage divider consisting of a known value series resistor (ex. r=1000 ohms) and the capacitor in question. An AC signal at a test frequency (ex. 2000 hz) is applied across the voltage divider circuit and the voltages (Vc and Vr) are measured with a (AC) volt meter. Xc = Vc / Ic. Note that: Ic = Ir = Vr / r. These calculated values can then be placed into the Cf formula. Except for the formula, a similar method can be used to calculate the value of an inductor. There are also inexpensive electronic meters available to measure resistors, capacitors and inductors. These meters are sometimes called LCR meters. Individual meters are also available for each electronic component mentioned, and some DMM (Digital Multi-Meters) can measure some of these components such as resistors and small valued capacitors.

Another way to find the value of a capacitance is through the RC time constant: $Ts = RC = RoCf$

$$Cf = \frac{Ts}{Ro}$$

After 1 time constant, 1t=T, the voltage across an empty charging capacitor will be about 63% of Vs:

$Vs = Vr + Vc$: Vr will go from Vs to 0v and Vc will go from 0v to Vs after ~5 time constants.

$Vs = \frac{Vs}{e^{(t/T)}} + Vs\, e^{(t/T)}$:If Vs = 1v , or as a relative value of 1, then: $1 = e^{(-t/T)} + e^{(t/T)}$
Extra: $Vs = Vs\,(e^{(-t/T)} + e^{(t/T)}) = Vs\,(1)$

$$Vc = Vs - Vr = Vs - \frac{Vs}{e^{(t/T)}} = Vs\,(1 - e^{(-t/T)})$$

First completely discharge the capacitor. Now with a resistor (R) in series with a charging capacitor, connect it to Vs and let the capacitor charge up to 63% of Vs while counting the number of seconds of time (t) it takes. This number of seconds is then equal to one RC time constant = Ts. For small capacitors, so as to be able to measure a reasonable amount of time greater than 1 second, use a very high value resistance for R. When smaller capacitors are used , they tend to require a high accuracy and low tolerance so as to be used in circuits, and because this method here can have timing error, this method is best suited for larger capacitors where a higher positive or negative (+,-) value (ie., farad units) tolerance is usually acceptable. Often a tolerance up to +,-10% is acceptable for most circuits unless otherwise stated.

$Cf = Ts / Ro$: calculating capacitance using the RC = Ts time constant

As a helpful example: Given $1uF = 1\,(10^{-6})F$ and $R = 1$million ohms $= 1\,(10^{+6})$: $Ts = RC = 1\,(10^{6})\,1\,(10^{-6}) = 1s$
This is generally not a practical value of time for most people to accurately measure, and it is basically too short or quick of a time to deal with, so it would therefore be better to increase R by 10 times, so as to have a value of 10 million ohms, and then Ts=10s

Because capacitors can store charge, they can maintain a voltage across their terminals of which can be used to help keep a fluctuating voltage more steady or constant, and this action is sometimes described as being an "electric flywheel" that accumulates and stores electric energy so as to be used later, and this is analogous or similar to a mechanical flywheel that has collected and stored the input kinetic or movement energy in its spinning or rotating mass with kinetic energy.

[This space for book edits.]

For the inductance of an inductor

A magnet in motion, causing a changing magnetic (force) field intensity upon that wire, will affect the electrons in that wire and cause a voltage (ie., KE energy gain in the electrons, joules) and current to be induced (caused, generated) in a wire, and particularly in a coil (ie., having many loops or turns of wire) of wire where the effect is combined or summed to effectively be greater or amplified than if it was just a single length and-or coil of wire. This concept is therefore called induction (to induce, affect and cause), and the coil is called an inductor. If the relative motion between the magnet and coil is in one direction, the current will be in one direction, and if the relative motion is in the opposite direction, the current will be in the other direction. With an electric power supply, an electric current can be sent through an inductor. If the value of the electric current is constant, the voltage across it will be equal to the supply voltage, and the coil essentially becomes a (DC) electromagnet with a constant magnetic field about it. In this condition, it is useless as a transformer. Depending on the coils dimension, it will also have a (D) resistance value associated with it which does affect or limit the supply current. If AC current (particularly changing in magnitude, and direction) is flowing in an inductor, the created magnetic field will also be changing and the induce voltage and current in that coil will be such that it will be in the opposite direction or polarity to the supply or input voltage.

An inductor converts or transforms the (kinetic) energy of the input supplied current (ie., electrons) into a magnetic (flux) field (B) having potential energy, whereas a capacitor converts the energy of the input supplied current into an electric field and potential energy that can even be stored for a long duration of time without any more input energy applied.

The inductance (L) value of an inductor is a measure of its magnetic field creation and energy storage ability. Inductance is a measure of the magnetic field created by the applied current current. Inductance is a measure of the ability to create or induce a magnetic field. A transformer is a common example of an inductor(s), and the two coils, which are generally electrically unconnected are said to have mutual inductance because they will affect each other, initially via (varying in strength) magnetic fields. Michael Faraday is credited to this understanding.

Inductance = $L = B / I$ = (magnetic flux) / (current) : inductance has units of Henry's (H)

B has units of webbers (Wb) or the number of magnetic flux (force) lines, and this is determined by the applied current . Current = I has units of amperes. The units of inductance are: webbers / amp = Henry's

Ex.: 1H = 1 Wb per Amp.

1 Tesla = 1 webber per square meter = 1 (Wb / m^2) : magnetic field strength, concentration or intensity of the magnetic "flux lines".

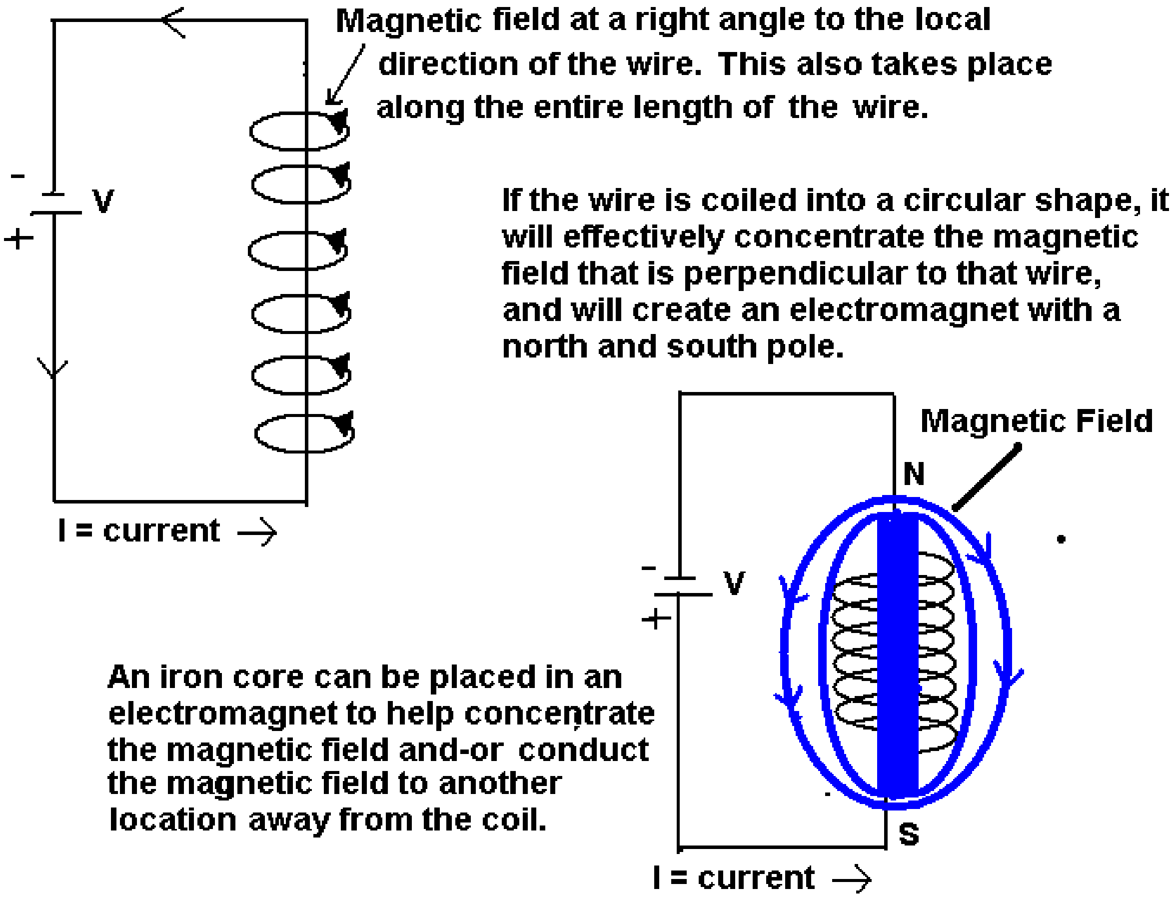
A coil is a good version example of a device with self-inductance When current passes through a coil, it will induce or create a magnetic field about it which will essentially "cut" (through) that coil and create an (opposing) current and ("back-emf" voltage, reverse polarity, opposing to current flow) voltage in the opposite direction to that voltage applied, and the result is that the current to that inductor will be reduced since there is less of a difference in voltage potential (ie., emf, the voltage) between the source voltage and the inductor. The inductance equation can be modified to include each wire turn (N) of a coil, which essentially sums up or effectively concentrates, adds to, and effectively magnifies the magnetic flux created or induced into a smaller area instead of a long length of wire, and therefor, the inductance of that coil will have a larger rating:

$L = N (B / I) = NB / I$: L = inductance i Henry's , N = number of turns, B = magnetic flux lines from one turn or loop, I = current in amperes (A)

Because an inductor reduces an alternating signal, it behaves much like a DC resistance that reduces or limits current, however, it will be called the reactance (Xl) of that inductor (and signal) since the effective AC resistance of inductor depends on the applied frequency of the AC or "(voltage) changing signal. Reactance has units of Ohms.

Passing a current through a length of wire produces a magnetic field that is curved perpendicularly around the center of that wire. A (opposite in polarity) voltage (emf, electric field) and corresponding current can then be induced (ie., like a simple transformer) in another or second wire that is parallel to that initial current carrying wire. The second wire, though parallel to the first wire, is actually then perpendicular to the direction of the magnetic field (flux or lines) direction of the first wire. **The magnetic field strength about a straight wire is: B = u I / (2 (pi) r)** . u is the permeabililty of free space = 4 (pi) (10^-74) , I is the current in amperes , (r) is the distance from the wire in meters. B is magnetic field strength in Teslas (T). The force on a length of parallel wire is: **F = L I B** , L is length in meters, I is current in amperes, and B is magnetic field strength, and F has units of Newtons.

With the previous understanding, given just one wire that is made into a loop or coil (ie., circular and spiral shape, like a spring, and usually coated or painted with a thin electrical insulation layer of paint) along its length. The (invisible) magnetic flux or field lines and the strength of the magnetism can "self induce" a voltage in the nearby (essentially parallel wire) loops or windings of the coil. This voltage will cause a current which in turn produces more magnetism. The magnetism or magnetic flux produced by each loop or turn of the wire in the coil is essentially summed together to produce a stronger magnetic field for a given amount of current. The resulting magnetic field of the entire coil will have a magnetic pole ("North" or "South", opposite poles) at each end. [FIG 263]



The more turns to make the coil, the greater the accumulated strength of the magnetic field produced. Each turn or coil will have a north pole in the center on one side of the loop or coil, and a south pole on the other side in the center. Placing magnets end to end or in series (North to South, and then North and South again) will create a stronger magnetic field and-or magnet. The energy of the electrons (ie., current) sent through that coil is converted to and stored as a magnetic (potential) field, and if the applied voltage and current to that coil then lessens or stops, the magnetic field decreases and essentially collapse down upon and passes through or "cuts" that coil again and induces (causes, creates) a voltage, much like a generator does, across that coil. Basically, a magnetic field will give electrons (ie., electric charges) enough energy to break free from their atoms and be free electrons (ie., current) in the wire. These free electrons now have a gained energy and can do useful work while releasing or using up their gained (kinetic) energy. The above figure of a coil is often called a **solenoid, and its magnetic field strength is B = u n I** , u is the permeability of free space, (n) is the number of turns per meter, and I is the current in amperes (A).

The first practical DC (direct current) generator was made by **Zenobe Gramme** (1826-1901), from Belgium, in 1869, and is type called a **dynamo** that has a commutator (ie., connection) ring that "(thin wire) or graphite brushes" would make contact with so as to deliver the power having more of a DC form with unaltering voltage polarity. In those times, there was no form of electrical rectification (such as with vacuum tube or solid-state diodes), and therefore mechanical rectification was the method used. Soon thereafter, Gramme also discovered that in a reverse manner, the dynamo was the basis of a DC powered motor, hence he invented the first practical DC motor to create rotational movement and-or power. An **alternator** is actually the basic form of an electric generator, and which makes AC electricity or power does not include a method to convert it to DC, and since the AC is useful in transformers and long distance wires so as to deliver energy. Essentially, a dynamo is a modified alternator. After Gramme made the DC motor, **Tesla** would invent the AC motor, and which also then showed people the usefulness of AC power. A **magneto** is an alternator that uses permanent magnets to create the magnetic field, rather than using electro-magnetic coils. A magneto system is often found in "(cord) pull start" petrol or gasoline engines where the force of the pull upon a cord by the user both moves and compresses the piston(s) and provides the energy to make the initial spark of electricity to cause the engine to run on its own power and generated electricity. In 1912 electric, high torque electric motors began to be used to start automobiles.

A basic form of one of the Maxwell equations is that EMF (electromagnetic force, voltage) induced is directly related to the rate of change (ie., speed) of the magnetic flux lines (B) with respect to time. This is also generally known as **Farday's Law of induction**.

voltage induced = emf = $-\frac{dB}{dt}$: emf = electromotive or electric force , B = magnetic flux , A stronger magnet will have a stronger magnetic field and-or more magnetic flux, and dB will then be higher.

: The faster a magnetic field cuts across a **wire**, or vice-versa, the higher the induced induced. Ex. The faster an electric generator spins, the higher the voltage produced. It is as if a higher force was in action to cause it. The higher the voltage (v = J / C) generated, the higher the current generated. dB / dt is the instantaneous change in magnetic flux with respect to an instantaneous (ie., momentary, brief, "quick", short, small, low) amount of time, hence the voltage is also an instantaneous value, and particularly with (rotating) electric power generators, and where the output waveform is a sine wave.

This induced voltage will then cause an induced (ie., generated) current to flow which will also create a magnetic field which actually opposes the original magnetic field applied that lead to its creation, and the voltage induced by that magnetic field is of opposite polarity to that which initially caused it. If the magnetic and-or flux field does not change, there will be no voltage induced in the other (output) coil of a transformer, hence transformers required AC electricity or pulsed electricity (ie., current) applied to the (input) coil for it to function as a (power) transformer and-or circuit isolation.

If there was no back-emf from the second wire, that second wire would then induce a voltage of the same polarity in the first wire and cause it to have a higher (ie., double) emf, and there would be a situation where the emf (v = J/Q) would keep increasing., however this cannot be the case when the input energy is limited to a certain value. There cannot be more energy out than that which as put in.

Inductance can be increased by using more side by side loops or turns of the wire so as to effectively increase the magnetic field strength, inductance and resulting generated voltage. The loops or **coil** of wire place a long wire into a smaller area that can be more affected by a relatively small magnet and its magnetic field.

Lenz's Law Formula: voltage induced = emf = - N dB / dt : very similar to Farday's Law of induction formula

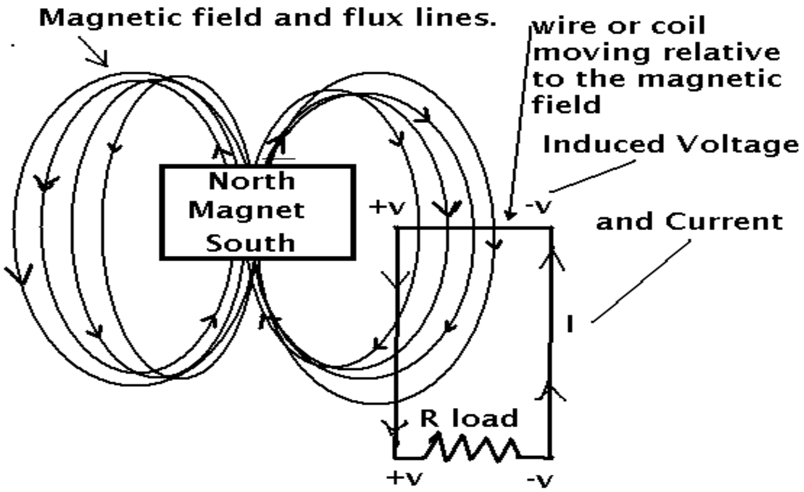
A common transformer which has two, non-connected, independent coils, functions by including another concept called mutual inductance. It may also be called as magnetic inductance. These coils are said as being only "magnetically (flux, energy) coupled", and that their (changing) magnetic fields (due to a changing or AC input signal) will influence each coil. The voltage produced in each turn and-or coil segment of wire is additive like small batteries in series, hence shown as a multiplication in the equation.

To create a simple **electricity generator** that creates a voltage and induced current, a single loop of wire is made to pass perpendicularly through a magnetic field, or vice-versa, and a small voltage and current will be generated. If there are N turns or loops in a coil of wire, the inductance and induced voltage will increase by that same factor of N and when the magnetic field effectively "cuts" or travels through only one half of the generators coil which has those turns of wire in the same direction, and so as the induced or generated voltage polarity and current will all have the same direction, and so as to not negate, reduce or cancel-out each other as a "back-emf" or voltage would. When the direction of relative movement of the magnet and coil changes to the opposite direction, the induced voltage changes polarity, and the induced charge or current changes direction, and this is the basis of AC electric power generation.

When a current is created or induced in a wire due to a magnetic field changing strength, the electron flow in the wire will cause the creation of a magnetic field about (ie., perpendicular to) that wire, and the polarity of this field will be opposite to that of the magnetic field which caused it. These opposite magnetic fields will then create a physical repulsion force applied to both the wire and magnet. In a motor that is to spin or rotate, this magnetic repulsion force is what causes the torque (ie., rotation force) which then rotates the rotor (ie., rotating) part of it.

To convert the mechanical-like input energy and-or force, to electrical energy, this force can be used to cause a rotation in both the turbine (ie., wind or water kinetic energy and-or force collector blades) and the electric generator which is mechanically connected via a shaft and-or gear(s) to the turbine. Remember, a non-changing magnetic filed just passing through a non-moving coil, or vice-versa, will not induce any change in voltage and-or current such as from being 0V and 0A. There would be no motion and-or kinetic energy available in this system so as to even be available to create, transfer to, and-or produce electrical energy. Gears can also be used to increase the speed of the rotation of the generator's rotor part , either to change torque (force) and-or its rotational speed (ie., "angular velocity") so as to have a maximum and safe energy output. Another method to alter the output electrical power after it is created is with a transformer so as to change the voltage and-or current available. Power = (Voltage)(Current) = VI watts = joules of energy / second. If the voltage changes by a factor of (n), the current will change by (1/n) since these two factors are inversely related if power is a constant value or product.

A basic representation of an AC electric power generator: [FIG 264]



Farday made some equations for the in a wire when it is moved past a magnet, or vice-versa. The equations are all somewhat similar. The faster the relative motion of a wire or coil, and the (perpendicular) magnetic field of an electrical generator, the faster the relative velocity of these two things and the greater the kinetic energy involved, and the faster the magnetic force is applied to the electrons in the wire and the greater the induced voltage will be. The stronger the magnetic field, the greater the number of electrons involved and the greater induced voltage (= J/Q) also. The length of wire perpendicular to and affected by the magnetic flux will cause a directly related increase in the generated voltage, and this is due to that there are more electrons being affected by the applied magnetic (force) field and given kinetic energy. A higher relative velocity between the wire and magnetic field, and a stronger magnetic field will effectively mean that the magnetic force will cause a higher amount of kinetic energy (Joules) in the electrons in that part of the wire. Remember that: voltage = (joules of energy / coulomb of charge) = V = J / Qc.

generated voltage = emf = - B v L : * , **B** = magnetic field strength or flux density perpendicular to the wire ,
v = motional velocity for a straight wire or angular velocity (¢ / t) for a rotating wire. **L** = length of wire = 1 turn , or set as N for number of turns of a rotating wire or coil. Due to Lenz's law, the negative or opposite value is indicated.
*** The above is a generalized equation and description of Faraday's Formulas.**
Extra: d = vt , v = d / t , dv = dd / dt = d¢ / dt

By using turns (ie., a coil) of wire, the voltage can be increased in an additive manner, and makes the size of the generator smaller and more practical, and since the addition is repetitive of the same value, this can be represented by multiplication by the number of turn: (total voltage) = (n turns) (the small voltage per single turn). This is much like placing batteries in series so as to increase the total voltage (or emf) available. The generated voltage with a generator is sinusoidal, hence the output is AC power. For the voltage and-or current at a particular instant of time, it depends on the angle of the magnets with respect to the coil. When the coil is perpendicular (ie., 90°) to the magnetic field, the maximum voltage is created. emf = (sine ¢) (B v L) . Generators and motors are nearly identical,except that a motor is often designed for high speed in many cases, and if this motor were to be used as a generator, a gearing system should be used so as to effectively increase and-or multiply the input speed (ie.,rmp) so as to have a usable and-or high enough voltage at the output of it.

The current (A or I) generated by a electricity generator depends on the value of the generated voltage and the resistance of the circuit. From V = J / Qc = I R we have: I = A = V / R .

Electrical Power = Pw = VA = V^2 / R = (emf)^2 / R = (B v L)^2 / R = B^2 v^2 L^2 / R = J / t = Fd / t = Fv

The **Lorentz Force** describes the forces upon an electric charge in an electro-magnetic field such as due to the presence of a magnetic and electric field acting upon it. There will be both an electric force and a magnetic force developed upon the charge. The Lorentz force is what causes a motor to rotate when electricity (ie., power = voltage and current [charges, electrons]) is passed through its coils, and of which are near a magnetic field. The interaction causes magnetic repulsion and the rotor (ie., spinning part) of the motor will then rotate. The direction of the electric and magnetic forces are at right angles to each other, much like the legs of a right triangle, and the resulting net force and direction is the vector sum of these two other component vectors.

$\overrightarrow{\textbf{Resultant Force}} = \overrightarrow{\textbf{Electric Force}} + \overrightarrow{\textbf{Magnetic Force}}$ **: the arrows indicate these are vectors which have a magnitude value and direction**

F = q E + q vB : q = charge E = electric field strength ,
v = velocity in (m/s) and is also a vector ,
B = magnetic field strength in teslas (T), here a vector
The value of vB is a vector product.

Protons and electrons will be directly attracted to the direction and source of an electric field. Protons will be attracted to the negative charges or source, and electrons will be attracted to the positive charges or source. It is of note that moving charges such as electrons in a wire will create a magnetic field perpendicular to and around that wire , and that a moving and changing magnetic field value will induce a (cause, produce, electric, free electrons, charges) current in a wire when they are moving relative to each other at right angle (90°, perpendicular to). The strength of the magnetic field created depends on the electric current in that wire, and the voltage induced in the wire due to the magnetic field depends on the strength of that magnetic field and how fast the strength of that field is changing - usually due to the relative motion of the wire and magnetic field. The higher the induced voltage (V = J/C = Energy / Coulomb of charges) created, the greater the current can be.

Neutrons are generally unaffected by an electric field since neutrons are considered as having no net electric charge. In a magnetic field, protons and electrons will experience a movement and change in the direction perpendicular to the magnetic field lines, each charged type will go in the opposite circular direction (CW or CCW). This will cause the electrically charged particle to go in a circular path.

Scientist, such as Einstein, have tried to consider and find if there is a unified or single source of the electric, magnetic and gravity (force) fields, and we know today there are other forces such as the nuclear weak and strong forces.

For creating a basic inductor component of an electric circuit, typically for frequency oscillators, tuners, and filters:

Lh = (permeability)(Nturns^2)(**A**rea of each turn) / (**l**ength of coil) : physical construction of an (coil) inductor

Lh = (u N^2 **A**m^2) / **l**m : u = permeability to magnetic fields, has units of (H / m) = (N / A^2)
Permeability is a measure of a materials ability to remain (permanently) magnetized.
It is also a measure of inductance per unit of length.
u = (magnetic field strength) / (nearby induced magnetic field strength) = B / H

We see that inductance is directly related to the number of turns of the coil, and the cross sectional area of the coil of which for a given current there is a greater magnetic flux and-or field created because the length of the wire and-or coil is longer and the resulting total magnetic field of the coil will then be greater. A basic formula for the minimum length of wire for a coil with thin wire is:approximately: **Coil Length** = (n turns) 2 (Pi) (radius of coil) = (n turns) (Pi) (diameter of coil), and you must remember to have some extra length for the straight leads and-or any connections to the coil. If the wire is thick and-or has thick insulation, and you want to be more precise, then the length of a single turn needs to be measured or calculated, and then multiply this by the number of turns of the coil.

For the total inductance of **inductors in series**:

Inductors in series essentially creates a longer inductor or "coil" with simply having more turns and length of wire.

Lt = L1 + L2 + . . . : this formula is similar to that for series resistors

For the total inductance of **parallel inductors**:

1 / Lt = 1 / [(1/L1) + (1/L2) + . . .] : this formula is similar to that for parallel resistors

For the reactance of an inductor

The reactance of an inductor (ie., inductive reactance) is essentially its ability to impede (ie., resist) an AC (alternating current) signal. The value of its reactance is also determined by the frequency of the applied AC signal to it. The impedance of an inductor is opposite in nature to that of a capacitor. For an inductor, its impedance increases as frequency increases, and at some point it will be like an open circuit or very high resistance to high frequency AC signals. Like capacitors, inductors can also be used as (frequency dependent) AC signal filters and in "tuned" (resonant frequency) oscillators. Reactance means how the inductor or capacitor reacts to the applied AC signal (ie, frequency).

$Xl = (2)(pi)(Fhz)(Lh)$: **reactance of an inductor**, **measured in ohm units**
$Lh = Xl / [(2)(pi)(Fhz)]$

The higher the input frequency, the higher the rate of change of the current going to it, and therefore, the higher the (ac) reactance induced because the rate of change of the (invisible) magnetic flux (lines) created will also be higher, and therefore the back-emf or reverse voltage induced is higher, essentially or effectively acting like a higher resistance impeding even more current flow. The equations for Xc and Xl are essentially, reciprocals of each other.

For a common example of an inductor, a typical audio speaker is an electro-mechanical transducer (ie., an energy or power transformer of sorts) that transforms or converts the input electrical signal energy to (vibrating, or pulsed) force and motion so as to apply pressure to the nearby air that acts as a sound conductor and transmits or radiates the air pressure or sound (a force due to compressed or decompressed, like a spring, air molecules). Our ears are essentially mechanical to electrical (nerve signals) transducers, much like how an electric microphone converts the received (sound, air) pressure or force into an electric signal. An audio speaker usually consists of an internal coil which is essentially an inductor or electro-magnet coil and which is standardized to be 8 ohms of impedance when a pure (AC) sine wave signal (voltage, current and frequency) having a frequency of 1000hz is applied through it. High power and-or high current speakers are often designed to have an impedance of 4 ohms.

For the wire length of an inductor: Given the circumference (C) of each turn, the basic length is simply the number of turns (N) times the Circumference length or distance. **Wire Length = Lw = NC** . You may then add on any additional length needed for the connection leads. From this equation,we have: N = Lw / C and C = Lw / N .

Some other common inductors are solenoids and relays which are essentially electromagnets to create a mechanical force or create an electrical operated switch..

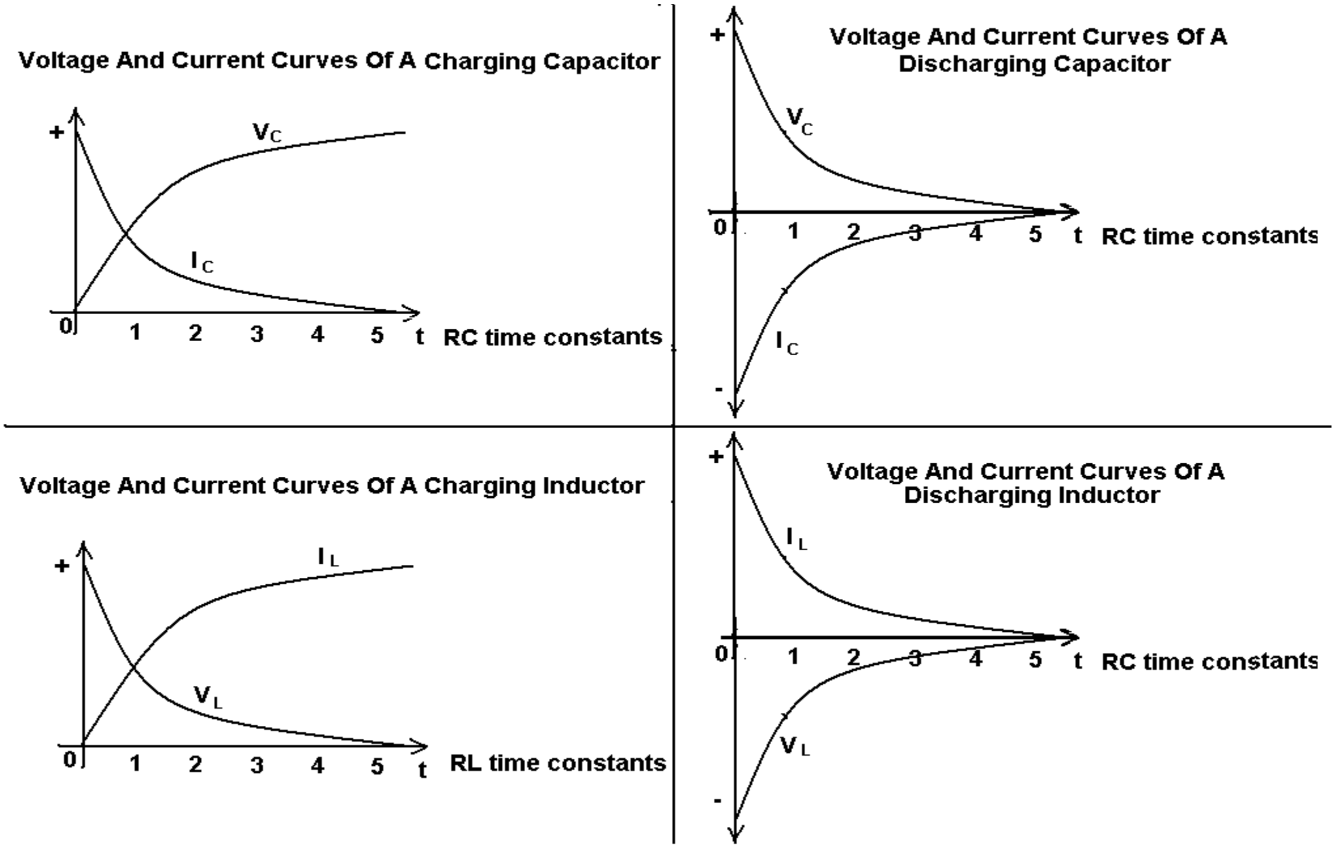
When a capacitor (C) and inductor (L) are in parallel to each other, such as in a (LC) tuner or "(LC) tank circuit", and each has its own reactance (X) to the applied input frequency, and the resulting or effective total reactance (Xt) and reactance formula is nearly identical to that of two resistors being in parallel ($R_{||}$) because reactance essentially limits current just like resistance does:

$Xt = \frac{Xc\ Xl}{Xc + Xl}$: **formula for two parallel reactances, such as in a LC tuning circuit**
At resonant frequency (Fr), Xc = Xl , and Xt or Zt is the highest possible.
(Xc + Xl) effectively becomes: (Xc + Xc) and-or = (Xl + Xl) = 2Xl = 2Xc ,and
Xt becomes: $Zt = Xt = Xc\ Xl / (Xc + Xl) = XcXc / 2Xc = (Xc)^2 / 2Xc =$
$= Xc / 2 = Xl / 2$

At what frequency (F) will Xc = Xl , We can solve this by setting Xc = Xl = (1 / 2(pi)FC) = 2 (pi)FL) , and we get the famous equation for the **resonant frequency of an inductor and capacitor:**

$F = 1 / [2(pi) \sqrt{LC}]$: Resonant Frequency Of An Inductor and Capacitor Circuit
$F = 0.159154943 / \sqrt{LC}$

Voltage And Current Curves Of A Charging And Discharging Capacitor And Inductor [FIG 265]



When done charging, the capacitor will store its energy in a electric field and charge. The (electric field). An inductor will store its energy in a magnetic field. When charging begins on a capacitor, the back-emf created at it 0, as like a short circuit, and the current will be at its maximum value.

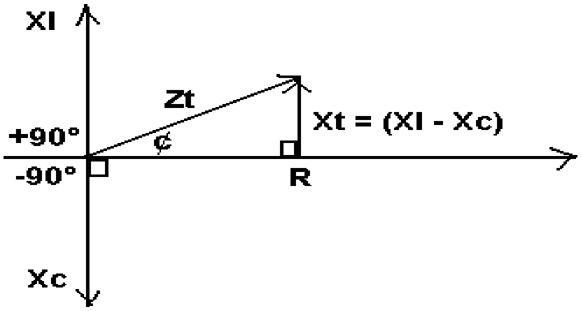
The discharging resistance or impedance and the corresponding time constant are generally not the same as the input or charging resistance and its corresponding time constant.

For a (magnetic field) charging of the inductor, the inductor behaves much like an open circuit with the full voltage available across its terminals. This initially fully impedes the current like a back-emf (reverse polarity voltage) at first and the current will then quickly rise in value to its maximum possible value, and the magnetic field and charge of the inductor will rise to its maximum possible value.

Note for example the change in the measured polarity or direction of the discharging current of the capacitor. This is so because the current is not entering the capacitor, but going out from the capacitor. If you do not reverse the leads of a voltage meter while measuring a voltage, you will also read a negative voltage during the negative half cycle of an AC wave, and in fact, you will also read a negative voltage across a component in a DC circuit if you switch the measuring leads around. An AC voltage or power source is much like taking the battery out of a DC circuit and switching the direction or polarity of it in the circuit, and very fast - either several to millions of times a second. This would be correctly called pulsed AC since the voltages are at maximum and not starting from 0 as in a typical AC signal such as a sine waveform.

The (dynamic) impedances or effective resistances of the charging and discharging capacitor and inductor are opposite or 180 degrees out of phase (ie., alignment, simultaneious) with each other and they can therefore effectively negate and-or nullify each other if they have the same magnitude or absolute value. These impedances are also both 90° out of phase with a resistor in series with it. It may be helpful to here to note a somewhat similar example that the common Sine and Cosine waves (and each instantaneous event or value) are very similar to each other but are not mathematical opposites or 180 out of phase with each other, but are 90 degrees out of phase with each other. Their "phase (or instance) shift" is said as being 90 degrees. Due to the above reasons, the total effective impedance to an AC input supply and-or signal is not simply R + Xl, or R + Xc, or R + Xl + Xc.. The total impedance is rather said to be a complex impedance that is composed of several parts and each being out of phase with the other two. The phase angle of the impedance due to a capacitance is -90 out of phase with that of the resistor, and this is said as being "leading" (already happened or earlier). The phase angle of the impedance due to an inductor is +90 out of phase with that of the resistor, and is this said as being "lagging" (or later in time). We can consider the value of the resistance (R) as a real value along the x-axis, and the other leg of this triangle would be the signed number sum of the inductive and capacitive reactances. If the inductive reactance is greater than the capacitive reactance, the circuit is said to be "inductive". If the capacitive reactance is greater than the inductive reactance, the circuit is said to be "capacitive". The effective resistance or total impedance (Zt) seen by the input signal is: [FIG 241B]

Total Impedance Of A Series RLC Circuit



When Xl = Xc, the phase angle is 0° and the circuit looks as "resistive" to the applied AC input signal.

From the Pythagorean Theorem:

$$Zt = \sqrt{R^2 + Xt^2}$$

Ex. An antenna for a certain radio receiver might be affected by some stray, nearby capacitance, and the antenna is then said as being "capacitive", and is then not being as efficient as it could be. This capacitive reactance can effectively be canceled or negated by using an inductor of a certain value which has the same reactance with the same applied input frequency.

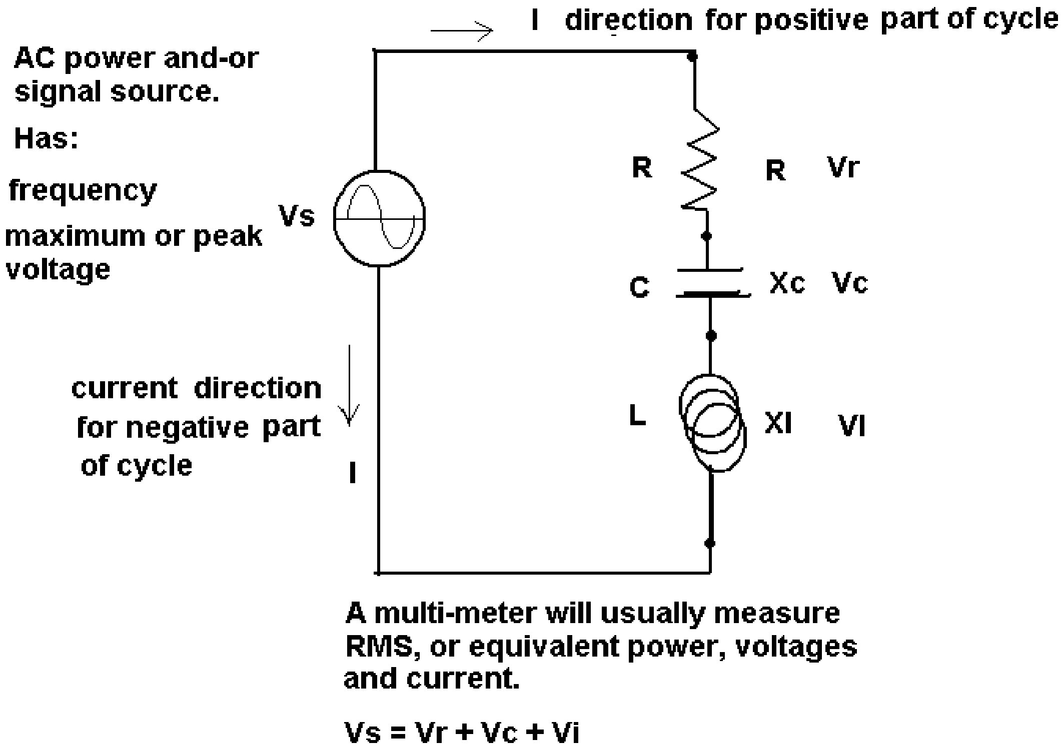
The concepts of Ohm's Law can be used for both DC and AC circuit analysis.

I peak = V peak / Impedance

It = Vt / Zt : AC , RMS, current through a RLC circuit and-or branch , **RMS** is the "root-mean-square" value of an AC voltage or current waveform. It is the effective or equivalent DC voltage or current.

Now for example, consider a certain given AC supply or signal frequency applied to a charging capacitor. If the charging resistance is very low, practically 0, the capacitor will quickly charge to that maximum AC supply or signal voltage which has its peak voltage at 90 degrees which is at one-fourth of its entire waveform period and-or cycle of time. A full cycle of a periodic waveform is a 360° waveform and it has a period of: P = Ts = 1 / Fhz. For a capacitor to charge up to the maximum input voltage during one 360° cycle of the input or applied waveform, the total time (5, RC time constants) of charging the capacitor must be less than or equal to one-fourth of the period time of the input frequency. In simple wording, the charging time of the capacitor, which is (5)(RC time constants), must be "fast" or short "enough" to properly handle one-fourth of the period time of the input frequency and signal, otherwise a portion of the input signal will get "clipped" (ie., lost, removed) or distorted.

An RLC (Resistor, Inductor and Capacitor) series circuit or current branch. [FIG 266]



Summarizing the basic electrical functioning of an inductor:

When a voltage supply sends a current to an inductor that has a low DC wire resistance, the current will be high. This high current will immediately create a high magnetic field about the coil and-or inductor. This growing or changing magnetic field will induce a voltage in the wire of that conductor and-or inductor, and this voltage will have a reverse polarity as that of the supplied voltage to that inductor. Due to this, this reverse polarity voltage is also called a back-emf or reverse-voltage emf. This voltage will reduce the effective applied voltage to that inductor, and the current to it will be very low at first since the back-emf is high, and then the current will increase as the magnetic field energy decreases over time and it is converted to electrical energy.

Voltage Divider Method To Find The Value Of An Inductor Or Capacitor

First, there are both capacitance and-or inductance meters available for purchasing, and as of the year (2022) they are widely available and relatively inexpensive. This note or discussion here has a forward reference to the general concept of the voltage divider that is shown after this one.

By having an AC voltage source and creating a voltage divider circuit with a resistor and either a capacitor or inductor in series with it, the value of that inductor or capacitor can be found from their reactance (ie., frequency related impedance or effective resistance) formulas:

From Ohms's Law: I = Vr / R amps , we have: R = Vr / I and Xl = Vl / I and Xc = Vc / I

From: Xl = 2 (pi) Fhz Lh , ohms , we have: Lh = Xl / [2 (pi) Fhz]

From: Xc = 1 / [2 (pi) Fhz Cf] , ohms , we have: Cf = 1 / [2 (pi) Fhz Xc]

For an example AC, series circuit, the AC voltage source might be 10 volts, and having an arbitrary sinusoidal frequency of say 1000hz. The resistance (R) also helps reduce the current to a safe level, perhaps 50mA. Hence R would then be calculated at: R = 10v/0.050A = 200ohms. Pr = (Ir)(R) = (0.50)^2 (200ohms) = 0.5Watts, hence use a resistor that is rated to handle at least a half-watt (1/2W = 0.5W = 500mW) of power (ie., loss in it as heat energy). For better accuracy, you can experiment with the value of the input power supply's or AC signal frequency. The voltage drop across a capacitor or inductor is equal to its reactance times the current through it, and this is Ohm's Law. Since a certain frequency will cause an associated value of reactance in an inductor or capacitor, by using a stable or constant voltage source, it is also quite possible to also measure or have a good estimate of the input frequency by measuring the voltage across the inductor or capacitor. A calibrated scale or chart can be constructed beforehand and checked via experimenting with a variable range of input frequencies.

Besides an initial pulse of current, DC current will not flow through any branch of a circuit containing a capacitor.

For an AC applied signal, although an inductor or capacitor have a reactance to the applied AC voltage and-or signal and will reduce the circuit and-or branch current and available power, there is no theoretical power loss in them like a resistor would have. The inductor and capacitor will eventually give any energy storage back to the circuit and-or load resistance.

An inductor and capacitor in series can create a filter, and in particular, one that easily passes a certain frequency better than both the higher and lower frequencies. At this (frequency band and-or range) pass frequency where the impedance is effectively 0 ohms, a safety resistor can be used in series with the inductor and capacitor so as to keep the current in that wire or circuit branch to a safe value. A resistor and-or wire resistance will also reduce the available power output, and increase the charging and discharging times of both the capacitor and inductor.

[This space for book edits.]

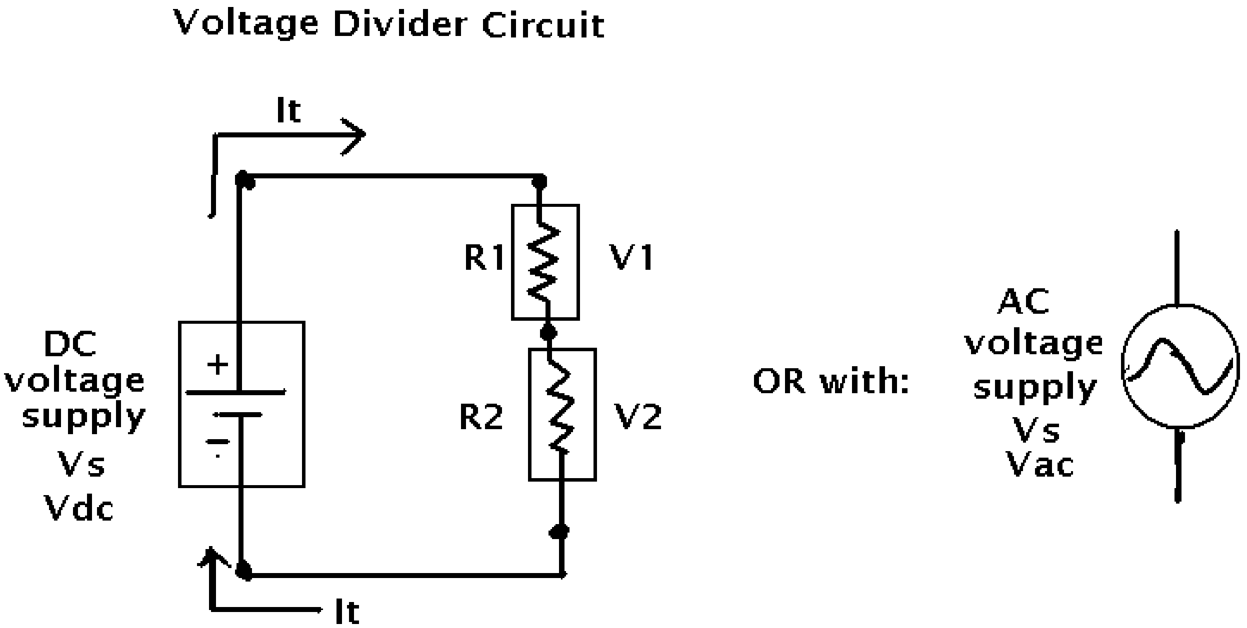
The Voltage Divider Concept

Whenever two or more resistances, and-or inductors, and-or capacitors are in series such as for AC circuits, each will have a certain value of resistance and-or impedance to the flow of AC electricity or current. There will essentially be a loss of energy trying to push that current though it and this results in voltage loss or drop through that component (a part or part of something larger, such an electric device and-or circuit). Because of this, there will be less voltage or (electrical, emf) potential energy available to the rest of the circuit. The higher the resistance to DC or AC, and-or impedance to AC signals (voltage, current,and frequency), the higher the corresponding voltage loss or drop in, through and-or "across it". There is a figure of an example voltage divider circuit shown below.

A common example of when a voltage divider circuit is needed is when a power supply being used is greater than 3Vdc and a voltage drop is then needed to reduce the voltage and current to a LED (that produces light) to its safe and recommended operating values. A voltage divider circuit will reduce the power to it and with a voltage of just 3Vdc is across that LED, and having about 20mA of (circuit, resistor limited) current through it. This circuit is also a form of voltage setting or regulation to the load, however a true **voltage regulator** can automatically keep the same or constant desired voltage to the load if the input supply voltage and-or load resistance changes. Most voltages regulators are not designed to increase the load's supply voltage if it is insufficient, but rater just reduce a larger supply voltage to the needed value.

A voltage drop across and-or through a component also means a loss of available energy or power in that component, and therefore a loss of power available to the rest of the circuit. For resistors, the loss of power is usually in the form of wasted heat energy, except when heat is actually desired such as for an oven and-or heater of some sort.

A voltage divider is a concept that the higher the impedance to (the same) current flow through two or more components in series, that the voltage drop or loss across and-or through it is directly proportional to its impedance. It will take a higher voltage to force a certain amount of current through a higher resistance to the flow of current. A circuit may be designed to include a voltage divider as a necessary part and-or function of the circuit, such as for example reducing the voltage to a certain usable and safe value or level; perhaps to control the volume in a radio by using a variable resistor controlled by the user via an external adjustable knob. The voltage divider concept is well known in the study of electricity and electronic circuits, study and applications of electricity. [FIG 267]



The voltage drop (V) across a component in a DC or AC circuit is equal to the current (I) through that component times the effective impedance (Z) to the flow of that current. If two of these values are known, the third value can be calculated by using Ohms Law ($I = V/R$):

$Vv = (Iamps)\ (Zohms)$: for two or more components are in series, the current is the same value through them

If the voltage is the same across each component in series, then their effective resistance is the same value.

Ex. Connected to an AC or DC supply voltage are two components (ex. resistor, capacitor, inductor) that are electrically connected in series with each other. It can be said that the (input) supply voltage is connected to and-or "across" those two components in series. Obviously, the sum of the voltages across each component cannot exceed the supply voltage, and in fact, it does equal the supply voltage. The actual voltage across each component will be less than the supply voltage:

$Vsupply = Vcomponent1 + Vcomponent2 + \dots$: voltages across series connected components

The current through each component connected in series is obviously the same for each, and that is the total (It) or supply current. The value of this current is determined by the supply voltage (Vt) and the total impedance (Z) to the flow of the generated or induced current.

$It = Vt / Rt$ or= Vs / Zt : It = Total current and $Zt = Z1 + Z2 + \dots$ = tatal (current) impedance

$I1 = I2 = \dots = It$ Using Ohms Law, substitution, and considering just two components in series:

$Vt = V1 + V2$

$Vt = (Z1\ It) + (Z2\ It)$ Since (It) is a factor to each term, and factoring it out, we have:

$Vt = It\ (Z1 + Z2) = It\ Zt$ solving for (It):

$It = \frac{Vt}{Zt} = \frac{V1}{Z1} = \frac{V2}{Z2}$: since the current (here, It) is the same value through series components

Indicated by the above equation for (It), and that each component has the same amount of current through it, when given just two components in series, the ratio of voltage across each component to its impedance is the same for each component, and this same ratio value equals the same current (here, It). Mathematically:

$\mathbf{\frac{V1}{V2} = \frac{Z1}{Z2}}$: **Equal ratio of voltages and impedances**. **Voltage Divider Equation** for two components in series, and if they are resistors: R1=Z1, and R2=Z2, and mathematically:

$$V1 = \frac{V2\ (R1)}{(R2)}$$

$$V2 = \frac{V1\ (R2)}{(R1)}$$

$Vt = Vs = Vin = V1 + V2 = (It\ R1) + (It\ R2) = It\ (R1 + R2) = (It)(Rt)$

If the output voltage (Vout) is the voltage across R1, then R1=Rout:

$Vout = V1 = V2\ (R1 / R2) = (It)(R1) = (Vin / (R1 + R2))\ R1 = (Vin / Rt)\ R1 = (Vin / Rt)\ (Rout)$

$Vout = Vin\ \frac{Rout}{Rt}$: A formula to calculate a series voltage across a component when the current is not known

$$\frac{V_{out}}{V_{in}} = \frac{R_{out}}{R_t}$$

: General equation for the ratio of corresponding voltages and impedances for series components. Vin = voltage across all the series components, Rt = total series resistance.

If you want a certain Vout, the proper value of Rout to achieve this must then be calculated from this formula:

$R_{out} = (V_{out} / V_{in})\, R_t$

In the above drawing, R1 and R2 can actually be one larger resistor with a lead output or terminal wire someplace between that larger resistor's end terminals.

If one, the other or both of the series resistors is made to be a variable resistor, the output voltage can likewise be made to be adjustable and stet to a needed value. This is an example of an **adjustable voltage regulator**. To regulate a voltage is to keep it at a steady or constant value for the circuit designed to work with that voltage. With a fixed value of resistance (ie., Rout) and the voltage across it is used as the output voltage, a problem can develop when a load (ie., that which draws the load of current and-or power such as another resistance, circuit application [ex. a radio, a speaker, motor, heater, a light, etc.]) is placed in parallel (ie., "next to", across its terminals or leads) to it so as to be powered by that output voltage. When two resistance are placed in parallel, their net or total resistance is actually less, and this will then affect the voltages of the voltage divider circuit, and since the resistance would be less, the voltage across it will also be less. A solution is to make a variable (user adjustable and set) voltage divider circuit or use a pre-made, adjustable voltage regulator circuit to supply power to experiments, projects and circuits.

Some basic ways to set an output or load voltage when there is a greater input or supply voltage are with resistors (Vr=IrR), diodes (Vd =~ 0.7), LED's (a red, amber or yellow led will drop about 1.8v to 2v, and a white led will drop about 3v to 3.5), and transistors being used as a variable resistance by varying the input base current, **Zener diodes** are a reverse voltage polarity (ie., setting, operation, bias) operated diode which "breaks down" and conducts at a specific manufactured and-or tested voltage, and so as to keep a constant voltage across it which is good for supply voltages that may vary by a few volts more than needed. Zener diodes behave like a common diode when forward biased. If must be noted that (common, single) LED's can only handle or pass relatively low currents of about 10ma to nearly 30ma, but (power) resistors and-or (power) transistors can handle more current and power dissipation, and of which is an undesirable waste of energy and a circuit should be designed so as to keep the power losses as low as possible, while maintaining circuit and-or load stability.

Today, pre-made voltage regulator circuits, sometimes called "modules", are relatively inexpensive to purchase, and most (but not all) convert a higher DC voltage to a lower DC voltage needed. Many modern voltage regulators are based on, or similar to, the common, inexpensive **LM317** IC (Integrated Circuit, "chip", general identification, however the **LM317T** is recommended), user adjustable (about 1.25vdc to about 37vdc, at 1.5A max limit before internal shutdown for safety, and typically used with a 5k ohms variable resistor) or voltage settable by using fixed resistors. The voltage dropout or loss across it to function is 3v minimum needed to function. This IC chip only has 3 terminal pins. Because these must drop a voltage so as to have a desired output voltage value, that voltage drop or loss within the voltage regulator passing the circuit current through it will also create an unavoidable, wasteful power loss in that IC, and a "heat sink" (and thermal conduction paste) should be considered to avoid damage to that chip. If the input voltage to the voltage regulator is close in value (say just 3 volts higher, as required for it to function properly) to the desired and set output voltage, then there is only a low voltage drop needed, and therefore a low power loss in that IC and a heatsink (or heat-sink) may not be needed. One nice feature of this particular IC is that the output voltage will remain the same, fixed at the desired value, even when the input supply voltage varies higher and-or the output load resistance varies. The LM317 chip manages to do this by sensing a small amount of output current that is fed back into a pin on the chip through a resistor, and this "feedback" or "sensing" current will actually be used to then automatically adjust, regulate and-or maintain the output voltage to the desired level. With a few extra parts, such as an AC voltage step-down (voltage reduction) transformer, 4 power diodes, and high capacity capacitor(s), especially at the input, and 4 power diodes, and two voltage setting resistors [note, the LM78XX fixed voltage regulators have these resistors built in], this voltage regulator IC circuit can also be made into an AC (such as from typical 120Vac household outlet voltages) to DC voltage regulator. The chip even has a short circuit protection at the output or load, and it will then essentially turn off the output current. The output current for this specific LM chip number is also limited to regulating a maximum of 1.5A of current. It is best then to use a transformer that can supply a minimum of 1.5A of current or greater. The diodes chosen must also be capable of handling a minimum of 1.5A of steady current, and the voltage ratings of the capacitors used need to be capable of safely handling the applied voltages so as to not be damaged. Capacitors with a voltage rating of 1.5 times higher or more than the max. input voltage expected to the LM317 chip are recommended. For a steady dc supply input to the LM317 type of voltage regulators, the input and output capacitors are optional, but small ones are often still recommended. Further ahead in this book, there is a circuit example of a variable voltage power supply based on the LM317. A premade circuit (called something such as a LM317 circuit board module or kit, voltage regulator) can also be purchased inexpensively (a few USD), such as from the **Ebay.com** website. Some of these kits include a LED digital display for the voltage and-or current, however, these small displays and-or meters are now relatively inexpensive to include in many projects. The transformer is usually sold separately, and is needed to convert AC household voltages to (usually lower) DC voltages. This is the most expensive part of a power supply, perhaps 20 USD new, and it is a good idea to save and-or obtain inexpensive and-or used or recycled ones if they are available. Due to this high cost, you may wish to place this into its own box and reuse it for various other projects and-or experiments. The LM317 has a maximum input voltage of about 40Vdc, but due to a voltage loss in it or "voltage dropout", 37Vdc is maximum. The common size and packaging of the LM317 is with TO-220 case (about 15mm by 15 mm), but the LM317L, LM317LZ and-or 78L05 version has the small plastic TO-92, three lead transistor-like case, and can handle 100mA of current, and is about half the price of the full size and power LM317. The **LM317HV** IC is capable of regulating 1.25vdc through 60vdc, 1.5A max., and with a voltage dropout of 4.2v. The **LM338** is a 5A version of the LM317. Similar to the LM317 are the preset (not generally adjustable, but one constant preset voltage by using internal resistors in the IC) voltage regulator IC chips designed for a specific output voltage such as the common **LM7805**, 5v voltage regulator (very good for USB projects) with a dropout voltage of about 2V, and a max. current of 1A to 1.5A - check data sheets with the L7805. Due to this voltage dropout, ,the input voltage will need to be at least 7V so as to have a 5V output. Another type of voltage regulator for power supply projects is called a **"buck converter", "boost converter", or "switching converter" (due to the [repetitive, oscillating] DC square wave pules used, typically having a frequency of several thousand hertz), "switching regulator"**, and these use a small transformer so as to either increase the output voltage and reduce the output current, or decrease the output voltage and increase the amount of current output, perhaps twice that of the input, and so these converters (or power inverters) will waste much less power than a series or inline voltage regulator which essentially operates as a active resistive voltage divider. An inexpensive DC-to-DC, step-down, buck-converter module is based on the **LM2596** IC chip. If you need a (voltage) step-up, buck-converter, check out the **MT3608 IC** and-or other circuit modules. **A (AC to DC, or DC to DC) switching regulator is usually between 90% and 95% efficient at converting the input power to output power.** A non-synchronous switching regulator with its AC to DC rectifying power diodes (like a bridge circuit) is very good, but is somewhat less efficient (maybe 10% less) than that of a synchronous regulator with its MOSFET's being used as fast (low turn-on and turn-off times, very low Vforward drop), low internal resistance, high current switches, and with lower internal power losses. These MOSFET's are in synchronous and have opposite (on/off) conduction states, and it improves switching time speed and therefore, output power efficiency. **Switching regulators are very helpful for charging batteries,** however they will mostly likely introduce **RFI (Radio Frequency Interference) noise** either due to the switching oscillator circuit itself and-or some noise as high frequency voltage spikes and-or "ringing" (some low-amplitude, higher frequency oscillations) in the output DC power even if the regulator has some basic noise filtering methods. This electrical signal noise might affect other sensitive electronic equipment - perhaps a sensitive radio and-or certain frequencies. A common switching or oscillating frequency for these devices is about 100Khz since the higher it is, the less power (Joules of energy / time) wasted and the more efficient it is. Common noise filtering methods for DC power are a low pass filter composed of a capacitor that will have a low reactance and impedance to high frequency signals and will then pass them to ground and pass the lower frequency DC signal to the circuit output. Another method is a ferrite [or iron?] (RF) **choke** - basically an inductor, either a bar or toroid [ring, "doughnut"] shape which has higher (ac) impedance and filter to higher frequency (ie., AC) signals and noise, therefore acting as an electronic signal filter to reduce the signal amplitude (ie., of the voltage, current and power) of higher frequency signals. This choke and the wire(s) wrapped on it are generally used in "common mode" filtering or rejection which means that a common (ac) voltage spike on the wire(s) or line(s) wrapped on this choke - much then like a transformer, but with the coils wrapped in opposite directions, will be reduced as the induced magnetic fields, voltage and current will effectively cancel each other out to an acceptable small or 0 level. The noise filtering methods, if any, on inexpensive devices are often not enough due to costs, but it is still possible to purchase noise filters and-or make your own after having a study on them and their design. A choke will pass DC current, but impede (changing) AC current. Even some "**pure sine wave**" power inverters (ie., 12vdc to 12vac) might still produce some RFI which may particularly affect some sensitive electronic devices and-or radio (RF) receivers and-or transmitters. "**Modified sine wave**" inverts are based on circuit shaping a square wave into a sine wave, and may produce more noise., but these inverters are less expensive, and are adequate for some devices.

Because resistors, capacitors, and-or inductors have an impedance (Zohms) to AC current or signal, these components can be used to make (frequency dependent) AC voltage divider circuits.

Current can be divided when it goes through a parallel branch or circuit. A parallel branch is essentially a **current divider** circuit or path that is part of a larger circuit. The sum of current through each parallel branch (b) will be equal the total supply current to all those branches. According to Ohm's Law, the specific current through a certain parallel branch is determined by the total supply voltage (Vb) that is applied to all the branches in parallel, and the total impedance (Zb) of that certain branch being considered. If a branch has several components in series, then each will also have that same branch current through it, much like when a steam that varies in depth, wide and shallow, or narrow and deep, will have the same total flow of liquid past each location along it if no other energy is input into that system at some location.

Total current available to parallel circuit branches = (current in branch 1) + (current in branch 2) + **. . .**

$It = Ib1 + Ib2 + \dots$ For just two parallel branches containing just resistors:

$It = \frac{Vb}{Rb1} + \frac{Vb}{Rb2}$ Combining fractions, and we also know that:

$It = Vt / Rt = Vb / Rt$ and for only two resistors in parallel, this becomes:

$It = Vb / [(R1\ R2) / (R1 + R2)]$, and:

$$It = \frac{(R2)(Vb) + (R1)(Vb)}{(R1)(R2)} = \frac{Vb\ (R1 + R2)}{(R1)(R2)}$$

$$\frac{Ib1}{Ib2} = \frac{Vb / Rb1}{Vb / Rb2}$$

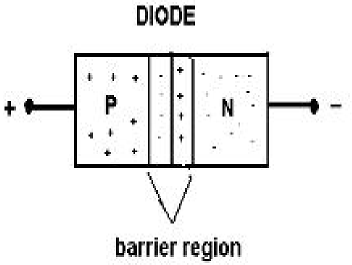
$\boldsymbol{\frac{Ib1}{Ib2} = \frac{Rb2}{Rb1}}$: **Ratio of currents and resistance of parallel circuit branches.**
This is an inverse type of ratio since current is inversely related to the resistance.
The lower the resistance of a branch, the higher the current through it.

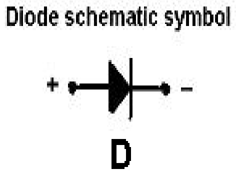
(Ib1)(Rb1) = (Ib2)(Rb2) = Vb = the same voltage across the two parallel branches

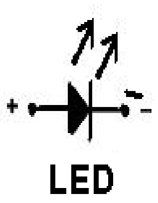
DIODE (An Electronic Current Flow, One-Way Or Direction Valve) : A passive device, but some power is lost in a diode

The word "diode" means "two-electrodes", but that is rather its physical description and not its electrical description. Its electrical description is much like an electronic one direction or way value or gate for current to flow.

An ideal or theoretical **diode** is an electronic device that conducts current in one direction, much like a mechanical valve that permits a fluid to flow in only one direction and is closed to the flow in the other direction. In actual practice and what can be manufactured at the present time, it is a device that conducts most current in one direction, and only a very small, usually negligible amount of current ("reverse current", or "reverse leakage current") in the opposite direction, hence it is not an ideal diode in terms of theoretical function, but it is still practical enough to be used in most circuits. An ideal diode also has 0 ohms of resistance like a short circuit or switch, wastes no power, turns on at any voltage above 0vdc, and has infinite impedance (ie., resistance) to the flow of current in the opposite direction, much like an open circuit. Most common (non-ideal) p-n silicon diodes, such as the very common, mass produced, and low cost (small signal power) **1n4148** "fast switching" diode in a small glass cylindrical case have a rated turn-on (forward or conduction) voltage of about 0.7Vdc, and the diode has a low ON or (forward) conduction resistance, usually less than 1ohm. It was first produced as the (very similar) **1n914** in 1960 by the Texas Instruments Co. It's maximum continuous rated current is 300mA. and has a maximum reverse voltage rating of 75v. Some 1n4148 diodes may have a continuous current rating of only 150mA to 200 mA. Its maximum on-off switching frequency is rated at 100mHz. General purpose low power (<=2A) silicon diodes are very common and inexpensive. [FIG 268]







A solid-state diode is composted of two pure crystalline metal pieces, often silicon, but could be germanium as used initially, and that were made to have an abundance of charge carriers of either free electrons (as for N or negative type material) or free "holes" (as for P or positive type material) so as electrons and holes can essentially move or be relocated through the crystal lattice structure of the materials. When the two semiconductor metals are joined together, the charge carriers of each type of semiconductor material will essentially cross at the thin junction region and create a (electrostatic, charges) conduction or voltage barrier (that must be first overcome by an applied external electric potential so as the diode can conduct electricity) across that effective "depletion [low conduction] region" or junction which can be thought of as being void of any charge carriers (ie., hence, a very high resistance to current, until it is overcome by a "voltage pressure or breakdown") which would allow easy conduction. The voltage to overcome a diode's junction or barrier region is called the barrier or "turn on" (conduction) voltage. When the **barrier region** is naturally created with a sufficient, limited number of charges (electrons and holes) near the junction, it will also prevent more charges from continuously neutralizing each other across the junction or barrier region and then that region growing larger in size. From this discussion, if someone was to call the barrier region a electrically neutral or neutralized region, I would agree with them.

For current to flow through the diode, it must overcome (be greater) or "breakdown" the current flow barrier at the semiconductor junction. The barrier (breakdown) voltage is about 0.7v for a silicon diode, and 0.3v for a germanium diode. At this voltage the diode is said to be fully on or conducting current, and having a very low resistance. Because this must be overcome to conduct electricity. The applied breakdown voltage will essentially be the force needed to push and conduct charge through the barrier region as if eliminating it. Because there is a voltage loss across a diode, there is also a power (P) loss through a diode (d) that is equal to:

Pd = (current through the diode)(voltage drop across the diode)

Pd = (current through the diode)(barrier voltage) , and:
Pd = (Id)(Vd)

The diode symbol on the right is used in electronic circuit schematics (ie., representative plans, diagrams, drawings), and it is symbolic of one of the first diodes used and that is the point-contact diode, and where a pointed tip of a wire was placed on the surface material of the diode so as to find a good location where (diode) rectification happened. The banded indicated side or end of a diode is the negative or cathode end.

Each diode will have a maximum voltage, current and power rating. Each diode also has a maximum reverse or "inverse voltage" that can be applied before a diodes barrier electrically breaks down and starts to conduct current in the opposite direction. This is a diodes breakdown voltage, and is usually much higher (maybe 25v to 1000v, check the data or information sheet or literature) than the "forward" or "turn-n" (conduction) voltage of the diode, such as 0.7v. These diode parameters, like any other circuit component or device, must be taken into consideration when making a circuit that has certain parameters (ie., values) and requirements. Some galena, germanium, and Schottky diodes have a low forward voltage (Vf or Vd) of about 0.25V, but common silicon general purpose diodes, they have about a 0.6 to 0.7v drop across them needed to conduct well.

At lower applied voltage levels before a diodes barrier voltage (about 0.7v) is reached, a diode behaves like an open circuit or high resistance to the flow of electricity. An ideal diode would turn on and conduct electricity at exactly 0.7v and always behave like either an open or closed circuit depending on the applied voltage. In practice however, diodes are not ideal, and some forward current will flow depending on the applied voltage that is below the "turn on" voltage. With applied voltages of less than 0.7v, the diode will essentially behave like a voltage controlled resistor or resistance. As a thought experiment, it will change from say 100kohms at very low applied voltages to, about 1 ohm at 0.7v when the diodes barrier or junction voltage is reached and it will essentially "turn on" or "switch on" to conduct (forward, normal) current like a low value resistor, and ideally like a short circuit or switch.

The **effective resistance of a diode** is: (voltage across the diode) / (current through it) = Vd / Id

Diodes are often used in or for: radios, removing voltage transients ("spikes", quick and large voltage electric pulses, such as from static electricity, lightening and other (high voltage, high power) electronic noise such as from inductors and motors), voltage references, and in some voltage regulator circuits such as for a full wave AC rectifier (ie., wave inverter) or "bridge rectifier" in electronic power supplies or signal conditioning and processing so as to create a near DC signal. Many semiconductor devices, such as (BJT) transistors, essentially have diode junctions within them such as between the base and emitter (pn) semiconductor materials, and it is important to first have a basic understanding of diodes so as to help understand transistors and other "active (electronically controlled, operated) devices". Sometimes diodes are used to protect electronic devices or components such as transistors (BJT's and FET's). For example, two reversed Zener diodes in series can prevent high voltage spikes from damaging the thin insulating gate of a FET by then conducting and shunting the energy to the ground and away from the FET transistor. The conduction voltage would be the (specific rated breakdown) voltage (Vz) of the Zener diode, plus the normal conduction voltage of a Zener diode (ie., Vd=0.7v). The "turn on" voltage of this arrangement would be: (Vz + Vd)

Because a radio wave (RF energy) received by an antenna is a very small amount, both in voltage and current, there is not enough voltage available to over come the conduction or forward voltage of a (0.7v) silicon diode, and rather a diode such a germanium with a forward voltage of about 0.25v is used. Still, even with a germanium diode, there will be signal power loss through the diode and this will reduce the audio output level. Some people have even applied a low ("bias") voltage across (ie., parallel to) a diode so as to help it conduct, and so that the diode is not damaged by a high current,, a very high resistance (such as a fixed safety resistor, say 10k ohms in series with a variable 1Mohm variable resistor) is in series with the battery of say having 1.5v or possibly 3 small solar cells if there is enough sunlight. It is also possible to amplify a weak radio signal before or after the diode by using a transistor, and in fact, a single transistor can be used as both a diode due to its base-emitter pn junction, and it can also be used to provide some signal amplification. In this circuit, a BJT transistor and-or amplifier is biased by a supply voltage, but is biased to be barely in the ON or conduction state due to the very low DC current allowed into the base by using a fairly high resistance and-or impedance to the AC signal. The base-emitter diode junction will then have a high resistance also. The base bias resistance is say 100Kohms to 1M ohms when the voltage source is about 5v to 12v, and this also prevents "loading" or "dampening" of the oscillations in the LC "tank" or tuning circuit, and it helps ensure that a highest voltage of the received signal is applied to the input of the transistor. An FET transistor can be used also, and it was designed to already have a high input impedance. **As a reminder, when two resistances are in parallel, the effective or combined resistance is less than or equal to half of the largest resistance, and is slightly less in value than the smaller resistance.** A signal will see or be affected by the combined resistance and-or "the load". If the load resistance is low, more current can flow. If the load resistance is high, less current will flow. With impedance matching, the most electric power (= V **I**) is transferred.

Power diodes can safely pass or handle currents >= 1A. The **1n4000** or= **1n400X** series (1n4001 to 1n4007) are low cost silicon diodes in a black cylindrical case, and are only capable of low frequency (a few khz maximum) switching applications such as for power rectification, reverse polarity protection and safety, and for circuit applications and-or experiments. The 1n400X series can safely pass 1A. The **1n4001** can handle a reverse voltage of 50V. **The 1n4007** can handle a reverse voltage of 1000 volts. The **1n540X** series are 3A versions of the 1n400X series.

A **thyristor** is like diode and a transistor combination, and having a third semiconductor layer. It has a third terminal between the other two layers, and it is called a gate which can turn the thyristor's conduction and diode action on or off, however it cannot amplify or modulate the current through the device like a transistor can. A thyristor is essentially a non-mechanical, electronic (semiconductor) relay. The **SCR** (silicon controlled rectifier) and **Triacs** are based on the thyristor. An SCR is generally for DC (ie., one direction) current and-or power (VI) control to a device, such as motors and dimmer circuits. A Triac is similar to an SCR,however it is made to also allow AC current flow, and is essentially two parallel SCR's in reverse connection. Triacs typically have a lower current ability than that of an SCR.

TRANSFORMER

Today, the common meaning of the word (electronic or electricity power) **transformer** is an electronic device to transfer power from one circuit to another, such as converting 120v AC signal (voltage, current and frequency) house-hold power to a safer, lower DC signal and power. A transformer can be designed to alter or change how that power (P = voltage x current, watts) will be transformed and output as either a maximum voltage or current. A transformer will have a maximum input voltage and current rating, and each transformer will have a maximum output voltage and current rating, and generally due to the wire gauge used. Transformers can also be used to electrically isolate two parts of a circuit since the power is transferred magnetically with a magnetic field extending from the input coil to influence or induce a voltage and cause an electric current in the output coil and circuit. The amount of current in the output circuit depends on the resistance of the transformer output coil wire and the external circuit attached to it.

The main construction of a transformer is essentially that of two (magnetic field) inductor coils placed near each other. The input power is transferred magnetically from the input or primary coil to the output or secondary coil. Many transformers have both coils or "windings" interwoven (crossing, among), next to (ie., parallel to) each other so as to be more efficient at transferring all their input power available to the output. The magnetic field of a wire created by current has a circular in shape around the length direction which will affect (ie., "cut", influence) another wire in parallel to it. This, along with using metal (magnetic conductors) to direct the current created or induced magnetic fields can increase the efficiency of that transformer. A power transfer efficiency greater than 90% is satisfactory and typical of a transformer. The ("dc", constant, natural, "ohmic") resistance of a transformer's internal coils (ie., inductors) of wire will cause an energy (joules) or power loss. Power = joules/second. Most of the energy loss is converted to and appears as heat energy.

For a magnetic field to induce a voltage and current in a coil, that magnetic field must be changing (increasing or decreasing) in intensity, growing or reducing in strength, so as the "magnetic (field) lines" are increasing and extending (ie., moving) outward and essentially "cut" (through or "across") those windings of the coil and induce a voltage in that coil. Either the wire (with electrons) and-or the magnet field must be moving with respect to each other. For maximum induced power, each should also be perpendicular to the other. A constant or steady magnetic field will not induce a voltage in a nearby stationary coil. Because of this, the input signal to a transformer must be a form of AC (or pulsed DC) power having an AC voltage and corresponding induced AC current. The initial pulse of DC current to an inductor or transformer will induce a temporary changing strength magnetic field and then it will remain at a steady level until the current is lessened or removed.

The coils of a transformer are magnetically coupled so as to transfer electric power magnetically. If the input and output coils of a transformer have the same wire thickness size and number of windings, the output voltage will be (ideally) the same as the input voltage. In a (voltage) step-up (ie., increase) transformer, the output coil has more windings or turns - often of a thinner gauge wire. In a (ie., voltage) step-down transformer, the output winding has less turns - often of a thicker gauge wire. Due to energy conservation, the output power will remain the same (constant) value as the input power. Since power = (voltage)(current), and is a constant, if voltage increases at the output, current will decrease. If voltage decreases at the output, current will increase, and this is an inverse physical relationship, and a mathematical relationship to express it:

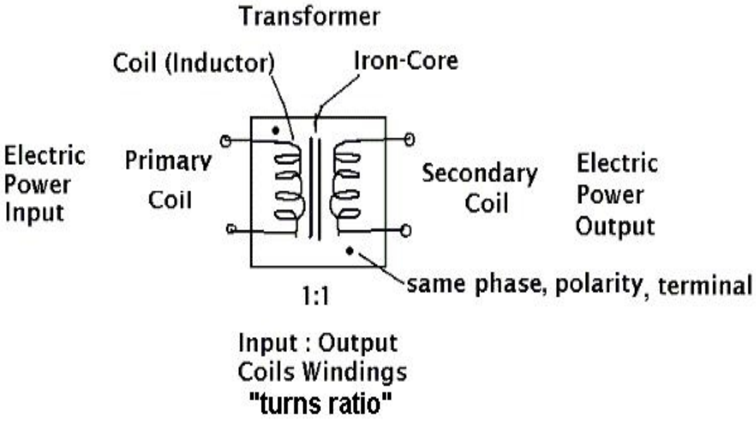
Power Out = Power In : due to "conservation" (no actual loss, only a transformation of) of energy or power
$Po = Pi$
$(Vo)(Io) = (Vi)(Ii)$ mathematically:

$\frac{Vo}{Vi} = \frac{Ii}{Io}$: the ratio of output voltage to input voltage is equal to the reverse (ie., inverse) ratio of the output current to the input current. These are "reverse or non-corresponding ratios".

Each transformer will have a maximum input and output power (voltage and current) rating. Even if the maximum output power drawn is not exceeded, if more current is drawn by the load device or circuit (ie., the resistance of the load circuit) than what that transformer is rated at, the coil can get hot and damaged. Fuses and-or circuit breakers with same current rating as that of the transformer can be used to protect the transformer and-or load circuit.

Can a transformer be used in reverse of that which it was designed and-or rated for? In theory, a "**reverse fed**" transformer could work, however we must remember the maximum current, voltage and power ratings of each coil (input and output coils) of the transformer. so as to not cause a thermal problem which will most likely damage the transformer and-or cause a fire.

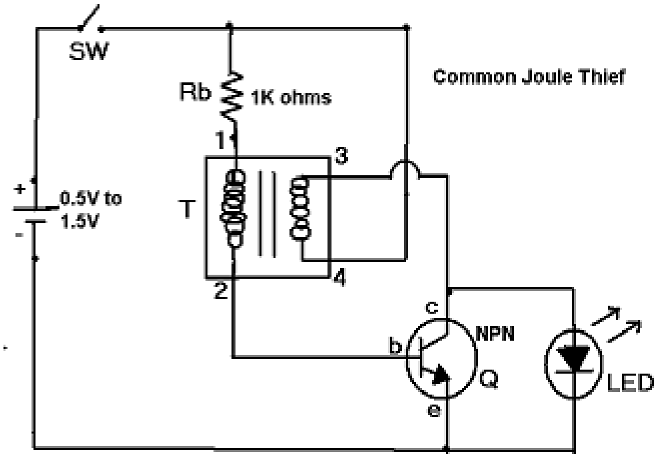
Electric power companies decided to transfer power to distant customers in the form of a very high voltage (thousands of volts) and low current. Placing a higher voltage on the wires effectively reduces power losses due to the high current resistance of very long transmission wires which would significantly reduce the available current and power (voltage x current) from the generator. This is because power available and-or power loss is related to the square of the current:
P = I^2R. Because this high voltage is impractical and dangerous to use for households (homes and small electrical devices), it must be reduced to a practical and safe level, and a voltage step-down transformer is usually used for that. By using a step-down transformer, household voltages supplied by the electric utility company and its "grid" (wires) system are reduced from a high voltage to be lower voltage - typically 240vac and 120vac so as to sufficient enough to be able to run household machinery and incandescent lamps. Still, this voltage is even too high for many low power devices such as radios and TV's which require far less power, and the voltage to them is reduced by using another transformer - often placed directly inside the device, or an external (120vac to DC) plug in transformer. [FIG 269]



In the above drawing of a transformer, you can imagine a pulsating AC (ex., from a 120v, 60hz, household power outlet) input voltage and current signal applied to the primary coil and then creating a corresponding (ex., 60hz) pulsating magnetic field which will extend outwards around it and interact with the secondary coil and induce an (AC) voltage across it. If the transformer is a 120vac to 24vac voltage step-down transformer , that turns ratio and-or voltage ratio is 120vac / 24vac or= 5 / 1 or= 5 to 1, and should be indicated as 5:1 on the packaging and-or data sheet. The iron metal core helps conduct and transfer the magnetic field and its energy from one coil to the other, and it improves the efficiency of the transformer so that the power output from the transformer is nearly equal to the input power to that transformer.

A very useful, small and inexpensive circuit with a transistor (small NPN plastic type), a resistor (~1K ohms), a small homemade transformer using two (usually in parallel) strands of thin wire (about 30 gauge, such as from a junked speaker coil) wrapped (about 22 or slightly more turns) around a small (iron particles) ferrite ring or core, a 1.5V penlight battery, and a white light LED that you may wish to explore is more popularly called a "**Joule Saver"** circuit, and which is sometimes incorrectly called a "Joule Thief". A more appropriate name and-or description is the joule saver and-or energy retriever circuit since most of the energy stored within a battery can be retrieved out from it. This circuit oscillates at several thousand hertz (cycles per second, here, pulsed DC) and boosts (ie., increases) a low voltage output of a 1.5v (or less) battery to about 3 or more volts necessary to make a LED give off a decent amount of light. Though voltages higher than about 3.5Vdc are not recommended for a white LED, but if those voltages are only briefly or temporarily applied as a pulse, there won't be as much of damage issue, and may actually improve the usefulness and-or amount of light (ie., photons, radiated RF energy) output from the LED. You may also look up the topic of pulsed led circuits for improved brightness and-or high brief flashes of light. The circuit is somewhat like a solar powered, low powered (small internal battery) garden and-or decoration light, and that charges up during the daytime light and automatically "turns-on" at night and produces some light, however those circuits seems to stop working when the battery has drained to about 1V. The Joule Saver circuit will continue reasonably working and providing some light to as lows as about 0.5 volts remaining in the battery. This circuit will help get (ie., not actually steal) or retrieve the remaining energy (ie., Joules) out of the battery so as to be useful and not otherwise wasted energy and resources. It is particularly helpful for making a small size flashlight and-or when only one, 1.5v standard or 1.2v (typically rechargeable) battery is available. Note that it is still generally always possible to connect batteries in series so to get create higher voltages necessary for devices. For example, connecting two 0.5v (ie., low voltage and-or drained) batteries in series will produce (0.5v + 0.5v) = 1v. Some experimenters have even powered a joule saver using a "voltaic pile" battery made from copper and zinc metal for each voltaic cell, and having just a few voltaic cells stacked in series so as to obtain a larger voltage. Between each piece of metal was a piece of paper soaked with an electrolyte of either lemon juice and-or vinegar, possibly with a small amount of dissolved salt. Possibly, a switch could be used to temporarily remove any battery in series so as to save some energy.

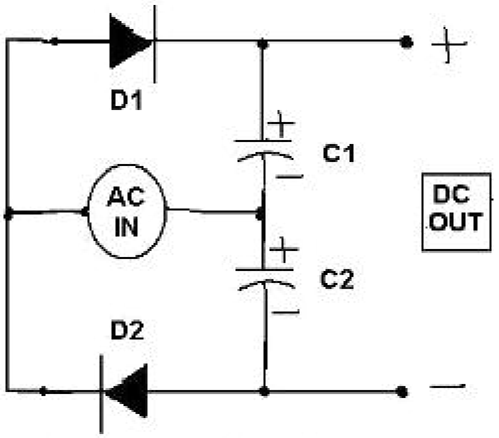
The circuit given below is the commonly available, standard and popular circuit of a Joule Saver circuit, and of which some people still experiment with and improve upon such as for the maximum brightness, efficiency and the longest "life" (time of use) of the battery(s) possible. For example, a small ceramic capacitor (perhaps 1000pf) can be placed across the base resistor (Rb). If an oscilloscope is available, you can see the waveform(s) produced on its display screen, and so as to help perform experiments and "fine-tune" (adjust) the device for maximum efficiency. The circuit is based on an electronic oscillator that oscillates at say at about 20Khz to 40Khz frequency depending on the circuit and its construction, and particularly the construction of the (transformer) coils. The waveform applied across the LED is similar to a pulsed square wave. The transformer output or secondary wires are reversed so as to apply a positive voltage to the collector of the transistor. The voltage waveform applied to the transistor is generally a short duration spike for each cycle of the waveform and-or oscillator. If possible, a circuit builder should obtain some low cost "alligator" clamp-ended leads (lead-in and-or lead-out wires) or "hookup-up wires" so as to more easily build and or-test circuits without the initial need for soldering and-or de-soldering. [FIG 270]



The led is a common white light output, 5mm or 3mm diameter LED, and requiring a DC current of about 20ma for full, and device-safe brightness. The transformer (T) is relatively small with thin gauge wire being 30 (typical) to 22 American Wire Gauge (AWG) of enamel coated wire, and with about 22 turns of each wires being in parallel ("**bi-filer**"), albeit not always indicated by the schematic diagram) to each other. This wire pair should be wrapped with a single layer around a circular shaped **ferrite** ("bead", torroid "doughnut ring" core) **core** that is about a 1/4 inch to 3/4 inch in diameter. The ferrite increases the inductance of the coils and permits the use of less turns of wire needed, and it is fast and has low magnetic energy losses of the electrical power. The transistor (Q) such as the **2n3904 NPN** is a low power, inexpensive, small black plastic npn silicon transistor. It has a current amplification or gain of about 100 to 300 depending on the current (200 mA max, 40 Vce, 625mW total power handling, with a cut off frequency [no more gain = 1] at 300 mHz.). A pnp type of transistor such as the common **2n3906** can be used, but you must then reverse the polarity of the battery so as to have a forward or conduction bias applied to that type of transistor. The battery should drain down to about 0.5v, but if a germanium transistor is used, the battery energy (ie., joules) can drain even lower because the turn on voltage of a germanium transistor is about half that of a silicon transistor or diode, hence about only 0.3v. Some common germanium transistors are the 2n1309 (pnp, gain of 90), 2n1307 (pnp, gain of 60). Because of the limited desire and availability of germanium transistors today (2022), they are currently several times higher in price than the mass produced silicon types. Germanium transistors generally have about half the power handling capability of similar sized silicon transistors, and a higher reverse bias "leakage current". You can experiment if the value of Rb should be slightly higher or lower when a germanium transistor is used, and so as to help conserve some energy of the battery. Two 1.5 batteries in series can give a long time of use for this circuit, and effectively allowing each cell to drain to 0.25v so as to have the minimum sum and voltage of about 0.5v needed for the circuit to produce some light.

If you have an oscilloscope, you can visually observe the oscillations of this circuit when placing the oscilloscope's input or sensor probes across one or more of this circuit's components such as the LED.

Here is a simple passive AC to DC voltage booster circuit of which for here is actually a voltage doubler circuit. There are also similar passive circuits such as to triple, and quadruple the output voltage. [FIG 270B]

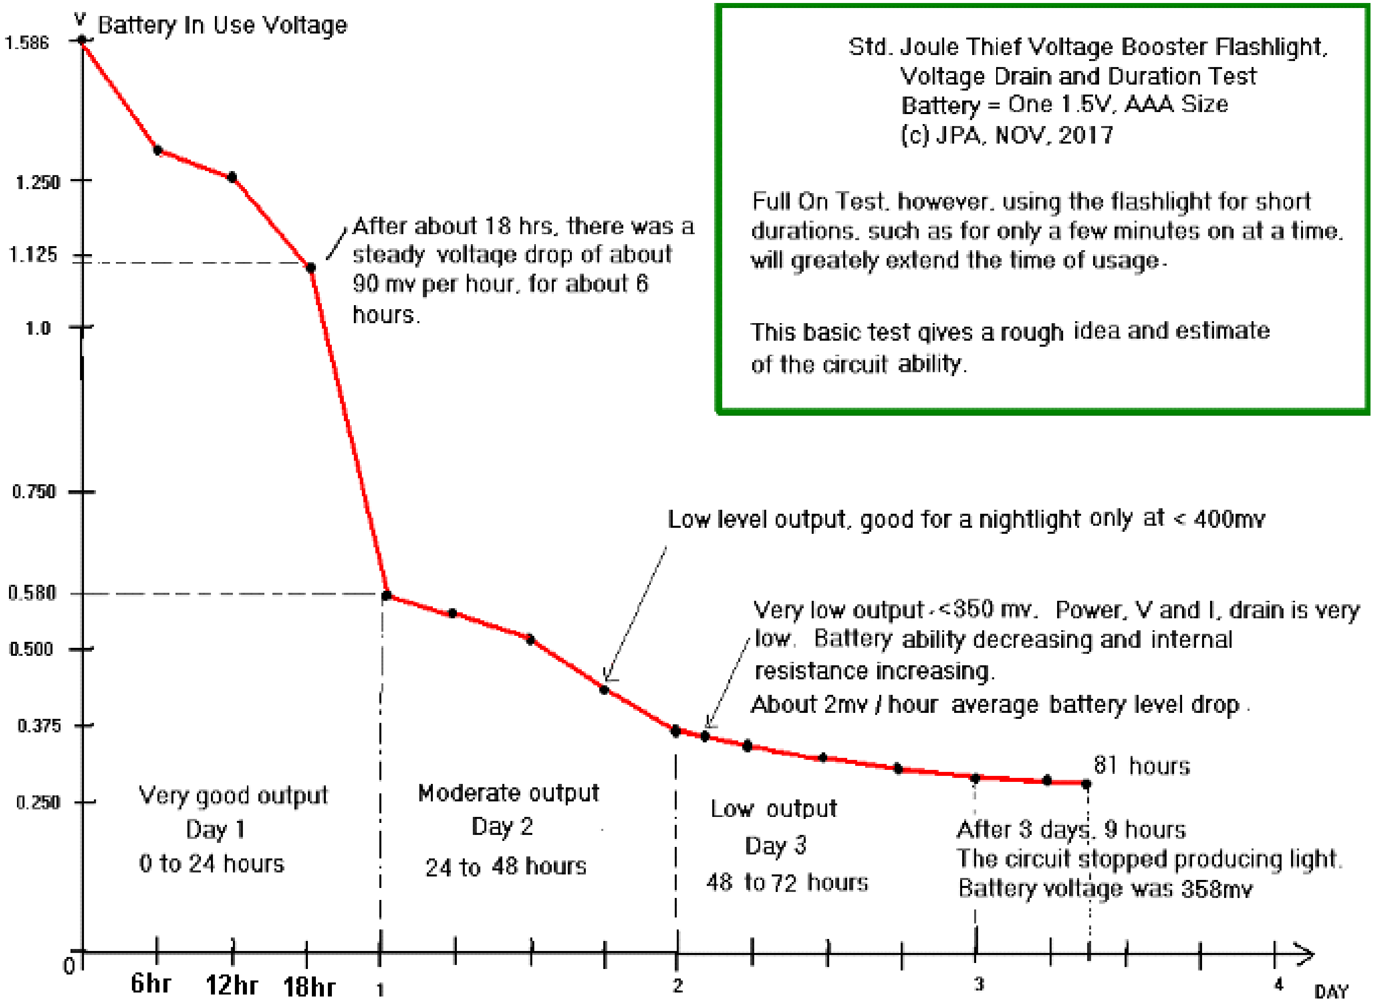


Vdc out =~ Vc1 + Vc2 + Vd = Vac rms + Vac rms + Vd ,
hence about twice the AC rms voltage plus
the voltage across the one conducting diode.
during each half-wave or half-cycle of the
input AC voltage waveform.

The values of C1 and C2 are identical, and will need to be found by experimentation with the load and-or current needed, but for the sake of simplicity, the larger they, are the better in terms of a higher output current. During each half-cycle of the AC input voltage, one capacitor will charge, and since both are in series, the total voltage available will be the sum that is on each capacitor, hence doubling and-or much like two batteries in series. The diodes direct the charging current, and they also prevent the capacitors from discharging back through the generator and-or the other capacitor.

An (active) voltage booster circuit was created and actually patented in about 1930, and this used a vacuum tube based amplifier and oscillator, and later, similar concept and patented versions by the early 1950's used the more fast and efficient - lower power loss, transistor. It should be of no surprise that if a transformer can boost an input oscillating (with a frequency, and changing in value) voltage, then an oscillator circuit could be used if the supply voltage is a DC supply voltage such as that from a portable battery, and so as to have a varying signal for the transformer to function. These concepts can be found in power inverters where a ("automobile") 12 volt or 24 volt, high load (ie., current) DC battery is converted to ("household") 120 Vac using an oscillator and transformer. Though the voltage is boosted, say 10 times, the maximum current is relatively low, being reduced say 10 times by the transformer. A 120W load on this type of inverter will require (from P=V/I, then: I = P/V = 120W/120V) = 1A of current. A 1200W load will require 10A, and very thick wire must be used for safety. Batteries save and-or create charge or current, and a high circuit current will deplete a battery relatively fast, and "deep cycle" batteries are preferred where they can be significantly depleted or drained without much negative effects, and are said to have a "longer life" or number of charging and discharging cycles.

The figure below shows the battery voltage of the "joule saver" circuit shown previously in [FIG 270] when working with a load (here, a mainly the LED) with respect to time. [FIG 271]



Std. Joule Thief Voltage Booster Flashlight,
Voltage Drain and Duration Test
Battery = One 1.5V, AAA Size
(c) JPA, NOV, 2017

Full On Test, however, using the flashlight for short durations, such as for only a few minutes on at a time, will greately extend the time of usage.

This basic test gives a rough idea and estimate of the circuit ability.

After about 18 hrs, there was a steady voltage drop of about 90 mv per hour, for about 6 hours.

Low level output, good for a nightlight only at < 400mv

Very low output -<350 mv. Power, V and I, drain is very low. Battery ability decreasing and internal resistance increasing.
About 2mv / hour average battery level drop.

After 3 days, 9 hours
The circuit stopped producing light.
Battery voltage was 358mv

Many small sized, low power solar powered "garden lights" have a small internal IC chip, a small rechargeable battery, and a few other components such as a small inductor (ie., no quartz version yet) working together so as to boost voltages between 0.9v and 1.5v to a 3v value for a white LED to function. This 4-pined low-cost, transistor-like chip is part of an oscillator circuit that forms a voltage "boost converter" and-or a "switching regulator". The most common IC for this is the 5252F, but there are some similar ones such as: CL0116 and XY8018 as of the year 2024.

[This space for book edits.]

Wire Gauges (AWG)

AWG = America Wire Gauge. This system is sometimes called the Brown And Sharp (B&S) gauge system. The thinner the diameter of a wire, the less effective "room", area and-or cross sectional diameter it has for passing current. There will be less free electrons to assist with conduction, and therefore, that thin wire resistance will be higher than that of a thicker wire of the same length. Just like a resistor component in a circuit, a higher resistance for a length of wire,the higher the voltage drop (loss) and power loss for a given current through it. A wire thickness and length combination must chosen so as the current though it does not cause it to overheat and melt its protective insulation and then be a danger to people and-or circuitry. With some high current devices, such as various toasters and heaters, it is recommended to not to use any extension cord wire since the total power lost through the wire may cause it to overheat due to the high amount of current (ex., 10A, for (120v)(10A) = 1200w) used in those devices. Some wire is also made and intended to be hot, such as in various heaters and toasters. Like the internal wire ("filament") in most incandescent light-bulbs, these wires may be a low resistance when power is not applied to them and they are not hot yet, but will have a much higher resistance and power loss through them when hot. Due to this initial cold, low resistance value, there is a high valued, temporary "inrush" of current which will stabilize to the normal operating current and its corresponding power rating. This inrush of current can cause a worn-out light-bulb filament to "blow-out" (melt to an open circuit, no circuit, no current, no light produced), when it is first turned on, unless some current control to it is used.

The longer a wire is, the more total resistance between its endpoints. There will be an increased energy loss or voltage drop across it for a given current, and therefore there will be an increase in power lost through that wire which will then not be available to the rest of the circuit. In most circuits for home use, this is usually not an issue. For high power or wattage devices, a long cord or wire can effect how that device operates, such as reducing available power significantly, such as needed for the speed and-or power of a motor.

Obviously, the thinner a wire is, more parallel wires or coil turns of it could be placed side by side per unit of length measurement of that wire. This is basically what the Brown And Sharpe (B&S), or (North) American Standard Wire Gauge is based upon and became the commonly used **AWG = American Wire Gauge.** Thinner wires will therefore have a gauge (ga.) number that is higher since more of them can be placed in parallel per unit of distance. For example 30 gauge is thinner than 20 gauge. With this system, the actual gauge number is an (stepped) integer value corresponding to a certain logarithmic (ie., an exponent) value. For this system, the wires are also assumed to be round and having a solid core, however multi-core or stranded core wire that can carry the same amount of current as a solid core wire, will be slightly thicker, but will have the same rated gauge. Basically, the AWG system is based on a wires internal cross sectional area and therefore, its conductance ability for current or electricity, rather than just its diameter dimension.

The reasoning and actual formula used to calculate a gauge for the AWG system is a overly complicated for the average person to always consider, but for simplicity, the gauges are based on cross sectional area and current ability, and some simpler formulas derived from some results of the AWG formula, are given below. Here are some key points and relationships of this AWG system:

1. When the diameter of a wire is half (ie., 0.5) of that of another, the gauge will increase by 6.

   . When the diameter of a wire is half of another, its radius is also half, and the cross sectional area is decreased by 4, and therefore, the conductance decreases by 4, and this is similar to saying that the resistance increases by 4.

   A1 = (pi)r^2 and A2 = (pi)(r/2)^2 = (pi)(r^2 / 4) , therefore: A1 / A2 = 4 and A2 / A1 = 1/4 = 0.25

2. When the gauge increases by 3, its cross sectional area is half, its (safe) conductance ability is half, and that wire can only carry half (ie., 0.5) the current, and this is equivalent to the resistance increasing by 2.

4. When the gauge increases by 10, the cross-sectional area is reduced by about 10, and the conductance is 10 times less, and this is equivalent to the resistance being 10 times more.

5. When the gauge increases by 20, the diameter decreases by 10. This is equivalent to saying that when the

diameter increases by 10, the gauge decreases by 20.

Wire diameter or "thickness" sizes can be expressed in mils (thousandths of an inch), or millimeters (mm, metric):

1 mil = 0.001 inch = a thousandth of an inch = 0.00254cm = 0.0254mm , mathematically, solving for 1mm:
1 mm = 39.37007874 mils = about 40 mils
1 cm = 393.7 mils =~ 394 mils
1/16 inch = (1/16)" = 0.0625 in = 62.5 mils
1 square-inch area = (1in)(1in) = 1in^2 = (1000mils)(1000mils) = (1000)(1000) mils^2 = 1,000,000 square mils
1 square mil = (1mil)^2 = (0.001 in)^2 = (0.001)^2 (in^2) = 0.000001 in^2 = a millionth of a square inch
= (0.0254mm)^2 = (0.0254^2)(1 mm)^2 = 0.00064516 mm^2
1 circular mil (CM) area has a diameter of 1 mil = 0.0254mm, and its area is: A =(pi)(r^2)= (3.14159265)(0.0254mm/2)^2 =
= 0.000506671mm^2 = (5.0671)(10^-4) mm^2

For the ratio of a square area to that of a circular area (Ac) having the same width or diameter, is to first consider or draw a circle in a square such that its diameter (d) of that circle equals the side (s) length of the square, say 1 unit long. Therefore s = d = 2r , where r=radius of the circle. The area of the circle will clearly be less than that of the surrounding square. The area of a circular mill (a thousandth of an inch) is less than that of a square mill, but by what factor?:

Ac / As = (pi) r^2 / (2r)^2 = (pi)r^2 / 4r^2 = **(pi) / 4** = 3.14159265 / 4 = **0.7853981** (ie., roughly about 79% or 80%)
We find that a circular mil is about (100% - 80%) = 20% less than that of the area of a square mil. The perimeter of the circle and square mentioned above also have this same ratio: **Cc / Ps** = 2(pi)(r) / 4 (2r) = (pi) / 4 = **0.875398163**

A wire diameter or gauge might be expressed in an area value such as square millimeters: mm^2, and to find the value of its diameter, you can use the area of a circle formula: A = (pi) r^2 , r = sqrt (A / (pi) , d = 2r. 6 AWG gauges lower is 2 times the diameter and 4 times the area.

For a stranded wire containing several smaller strands of wire, the notation of its structure is usually expressed as:
AWG # "Number of strands / AWG gauge"

Some Common AWG and their corresponding approximate diameters, thickness or width. Resistance at ~ 72 °F :

Gauge Number	**Inches**	**Millimeters**	(Solid copper wire is considered for the other parameters). 1in.= 2.54cm =25.4mm

As you can see in the above data, it is easier for most wire installers and users to use simple gauge numbers than trying to remember the very small differences between the diameters of each gauge of wire. There is a pattern that can be had from this data, and a basic formula was derived out from it so as to fit that data. The following formula is based on the fact that when the gauge decreases by 20, the thickness should increase by a factor of 10 for each instance of this, and resulting in a more general formula that will include a variable for each instance of this process where the gauge decreased by 20. We now have this factor to multiply to the diameter: 10^instances or= 10^x. We will use AWG #50 and its corresponding diameter as the starting reference value for this particular formula, and so as to have a formula with only one unknown variable, and that is the gauge number of which you are trying to find the thickness or diameter of:

Considering gauge #50 which is 0.001" = 1mil : this should be memorized if using the following formula:

Thickness of Gauge: = (0.001") 10^((50 - Gauge#) / 20) : **SIMPLIFIED WIRE THICKNESS FORMULA BASED ON 50AWG = 0.001"**

Ex. What is the thickness or diameter of 28 AWG?

Thickness of 28 AWG = (0.001") 10^((50 - 28)/20)
= (0.001") 10^(22/20)
= (0.001") (10^1.1)
= (0.001") (12.59)
Thickness of 28 AWG = 0.0126 inches

Thickness of Gauge = (0.1") 10^((10 - Gauge#) / 20) : **ALTERNATE SIMPLIFIED WIRE THICKESS FORMULA BASED ON 10AWG = 0.1"**

Extra: After solving for Gauge #:

Gauge # = 50 - 20 log ((1000)(thickness in.) : **AWG #** : **1 inch = 2.54 cm = 25.4 mm = 1000 mils**
Gauge # = 10 + 20 log (0.1 in / thickness in) : **Alternate AWG #** **and 1 mm = 0.03937 in = 39.37 mils**

Resistnace Estimation: For each increment in AWG gauge, the resistance is about n =~ 1.25 times greater
Ten guages higher is ten times more resistnace.

This value of : n=~1.25 can be found from the geometric series: R , Rn , (Rn)n , ((Rn)n)n .... : R = resistance
R , Rn^1 , Rn^2 , Rn^3.......
Letting: Rn^10 = 10R : at ten AWG gauges higher

After solving for (n) by using logarithms, we find **n = ~ 1.258925** : This is also the 10th root of 10

Two AWG gauges will result in a factor of: (1.258925)(1.258925) = 1.5848931925 =~ 1.585 =~ 1.6

Some people in the United Kingdom (UK, England area) may still use the (outdated) **Standard Wire Gauge (SWG)** which is also called the British or Imperial wire gauge. For some basic reference, here are some SWG gauges and their approximate diameters: 33 SWG = 0.25mm, 25 SWG = 0.5mm, 19 SWG = 1mm. 14 SWG = 2mm. 11 SWG = 3mm , 8 SWG = 4mm. 6 SWG =~ 5mm. 4 SWG =~ 6mm, 2 SWG = 7mm **SAE gauge is the Standard American English gauge** or Standard Automotive Engineer Gauge for automobile wires and for screw diameter and pitch (ie., threads or turns per inch). An SAE Gauge wire size for an equivalent number AWG wire gauge will be slightly less or thinner in value, hence its maximum current will also be slightly less. These references to other and-or outdated guages is still useful for older devices.

Ampacity (Maximum Rated Current)

Ampacity is a word formed from the words "amps" and "capacity", and this word may sometimes be discontinued and superseded by other words such as "safe capacity" or "maximum amps" to express the maximum safe current in a wire. As for now, we will consider the word "ampacity" to be the recommended, safe heat and maximum rated current passing ability or capacity of a certain size [thickness] and-or type (element, copper, aluminum, etc.) of wire, and it is usually specified for a certain air temperature such as 20°C. The maximum temperature rating (typically some tested value between 60 °C =~ 120 °F and 90 °C =~ 180 °F) for a wire is usually determined by its insulation material, and clearly, if the insulation is hot and-or melting, a thicker wire is then needed and-or a lower amount of current used. The maximum current value rating is lower for thinner wires since they have a lower conductance per cross sectional area and a higher resistance per unit of distance. If the diameter (or radius) of a wire doubles, the cross sectional area (A) increases by 4:

A2 / A1 = (pi)(2r)^2 / (pi)r^2 = 4(pi)r^2 / (pi)r^2 = 4

Even though a wire has a recommended maximum rating, a further safety margin has been set by the National Electrical Code (NEC) of the USA, and most likely for any country. In general, it states that in a circuit branch and its given wire, the maximum current of that wire should be no more than 80% of the wires ampacity rating.

BELOW IS A LIST OF SOME TYPICAL AMPACITY RATINGS OF COMMON **SOLID CORE COPPER WIRE** AT ROOM TEMPERATURE, AND SHORT DISTANCES - NOT FOR LONG DISTANCE POWER TRANSMISSION, AND NOT FOR HIGH FREQUENCIES WHERE THE CURRENT WILL TEND TO MOVE ALONG THE SURFACE ("SKIN" OR WIRE SURFACE EFFECT), AND THE EFFECTIVE WIRES RESISTANCE, HEAT AND POWER LOSSES EFFECTIVELY INCREASE. TECHNICALLY, IF A WIRE OF A FIXED LENGTH AND WHICH THEN USUALLY HAS A FIXED RESISTANCE AND-OR AC IMPEDANCE THEN CARRIES MORE CURRENT THAN A PREVIOUS AMOUNT, IT WILL THEN CAUSE A HIGHER VOLTAGE LOSS OR DROP IN AND-OR ACROSS IT DUE TO OHMS LAW (V = I R = A R). THIS WILL HAVE MORE OF AN AFFECT, AS A PERCENTAGE, ON THE VOLTAGE OUTPUT ON LOW DC VOLTAGE LINES THAN ON THE TYPICAL HIGHER AC VOLTAGE POWER LINES WHERE TYPICALLY LESS CURRENT IS USED SO AS TO PROVIDE THE SAME AMOUNT OF AVAILABLE POWER (ie., energy/time).

AWG#	**MAX. RECOMMENDED CONTINUOUS (DC) CURRENT = AMPACITY RATING BASED ON DIAMETER**
0	A safe recommended, maximum value is 125A , : this gauge is also identified as AWG 1/0
2	A safe recommended, maximum value is 115A.
4	A safe recommended, maximum value is 85A.
6	A safe recommended, maximum value is 60A.
8	47.6 A =~ 50 A
10	30 A : needed for some high current household devices and-or some 12v vehicle systems
12	18.8 A. : the modern, common wire gauge required for many household (homes) and its electrical devices -
14	11.8 A =~ 12A - 18.8A =~ 20A
16	7.4 A
18	4.6 A =~ 5 A
20	2.96 A =~ 3 A
22	1.87A :this and AWG 24 are common ("hookup") wire gauges for many homemade electronic projects, ~ 2 A
24	1.18 A =~ 1A
26	0.74 A =~ 0.75A = 750mA
28	0.46 A =~ 0.5A
30	0.294 A =~0.3A : this is a common, fine wire gauge for making homemade coils such as for a voltage booster
32	0.186 A

The formula used for the above data is based on AWG 10 of solid copper wire with a ampacity rating of 30A, and the fact that for every 3 gauge increase, the cross-sectional area and conductance is halved (1/2 = 0.5). It must be noted that area is not linear or proportional to the radius or diameter of a wire, but rather it increases exponentially by the square of the radius. If the diameter or radius doubles, the area and conductance increases by 4, the resistance decreases by 4, and max. current can increase by 4, and this is the case when the AWG number is 6 less.

ampacity = (30A) 0.5^((Gauge# - 10) / 3) : **A basic ampacity formula for AWG solid copper wires**

This book does not have a table of powers of 0.5^x, but this can be used instead if needed:

From: ln 0.5 = -0.693147181 , we have: e^(-0.693147181) = 5 , and raising each side to the (x) power, we have:

0.5^x = e^(-0.693147181)^x = e^(-0.693147181 x) = 10^(-0.301029996 x) : a form of: n^x = (e^a)^x = e^ax

ampacity = (30A) 0.25^((Gauge# - 10) / 6) : **Alternate basic ampacity formula for AWG solid copper wires**

and : 0.25^x = e^(-1.386294361)^x = e^(-1.386294361x) = 10^(-0.602059991)^x

Because a wire has a maximum current rating, we can find the maximum voltage that can be applied to that wire:

Vmax = (Ampacity Rating) (Resistance of the wire) : has the form of: Vmax = Imax R or= V = I R

Because a wire has a maximum safe current or ampacity, and a voltage (Vmax) rating, there will be a maximum safe power loss in that wire = Pmax. The formula is based on: Power = Voltage x Current = V I = I^2 R = V^2 / R

Pmax = V I = (Vmax) (Ampacity Rating) or:

Pmax = I^2 R = (Ampacity Rating)^2 (Resistance of the wire) or:

Pmax = V^2 / R = (Vmax)^2 / (Resistance of the wire)

For increased safety and-or reduction of power losses in a wire, use a wire that has a greater current ability than what is actually needed for the total amount of amps needed and-or used for all the devices in series that are powered by the same power supply. It is possible to have other electrical devices connected in parallel (ie., another current branch) to the battery, and of which thinner wires can be used if they are rated for the current needed or used by the load device. Be sure to consider if the total current drawn from the battery from all the powered devices is below the maximum amount that the battery is rated for. For safety, fuses and-or circuit breakers should be used on each current branch from the battery. To reduce power losses in a wire due to increased length and its increased resistance and voltage drop (ie., energy loss) across it, use a thicker gauge of wire.

When current is drained from a battery, it will also reduce in voltage. Generally, most 12v lead-acid batteries are considered "dead" or drained at about 10 or 11 volts, and this is because it is below the rated voltage of the battery, and that there is no guarantee that it is sufficient for the devices being powered. At 11 volts or less, there is still useful power in a battery for devices designed to operate at lower voltages, and you should then consider having a voltage regulator so as to have a lower, but stable and-or adjustable voltage supply. Deep-cycle batteries can hold their rated voltage much longer than non-deep-cycle batteries, therefore they can deliver much more of their internal energy storage as useful power during a time period of usage. Some rechargeable lead-acid batteries area rated as deep-cycle, and some rechargeable batteries are also known as automatically having a deep-cycle like quality, such as with the lithium types.

Batteries are charged so as to store those charges for later use, and high current devices will drain those charges faster, and this is why some battery systems use batteries connected in parallel so as to have more (energy and-or power) capacity and ability, and at the same supply voltage. This greater energy supply can be used to transfer or deliver more total energy or power (VI) for a longer time. Total power = (total energy) / (total time) = (energy / time unit) = = (joules / time) = (VI) / time , such as watts / hour. A device may use and-or be rated in (watts / second), and to find how many (watts / hour) it uses or used per hour, multiply the number of (watts / second) by 3600s since an hour is 3600 seconds of time (T):

$$\text{total power} = \text{total watts} = \frac{\text{watts}}{\text{second}}\ (\text{number of seconds}) = \left(\frac{\text{watts}}{\text{second}}\right) T_s \quad : \text{for 1hr of time, use } T_s = 3600$$

$$\text{total power} = \text{total watts} = \left(\frac{\text{watts}}{\text{1 hour}}\right)(T_h) = \left(\frac{\text{watts}}{\text{3600s}}\right)(T_s) \quad : 1000\text{w} = 1\text{kw} \ , \ \text{ex: } 500\text{w} = 0.5\text{kw}$$

Thick wires are often made by stranding many thinner diameter wires together, and this helps to keep a thick wire more flexible so it can be bent around turns and-or rolled up on a reel. .

Though not mentioned much, and typically discouraged for good reason, in an emergency or difficult situation, it is possible to use two identical lengths of identical wire connected in parallel, so as to effectively create a thicker wire to double the current ability. If the wires are not identical in diameter and ampacity (max. ampere rating), the maximum possible current should only be considered as twice the maximum current or ampacity of the thinner diameter wire.

A wire has some resistance (Rohms) to current, and it will have a voltage and power loss in and through it. A wire could get hot and be a fire hazard. If the power loss is significant and cannot power a device safely and-or properly, then a thicker wire should be used since they have less resistance, and then there will be less of a voltage loss across it, and more available to the device being powered.

Wires of long length will have more resistance, and therefore will have a higher voltage drop or loss across and-or through them, and therefore a higher power loss through them: P=VI. If needed, it is sometimes possible to raise (increase, "step-up") an (AC) voltage or current with the aid of a transformer, but the total **power** available cannot be increased. Because power loss is related to the square of the current through a wire or resistor: P = I^2 R, which is sometimes called the **Joule-Lenz Law** of ohmic or resistive heating or loss (of power) and which is exactly compatible with Ohms' law (I = V/R), power companies usually generate and distribute their output power in the form of a very high voltage so as to reduce power losses due the otherwise large amount of current that would need to pass through that resistance of a very long wire. This will also prevent the wires from getting too hot and melting as it transfers all that power from one location to another. With this system using a relatively low amount of current, the magnetic field around the wire will be kept relatively small, but the electric field about the wire will be relatively high. These wires from the power company are often called "power" or "transmission" lines, and because of their high voltage, there is an increased chance of "arcing" (ie., sparking, short circuiting) to nearby objects of lower resistance, and therefore being a safety and fire hazard. These high voltages will be stepped down to lower voltages for cities and homes by using a local (nearby) transformer so as to have a more manageable, practical and safe voltage level. High towers hold the high voltage wires up off the ground, and large insulators prevent various arcing problems due to the metal tower itself, and also to insulate the wires from rain, moisture and snow which may promote arcing. Typical rain water does not conduct much electricity at low voltages, but at high voltages, it can "break down", where the atoms are "ionized" (separated into atomic parts) and can then conduct charges (electricity, current) fairly well, and therefore may cause arcing and-or (a low resistance path) "shorting out" into and through nearby objects (particularly metal, trees and people) and into the ground. This amount of power is very dangerous and can pass through and cause serious life-threatening injury to people and-or fires.

Metric Wire Gauge (MWG)

MWG Gauge = (10) (wire diameter in mm) , mathematically:

(wire diameter in mm) = (MWG) / 10

Extra: For the rated conductance and-or resistance of a specific metal see the topic in this book of:
A List Of Common Metals And Their Relative Electricity Conductance

POWER

Energy is the ability to do work such as applying a force to an object for a certain amount of time. Force is the application of energy, and then all that energy can be transferred to that object if there is no energy losses during the transfer of that energy. This transferred and gained energy in the object is usually transformed or converted to kinetic or motional energy of the object and giving it a faster motion, speed or velocity. The basic unit of energy is the joule (J). Power is a (average) measure of how much energy is available or used (ie.,transferred) during a certain amount of time or time period.

Watts are the units of power. Power = (energy / time) watts = (joules / time) watts.

1 Watt of power = 1 Joule of energy used per or during 1 second of time = 1 Joule-second = 1W

1 W = 1 J / s . The watt is named after James Watt who invented a newer, more efficient and more powerful
steam engine for boats and other machinery.

For an example of electrical power: A 1 ohm resistor having a total (electric, electron) current flow or conduction of 1 Ampere = 1A constantly through it for 1 second, will gain a total amount of energy of 1watt, mostly in the form of (often wasted) heat energy. A formula is shown below. The source that supplied that energy will have correspondingly used and-or lost 1 watt of energy or power. Usually for resistors, the gain in energy is seen as a gain in heat or temperature, and the power it gained is usually called a power loss or power drop in or through it because its no longer available to the rest of the electrical circuit. Power losses should be avoided since it is usually wasted energy, time, money and resources.

For electricity and circuits: P = V I = (IR)I = I^2R = V (V/R) = V^2 / R : with units of watts (W)

From Ohm's Law of: current flow = voltage (ie., emf) applied / resistance = I = V / R = voltage / resistance.

A voltage (emf, electromotive, electrical or electronic force due to electrical charges attracting or repelling) of 1 volt applied to a circuit having 1 ohm of resistance will induce or create 1ampere of current to flow through that circuit.

Mathematically, from Ohm's Law:

V = I R : Voltage can be thought of as the force or pressure to the available current and giving it kinetic energy. Voltage is also called the electromotive force = "emf", and voltage is also called the potential difference between two points since it will take a difference in this force or pressure so as to have any current to flow, and at a value due to that net voltage value of the difference. For example, If one point in a circuit is measured to be 302v and another point is at 300v, the potential difference between those two points is (302v - 300v) is only 2 volts, and this 2 volts may be across a resistor, and the current through that resistor is determined by that voltage, energy or (emf) difference, loss or drop of and across it: I resistor = Ir = Vr / R ohms .

.

1V = (1A)(1ohm) The greater the current (I=V / R), the more electrons (ie., matter, mass) with kinetic energy, and the greater the total energy being transferred. Power = (voltage)(current) = VI

When 1 joule (J) of energy is applied to 1 coulomb (c) of charge (Q, such as electrons), that charge will gain 1 joule of energy, and the energy density and-or electrical potential (ie., voltage, emf) ability of that stored (in electrons, as motion) energy is called 1 volt:

1J / 1c = 1 volt. :This energy is often the (kinetic, moving) energy or power gain of the electrons moving through a wire or circuit. This energy stored in the electrons as kinetic energy ca be used to do useful things.
Ex. 2J / 0.5c = 1V , Ex. 2J / 2c = 1V , Ex. 4J / 2C = 2V

Mathematically rearranging: 1V = 1J / 1c we have:

1J = 1V 1Qc : or 1 coulomb of charge at 1 volt of potential energy contains 1 joule of energy
For another ex.: 2 coulomb of charge at 0.5 volts will contain 1 joule of energy

The product of the voltage potential and the amount of charge having it, is equal to the total amount of energy in that charge. Another description is: When 1 volt of electromotive force (emf) is applied to 1 coulomb (c) of charge (Q, such as electrons) for 1 second, that charge will gain 1 joule of energy. This may sometime be expressed as: J = V C

1J = 1V 1Qc : Extra: The units of force are commonly newtons (N), 1N = (1 kg)(1 m/s^2). 1J of energy was initially defined as the energy used for and transferred by a force of 1N constantly applied to a 1kg mass for a distance of 1meter, and this will accelerate (change of, increase its speed) it to, or by 1 more meter per second if there is no losses (undesired transfers or wastes of energy) of that energy.

1J = 1N-m = V C = energy = work = (force)(distance) = (mass)(acceleration)(distance) =
= (kg)(m/s^2)(m) = kg m^2 / s^2 = kg-m-a

Also, mathematically: **1V = 1J / Qc , Voltage is the joules of (electric potential) energy per coulomb of charge. V = J / Q = (I)(R)**

Considering and dividing each side of the above equation by the time used so as to find energy used per second or unit of time, will result in the following definition of the watt unit of electrical power:

Since 1A = 1 coulomb (c or C) of charge (Q) particles (ie., electrons, current) passing a point per second = 1C / 1s:

1J / s = 1V (Qc / s) = 1V 1A = 1W : 1 watt of power or energy used

Mathematically, 1 joule is also called a "watt-second" = 1 watt of energy applied for 1 second = **1Ws = 1J of energy**

In relationship to Ohm's Law we find that power is:

Pw = V I = (I R) I = (V) (V / R) = I^2 R = V^2 / R

Also, from the above equation, we can derive:

V = J / Q : voltage (emf) is equivalent to the energy (joules) per unit (coulombs) of charge. Voltage can be thought of as a measure of the (potential) energy available that can create the electromotive force (emf) needed to move (attract and-or repel) charges such as an electric current. More voltage means more energy and electric force or ability to move charges.

Mathematically from this, we can derive:

J = QV :If the charge particle or mass was a single electron, there is a measure of the (kinetic) energy that 1 electron will gain or loose going through a 1volt potential difference (emf = electromotive force). This amount of energy is often called an electron volt: **1 eV = 1.602 (10^-19) J .** Besides this point, protons and especially electrons are traveling very fast, and even though an electron has a very small mass, its kinetic energy (KE) is significant and is verified, for example, when resistors get warm, and in electrolysis (ie., electro-chemistry). An electron being repelled by other electrons reduces its kineitic energy. This is often spoken as simply electrons strking an atom, and-or a collision of sorts.

When an electron breaks free from its atom, the remaining atom is said to be ionized. Electrons farther out in orbit around the nucleus of the atom are easier to break free because the electric force (ie., Coulomb force) that holds them in that orbit position (ie.,radius, distance) is less. It will take less applied energy or force to break them free from their atom. This amount of energy is sometimes called that electron's ionization energy or ionization potential. Dmitri Mendeleev who is generally credited to making the first practical periodic table of elements discovered the concept of ionization energy. When an atom has a larger number of protons, its nucleus is larger and it also has more electrons and with some at a farther distances from the nucleus, and the ionization energy required to free more distant electrons is then even less. A hydrogen atom which has only 1 electron relatively close to its nucleus will require a relatively high amount of electron volts to break that electron free from its close orbit with a high electric attracting force.

For hydrogen, the ionization energy is often noted at about: 13.6 eV or = 1312 kJ / mol of hydrogen atoms.

An electron can also go to a higher orbit or "(electron) shell" after gaining a certain amount of energy that is less than the ionization energy for it to break free from the orbit of that atoms nucleus, and if this, or possibly another electron falls back to a lower orbit, its gained energy is then released as some form of electromagnetic radiation (light, xrays, etc) energy.

The minimal ionization energy required to split a water molecule into its hydrogen and oxygen gas elemental components of each water molecule, is said to be about 1.23V. This electro-chemical process is usually called **electrolysis**. The hotter the water, it and its electrons have more gained (thermal and kinetic) energy and the ionization energy will be less. Using a voltage higher than 1.23V is often said to be unnecessary and a waste of power, particularly with current passing through the water having a small amount of an electrolyte substance to allow the movement or conduction of current (ions and electrons, in opposite directions) between the two electrodes (+ pos ,and - neg). The higher the temperature of the water solution is also an indication of wasted energy in the form of thermal energy, and is usually caused by applying too much power (voltage and-or current) and-or that the effective resistance of the water solution is high and power is being wasted through that resistance.

Extra, from: 1 eV = 1.602 (10^-19) J , solving for 1J by dividing both sides by 1.602 (10^-19), we have:

1J =~ 6.2415 (10^18) eV : = 1J = (1Qc)(1V) = (1 coulomb of electrons)(1 volt) electron volts ,

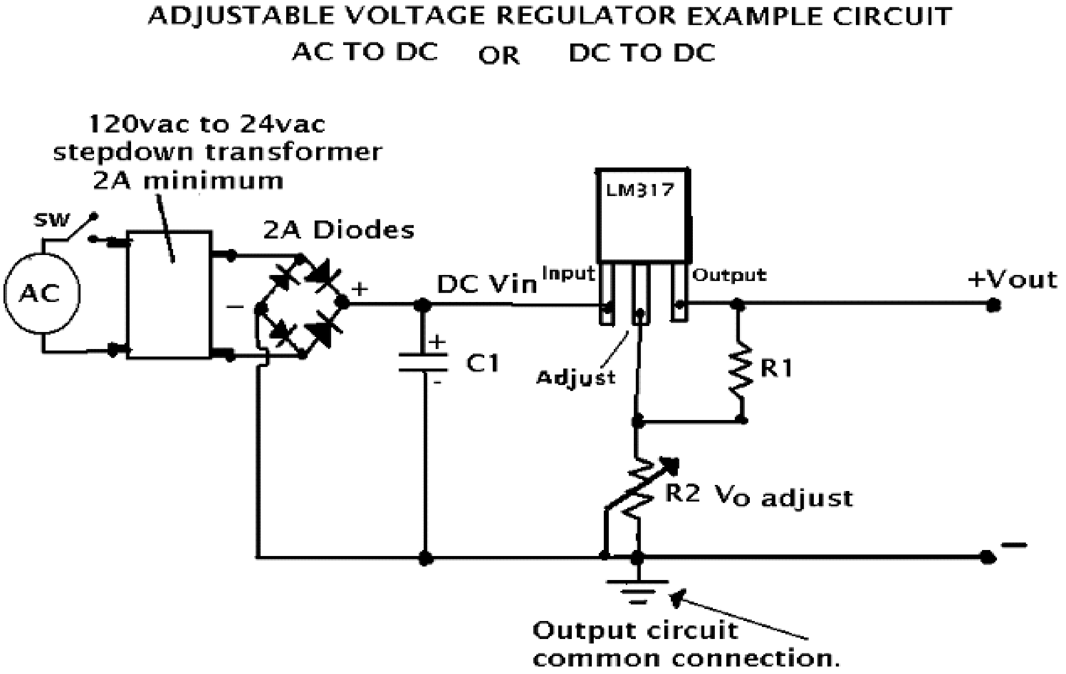
As a reminder and comparison to the above values, this was stated previously in this book:

1C of charged particles or electrons = (6.24)(10^18) charges or electrons,
and if each side is divided by the factor of (6.24)(10^18), we find the
charge (Qc) of 1 single electron to be: 1.602564 (10^-19) C

From: V = J / Q , we have:
J = Qc V , and if the amount of charge is 1 electron, and V=1 volt:
(1.602564)(10^-19)C (1V) J = (charge of an electron)(1V) J = 1ev

Below is an example circuit so as to have a relatively inexpensive, adjustable or variable **electric power supply source** for electronic devices, circuits and experiments. In particular here, only the voltage is adjustable. You can make or purchase such products already built.

Adjustable Voltage Regulator Power Supply Example Circuit This one uses the LM317 or LM317T IC . [FIG 272]



A note about the LM317 linear voltage regulator IC was previously mentioned in this book. There are many similar IC's available, in particular, they are not meant to be adjustable, but rather have a fixed, predetermined output voltage such as 3V, 5V which is the common USB devices voltage, 6V, 9V, 12V, and 15V. You can look-up or research the LM317 IC **data sheet** (device information and-or specifications) and-or packaging notes for the LM317 specifications, notes and example circuits of which the above circuit is actually based upon. You do not need a LM317 integrated circuit to make a stable or constant voltage supply, but it is inexpensive (about $1.00 to $3.00 USD, depending on the quantity purchased) to obtain and implement (use) and simple to use in a circuit. The LM317 type of "series" voltage regulators have an adjustable or variable output. A premade LM317 voltage regulator circuit can also be purchased inexpensively, such as from the Ebay.com website. The transformer is usually sold separately, and is needed as part of the entire circuit to convert AC household voltages to DC voltages. The circuit indicates a transformer with an output of 2A minimum, and this will ensure that the full rated 1.5A output current of the LM317 can be achieved if so needed, otherwise a lower output current from a smaller transformer can be used, however if too much current (perhaps from a shorted output circuit) is drawn from it, it could damage that transformer when the LM317 cannot shut-down its output at currents less than 1.5A. An "inline" (ie., series) fuse (of a necessary value, for example 0.25A, 0.5A, etc) should be used to prevent circuit damage issues for either this power supply and-or equipment such as an expensive and-or vital radio. Here are some notes for the above **LM317 IC, Adjustable Voltage Regulator Circuit:**

Vin = The input voltage applied to the LM317 input pin should be about 3vdc min. to about 39vdc max. There will be a voltage drop (ie., a "dropout voltage") across this IC due to its internal circuitry, and will therefore, it will not be available at the output. The power loss in this IC is the voltage drop across or through it times the current through it. P=VI To reduce power losses in the chip, use a minimum input voltage to it, say only 3 or 4 volts higher than the output voltage. Once the minimum input voltage is reached, any higher input voltage can be regulated (a steady v.).

Vo = 1.25vcd to about 37vdc , The max. output voltage depends on the input voltage. This voltage is adjustable via a variable resistor (R2), but can be set or fixed at a desired voltage using a fixed resistor for R2.

Io = 1.5Amax. Higher output currents will be sensed by LM317 IC and it will stop the flow of current.

The transformer, diodes and in general, the capacitors, are not needed in the input power supply is a DC voltage such as from a battery.

Transformer and Diodes = Common AC household power can also be used if it is converted to a form of DC with by using a capacitor "ripple filter" and-or temporary energy storage circuit. Usually this circuit consists of a transformer, and four, 2 Amp (or more) power diodes (or a premade full-"bridge" rectifier) so as to make a full ac or sine wave rectification (to having one (curent flow) direction and-or voltage polarity, hence [unregulated] dc), and eventually to have a fairly steady [ie., regulated, low fluctuations, changes, low "ripple voltage"] dc voltage by using a large capacitor.

The output voltage of the transformer should be in the range of about 3vac to 30vac that the IC can regulate, and be able to deliver the amount of current needed (up to 1.5A max.). The transformer should be rated at about 2A or higher for safety if 1.5A will be needed. The maximum output voltage of this regulator circuit also depends on the maximum available voltage of the transformer, or DC input voltage such as from a battery. If possible, the circuit can be constructed to allow both house power and also have terminals for a DC input voltage supply. **If the voltage regulator circuit is DC input powered only, then a transformer and diode(s) are not needed -** using the transformer with a steady DC current is also not even possible, and diodes will cause a waste of DC power due to the voltage drop across them. It is possible to use a power diode(s) before the load circuit so as to obtain very low voltages if necessary.

IC Pins of the LM317 = External electrical contacts: Looking at the actual front or "top view" side of the 317IC chip, from left to right are the internal-external terminals or pins: 1=adjust , 2=output on center pin , 3=input.
The pins shown in the figure or schematic are not numbered, but are just indicated as for what it is for, and to make the rest of the circuit drawing easier to understand. Look at the IC packaging for the pin numbers and-or corresponding function of it. **These pins and or the IC chip itself can be thought of as equivalent to that of a high current or power transistor** with its collector pin being the input pin, the emitter pin being the output pin, and the base pin being the adjust pin for the amount of current passing through the transistor from the emitter to the collector. This concept is essentially varies the collector to emitter (CE or C-E) resistance of a transistor, and therefore it can vary the voltage drop across it and any other output resistors which for this IC are generally not in the output current circuit, but are relatively high in value and are rather used to provide a current reference, control or bias (electronic circuit settings) amount to the M317 IC so as to automatically adjust its output voltage to be a stable or constant desired value. There are also low current LM317 available that look like small plastic transistors.

R1 = a value of 220 or 240 ohms is typical

R2 = User selectable for a fixed output voltage such as by using 1 fixed resistor, or a selectable resistor by using a user selectable or operated rotary switch (ex. single pole to 6 throw = 1 input pole or terminal, to 6 possible output poles or terminals), or use a 5k ohm linear variable resistor so as to have a variable output voltage. Here, the center terminal (pin 2) of the variable resistor should be connected to pin 1 or pin 3 of the variable resistor in such a manner that the output voltage increases as the variable resistor (potentiometer = "pot") is turned clockwise. This output voltage setting of the power supply can be indicated at the adjustment knob to this variable resistor, and can be done with simple pen lines on paper and set affixed with tape or glue during the calibration of those lines. An analog voltmeter is also typical on power supplies so as to quickly set a good rough value or approximation of a voltage. There are also inexpensive,small LED voltmeters that will normally display 3v or higher voltages.

The higher R2 is, the lower the "(IC chip) sensing current" and the lower the output voltage of the LM317 IC circuit. Though not often needed, an optional capacitor, say 10uF, across R2 can help improve the output voltage stability by helping to maintain a steady "sensing current" and therefore helping to reduce any output ripple voltage due to input and-or load impedance and current fluctuations.

C1: 0.1uF, usually for AC to DC conversion, and is optional if the input is from a DC source which may briefly vary in output power. Also use another capacitor of higher value, perhaps 1000uF or higher, if the input is from an AC source, such as from the output of a transformer and rectifier diodes, so as to have a more constant valued, consistent, "steady" or "smoother" DC voltage without much, or possibly no variation or "ripple" (rises and-or declines) in the value of the input and output voltage of the IC. Make sure the voltage rating of this capacitor is higher by at least 1.5 times the maximum voltage across it. Another optional high capacity capacitor (ex. 1000uF) is often used at the voltage output of the IC, but a smaller 10uF capacitor is typical and optional.

SW: is the main voltage regulator circuit power on-off switch. This should be used between the mains house power and the transformer. Another switch can be used at the output terminals, or better yet, at the input pin to the LM317 IC chip, and so as to be able to immediately turn on or shut off any power to the load that is still available in high storage value capacitors if used. To prevent fire and other damage, do not connect the household power to the transformer until the circuit is built and ready to use, however the transformer can be initially checked before connecting any circuit to it, and so as to determine and-or check its output voltage(s). In general, unplug or switch off the transformer and-or power supply from the household power when it is not in use, and or when checking it. Before examining a circuit and to avoid a potential electric shock, it is a good idea to first discharge any large capacitor in a circuit by connecting a low resistance conductor across its two terminals.

Fuse: A slow-to-blow ("slowblow") or melt to be an open circuit, 0.5A safety fuse is also recommended in series with the primary or input coil of the transformer. The LM317 IC has a max amperage ability of 1.5A, however there may be a short in another part of the circuit, and which can cause circuit damage, and or a fire due to high heat. Due to this it is best to consider a 2A fuse in series with the output transformer. There may be some low current, resetable circuit breakers which can be used in place of a typical (thin metal, one time use) fuse.

Power, On-Off Light: A LED can be used as a power on-off indicator to the LM317. If it is a red, yellow or green LED, it will require about 15ma of current to be bright enough, and about 2V to turn on. With a 24V input to the LM317, the safety resistor (Rs) to the LED will need to drop (24V - 2V) = 22V. The resistance of this resistor will be about: Rs = Vr / Ir = 22v / 0.015A = 1466 ohms. This light and series resistor parallel (to the LM317 input) branch circuit will be placed from the input of the LM317, and will need to be connected to the resistor and LED in series, and then to the common circuit ground so as to have a complete circuit or path for the current to flow through the LED. A white or blue LED will require about 3vdc at 20mA to 30mA of current. Typically, LED's are sold with the positive (+) or "anode" lead being the longer of the two LED terminals or leads. The shorter lead is the negative (-) or "cathode" lead and is usually attached to the small reflective cup that holds the LED's semiconductor diode

Voltage And Or Current Meter - This is optional. A voltage meter (digital or analog) will be able to indicate the actual voltage at the output terminals of the voltage regulator. It's leads which may include a series, current limiting resistor(s) and possibly a switch to set the range. The meter and its safety circuit will be placed across the output terminals of the voltage regulator where the available output power of the voltage regulator circuit is accessed.

There are some similar IC voltage regulators available with a lower voltage dropout (ie., or loss, necessary for the regulator to function, the **LM317 needs about 3V** to operate, hence the input voltage will need to be 3v extra than the desired output voltage), a LDO voltage regulator, of about 1.5V or even less, and these are ideal when the supply voltage is just enough or close in value to the output voltage needed, however, if the input voltage needs to be reduced significantly, there will still be a significant voltage and power loss in the IC. Because of the low operating voltage or dropout voltage, these regulators will not waste as much internal power as standard voltage regulators, and could save several watts of power. The power loss in these IC's may be only 50% as that of a standard 3 volt dropout regulator.

Voltage regulators, even of the same identification number can come in various cases or packaging and ratings. The TO-92 is the typical small plastic case often used for transistors, and it is about 5mm wide by 5mm high Multi-pin chips or DIP (Dual Inline Packages) have pins on both (L and R) sides of its plastic case and can be placed into sockets so as to be removable. The LM317 for the above circuit used the TO-220 case which is about 10mm wide by 15mm wide . There are other voltage regulator IC's similar to the LM317 which can pass more current and handle more internal power loss, and they should then also have a **heat sink** (or heatsink, heat-sink, a thermal conductor of heat, "to draw away heat", the LML317 , of the 220 case size or larger, typically has a max. power of 15W or possibly more) and thermal conductive paste applied to them so as improve heat transfer and-or removal, and so as to prolong its useful "life" or time of functioning:

IC and Max. Current Rating : LM317 1.5A , LM350 3A , LM338 5A : all generally require heat sinks

Using the LM317 as a constant amount of current power supply

Due to a fixed or set constant or regulated output voltage, if the value of the resistance of the load device being powered by the LM317 changes in resistance, the amount of current going to it will then also change. This can be problematic and can cause the load device to not perform as expected, and or get damaged by excessive current. For example, an LED that has a maximum load current of say 30 mA. To obtain a stable or constant current from the LM317, the resistors R1 and R2 shown in the above circuit are to be removed, and replaced by a (calculated) resistor connected to the output pin of the LM317 IC. The load device will be connected to the other end or terminal of this resistor, and also connected to this terminal of this load resistor is a wire going directly to the adjust pin of the LM317. The LM317 is designed to have a stable or constant output voltage by having the voltage on the adjust pin to always be regulated (ie., automatically adjusted to internally the IC) so as to always have 1.25V regardless of the load's current drawn by the device being powered.

With this minimal circuit mentioned, the resulting output voltage to the load device will then be determined by the input voltage as usual, less the ("dropout") voltage lost through the LML317 to function as a voltage regulator, and less the 1.25V across this current regulating resistor between the LM317 and the load device. To calculate the value of this current regulating resistor (Rcr) use:

Rcr = Vcrs / Icrs = 1.25V / (constant load current desired) , ohms : cr = current regulating resistor

An example of where this circuit can be used is to add or remove a LED diode(s) that are in series electrical connection, and so as to still have the desired current going through those LED's, and without the need to redesign the circuit to increase or decrease the current through those series LED's. In this example the modification would most likely be a series (safety) resistor being changed in value.

Due to the constant current through the resistance of the load device, it will then, according to Ohms's Law (V = IR), also have a constant voltage drop across it if its resistance does not change.

If needed, another LM317 can be used in series as a voltage regulator before the LM317 being used as a current regulator. This would then make a good power supply for experimental purposes and for collecting performance data of the load device.

The maximum current output of the LM317 is limited to 1.5A, however, there are external circuits available which can increase this value, and of which is usually involves using a high current, power transistor capable of handling or safely passing several amps, say 5A of current through it, and yet the LM317 maintains it set voltage output to the load. There are other IC's that are similar to the LM317, and of which have higher current such as 3A and 5A. A heat sink is always recommended with any voltage regulator and-or transistor when passing current of more than 1A through it.

A constant current regulator has good possibilities for charging up batteries at a constant amount of current, and so as to reduce the total charging time needed. The typical recommended amount of current to charge a battery is 10% or less of that batteries maximum rated output (ie., the load current = current to the load) of current.

Here are some very similar 3 pin, leads or terminals IC's that are similar to the LM317, however these are more modern ones that are becoming available and of which have a **low voltage dropout** or minimal voltage loss across them - typically 1.5v max at higher regulated voltages and this value will be less at lower voltages, perhaps 1v. This low voltage dropout also means there is less power loss in these IC's. These IC's are about twice the cost of the LM317.

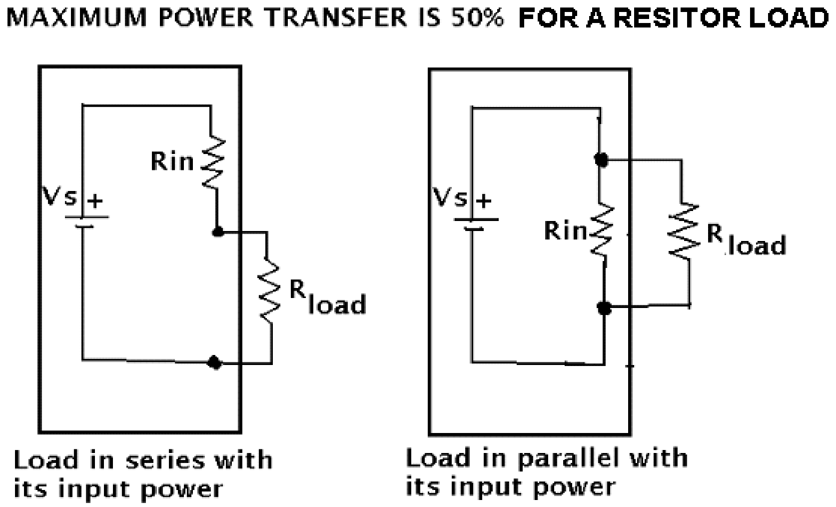
IC and Max. Current and Power Rating : LM1086 1.5A , 15W : for these, LM may sometimes be noted as LT .
and Max Power Dissipation Rating: LM1085 3A , 30W These voltage regulators are also noted as
Please use a heat-sink LM1084 5A , 45W requiring a capacitor at the output to ground -
(a thermal absorber and radiator LM1083 7.5A , 60W for stability, about 10uF. An optional resistor,

with a large surface area)

say 4.7K, across a capacitor can be used as a safety resistor to slowly drain its charge.

MAXIMUM POWER THAT CAN BE TRANSFERRED TO A RESISTIVE LOAD

[FIG 273]



Given a power source or supply as indicated in the box in above drawing, the **maximum power that can be transferred to a resistive load** is 50% of the supply power. This may bring to mind the concept of an equal and opposite force. In the above figure, Rload is the load or external device being powered by the power supply. This also implies that 50% of the supply power to the load is lost and-or not available to the load. Rin represents all the internal resistance of the circuit of the source of energy. So as to have the maximum power condition to the load, the load impedance is the same (ie., "matches", "impedance matching") as the source impedance. Due to this power transfer concept, given a certain value load or impedance, a circuit is often designed with an internal or source impedance equal to this load impedance value so as to give or transfer maximum power to it. It is of important note that if the power supply is a battery, that its internal resistance will increase as it drains of stored current and-or energy, and therefore there will be more internal power loss to that batter and it will also increase in temperature which can physically degrade the battery.

In the left figure, the total internal resistance (Rin) is in series with the voltage source and Rload. This is essentially a voltage divider circuit. In the right figure, the total internal resistance is in parallel to the voltage source and internal resistance. This is essentially a current divider circuit. Note that a battery also has an internal resistance, for example 1 ohm, and this will limit current and cause a voltage drop and power loss internally of the battery. In general, the more a battery is drained of charge, the less voltage is will have, and the greater its internal resistance such as due to its chemical composition of the electrolytes.

In the above figure, the impedances shown are represented as resistances, but it could actually be composed of various resistors, capacitors and inductors which have a net impedance to the flow of AC signals (voltage, current, and frequency). Capacitors and inductors have a (AC, frequency dependent) reactive impedance which limit current much like a resistance would, but the electrical formula for maximum power transfer is more involved than that for resistors, and is beyond the scope of this book. Note that even a power source has a small internal (series) resistance which may be about only 1 ohm or less, but it could be significant for some circuits, especially if a battery's voltage is getting lower and its internal resistance is increasing and the available output power from that battery power source is greatly reduced by a growing internal resistance. Also:

At maximum power transfer to the load:

Pload = 50% Psource and here:

Pload = (load voltage)(load current) = (load current)^2 (load resistance) = (load voltage)^2 / (load resistance)

Why is it limited at only 50% maximum of the source power?

For the load in series with the power source, if you increase its resistance, you will increase the voltage across it due to the voltage divider concept, but then reduce the current through it since the total resistance is now larger. If you decrease the load resistance, you will decrease the voltage across it.

For the load in parallel with the power source, if you decrease its resistance so as to increase the current through it, there will actually be a larger voltage drop across the resistance of the battery or power source because that resistance will become more significant and a larger power will be lost through it and it will be unavailable to the load resistance. When a battery is shorted (ie., no load, 0 ohms external resistance), all of its power is lost internally through its internal resistance and it will get hot (due to electric energy converted to thermal energy) and possibly damaged, and-or it could vent gas or explode due to the force or internal pressure of the hot gasses created.

Even for a capacitor as a load (like a [charge storage] battery) and being charged with energy, a maximum of half of the supplied energy is wasted just to charge it. It is usually wasted due to the internal resistances of the battery and-or wires.

From V = J / Qc , we have: J = VQc ,

Due to the maximum power transfer theorem, the maximum energy delivered to the capacitor and stored is equal to only half (1/2 = 0.5 = 50%) of the supply energy used to charge it up, therefore, the above equation needs to be modified for use with a capacitor:

Dividing both sides by 2: J / 2 = (VQc) / 2 : (1/2) = 0.50 = 50%

If you were to lift an object to a height, due to equal and opposite forces of which acts like a resistance to movement that you must then use energy to overcome, half of the total energy you used will be wasted as heat by your muscles, etc, and the object will gain the other half of the total energy in the system. This energy will be stored as gravitational potential energy (GPE) until it is released to fall and to where the GPE will be turned into more and more kinetic energy (KE) as it falls and-or is being pulled by the gravitational force of Earth and the object gets faster and faster due to the constant force and resulting acceleration in velocity of 9.8m/s^2. In short, only half of the total energy involved with this system or instance got transferred to the object.

Energy Storage In A Capacitor

Maximum energy stored in a capacitor = Jmax = (1/2) (supply energy joules) = (VsQc / 2) joules

For a relationship of energy to just a capacitors voltage and a capacitance, a charged capacitor can store this much energy:

From: $Cf = Qc / Vc$ mathematically:

$$Vc = \frac{Qc}{Cf} \quad \text{squaring both sides we have:} \quad (Vc)^2 = \frac{(Qc)^2}{(Cf)^2} \quad \text{therefore:} \quad (Qc^2) = (Vc)^2 (Cf)^2$$

From: $Jc = \frac{Vc\ Qc}{2}$:Joules of energy in a capacitor. , Using substitution for the above expression for Vc:

$$Jc = \frac{(Qc)\ Qc}{(Cf)\ 2} = \frac{(Qc)^2}{2\ Cf} = \frac{(Vc)^2\ (Cf)^2}{2\ (Cf)^1} = \frac{(Vc^2)\ (Cf)}{2}$$

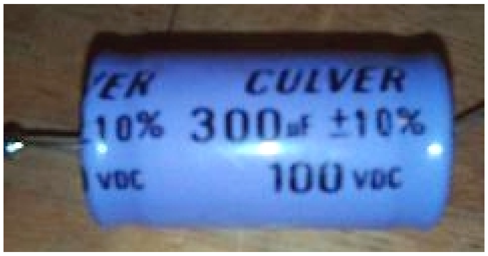
: Energy available in a capacitor, and it's exponentially related to the voltage across it.

Consider a 1F capacitor charged up to 1 volt across it, its energy is 0.5J
Consider a 1F capacitor charged up to 10 volts across it, its energy is: 50J , which is 10^2 = 100 times more than when it was charged to 1 volt.

Here in the image below is a fairly large capacity (300uF) non-polarized (NP, having no specific + or - terminals) capacitor that is typical of being used in audio circuits, power supplies, etc. and where relatively high amounts of current and-or power are involved. The capacitor is indicated as being made by the Culver company. The size of this capacitor in the image is about 4cm long, by 2cm wide or in diameter. It is rated at 300uF, with a tolerance of +,- 10%, and having a maximum voltage applied rating of 100Vdc. Due to the tolerance rating, the actual capacitance may be between 270uF and 330uF:

300 uF - (10%) of (300 uf) = 300 uF - (10%)(300 uF) = 300 uF - 30 uF = 270 uF and:
300 uF + (10%) of (300 uf) = 300 uF + (10%)(300 uF) = 300uF + 30 uF = 330 uF : a total range of: 330uF - 270uF) = 60uF

[FIG 274]



The "**energy density**" (EDc, or energy storage capacity) of a capacitor (c) is the amount of energy that can be stored in the volume or weight of the capacitor. This value is sometimes used for comparing various energy storage devices. A high EDc is usually desired, and at a low cost.

EDc = energy per unit of weight = Jc / weight

As an indication of the amount of energy or power in a battery, a battery is given an **amp-hour (Ah) rating,** which is how much current (A) can be safely drawn per second for 1 hour. A battery rated at 10Ah, can supply 10 amps (=10 Coulombs/s) of current for 1 hour before its considered drained or impractical to use for the rated voltage. That same battery can also have less of a current drawn over a longer period of time such as for example. 5 amps for 2 hours is equal to the same amount of energy as 10 amps for 1 hour = 10Ah. 10Ah = (10amps)(1hour) = (5amps)(2hours). = (5)(2)(amp)(hours) = 10Ah. There will be some energy left in the battery, but its voltage will be less than its rated voltage. Deep cycle (charge and discharge ability) batteries have a relatively high amp-hour rating. We see that an amp-hour rating is really an indication of the amount of current that can be drawn and the total expected time of that. Note that since a battery has a small internal resistance, and if more current is drawn, the larger the voltage drop across its internal resistance, and the lower the available output voltage. Batteries are often tested using an expected load of current such as for the headlights (having a resistance) of an automobile so as to determine the actual available output voltage and status of that battery.

The energy in a battery may also be rated in terms of milli-amp hours (mAh). 1000mAh = (1000)(10^-3)A = 1.0Ah

Ex. 500mAh = (500)(10^-3)A = 0.5A for 1 hour

Since 1A = 1 coulomb of charge per 1second = 1Qc/1s
1Ah = 1coulomb of charge per 1second, for 1 hour = 1 amp for 1 hour , since 1 hr = 3600 seconds:
(1coulomb / 1s) x 3600 seconds = 3600 coulombs of charge in 1 hour

Since J = (Qc)(V) , and if this specific battery is rated at 1.2V :

J = (3600coulombs)(1.2v)
J = 4320J of energy

From: Watts = Vv Ia

The total energy or power available in a battery can also be calculated as:

Wh = (average usable voltage)(amp hour rating) = (Vav Ia)(h) = Wh = (W)(h) = **watt-hours** = total watts used for that many total hours

The average usable voltage corresponds to the battery's (usable, and safe for the battery) amp hour rating.

Ex. A battery rated at 12v and having an amp-hour rating of 50ah, can supply a rated maximum of (12v))(50a) = = 600 wh or= 600 watts for one hour. If this energy was applied to a 100w motor, then 600wh/100w = 6h of total running time of that motor can be expected. This also does not mean that the battery is completely drained of energy and having a very low voltage, but its output-load voltage may be 11V of which is less than its rated 12V working-usable, expected or rated value.

watts = Joules of energy per second = J/s ,

watt-hours = Wh = (J/s)(1hr) = (J/s)(3600s) Joules of energy = W-h : Wh is essentially joules of energy per hour

Electric power from the electric power generation plant is usually measured with an outside household meter and sold in units of kilowatt hours: KWh units. At April 2020, the average residential (home, household) cost of 1KWh of electricity in the United States of America (U.S.A) is 13.31 cents =~ $0.1331USD

1KWh = 1000Wh = 1(10^3)Wh :1 kilo-watt-hour = 1000 watt-hours
This is equivalent to a total of 1000W of power delivered and-or used for a total of 1 hour of time and not necessarily between 1hour of continuous time, but can be spread out over various amounts, times and durations of energy usage. Once 3600J of energy have been delivered and used, that is equivalent as equal to 1 watt-hour = 1Wh of energy. 3600J/1hr = 3600J/3600s = 1J/s = 1 watt .

1KWh = (1000)Wh = (1000)(Wh) = (1000)(3600J) = 3,600,000 total joules of energy.

To convert a value of watts into equivalent kilowatts, divide that value by 1000: x watts / (1000w/kw) = z kw
To convert seconds to hours, divide the amount of seconds by 3600: x seconds / (3600s/h) = z hours
To convert minutes to hours, divide the amount of minutes by 60: x minutes / (60m/h) = z hours

Ex. A 100W = (100J/s) appliance that is ran (ie., turned on) for 10 hours, used a total amount of energy of:
(100W) (10h) = (100)(10)(W)(h) = 1000 Wh = (1000Wh / 1000) KWh = 1 KWh.
The total cost is: (Total KWh used) (cost per 1 KWh)

Total cost = (1KWh) (13.31 cents / KWh) = (1)(13.31) cents = 13.31 cents
Note also that 100W is equivalent to: 100 Joules of energy / 1 second and if this continued for a total of 1 hour = 3600s: 100J/s x 3600s/h = 360000J/h

Ex. Household or residential electricity is set at about 120vac in the U.S.A. How much current does a 100w appliance draw or use each second:

From: Power = (volts)(current) Watts = (V)(I) W we have:

Ia = W / V = 100w / 120v = 0.833A = 833mA : It could be also said that for every 100w, 0.833A is drawn. And:
The cost of 100watts per hour or 100Wh is from:
(cost / 1000w) = (cost / 1Kw),
Since 100w is only a tenth of 1000w, its cost is also a tenth:
cost per 100Wh = ((cost per 1KWh) / 10) ,
and for the above example: (13.31 cents) / 10 = 1.331 cents.
To run a 100W appliance for 1 hour will cost 1.331 cents

The wire to this device or appliance must be rated to safely handle a current of 0.833A or more. It must have an ampacity (or maximum continuous current rating) rating of this value or greater.

The effective current resistance or impedance of this 100W device or appliance is:

Ro = Vv / Ia = 120v / 0.833A = $144.\underline{1}$ ohms

Another useful equation is:

$$\text{Total Energy} = \text{E joules} = (\text{Power})(\text{time}) = \left(\frac{J}{s}\right)(s) = (V\,I)(s) \text{ joules} \quad \text{or=} \quad \text{VAs}$$

Ex. A 12v , 50 aH rated battery can supply a rated and safe maximum power of:

P = (V)(I) = (12v)(50A) = 600W of power , and since this is rated for 1 hour, hence 600 wH =
600 watt-hours of total energy

Pin = Pout
wH in = wH out : note that the number of watts and hours need not be the same, just as long as their product is the same. Considering a 300w device being powered by a 120Vac inverter:

First: From P=VI , I = P/V = 300w/120v = 2.5A

From wH = (watts)(hours) , hours = time = wH / watts = 600wH / 300w = 2h , max.
For the battery and its current out, another formula is: max. time = aH / A
And:

energy in = energy out : Joules
600 wH in = 600 wH out
(12v)(50A)(1H) = (120v)(2.5A)(2H) , note also that at 120v, the max safe, available current is: 600w/120v = 5A.
The voltage increased by 10, and the max. amperage decreased by 10.

600 watts for 1 hour = 300 watts for 2 hours : the lower usage rate (energy/time) of the available energy, the longer the available time of usage of the available energy.

Ex. For a 48v , 50aH dc battery system, such as by connecting 4, 12V batteries in series connection:

For this battery, the maximum rated amount of power usage is: P = VI = (48v)(50A) = 2000w for 1 hour , and this corresponds to 2000wH of energy , Joules

P in = P out considering the maximum rated value for this battery and-or system:
2000w = 2000w
(V)(I) = (V)(I)
(48v)(50A) = (120v)(16.67A) : notice the high amperage from the battery into the 120Vac power inverter, and this requires very thick and-or short cables, typically 3 feet. Copper pipes flattened at each end with drilled holes can be used. Note that the voltage was increased by 4, and the current decreased by 4, still, to get that 16.67A for the device being powered, 50A is actually drawn from the battery.
And:

energy in = energy out : Joules
wH in = wH out : Joules , wH = The product of: (watts)(time) = (watts)(hours) , with units of Joules
2000 wH in = 2000 wH out : considering the max. rated and safe values for this example
(48v)(50A)(1H) = (120V)(A)(H) , now considering if a 300w device is being used, I = W / V = 300 / 120 = 2.5A
(48v)(50A)(1H) = (120V)(2.5A)(H) , after solving for H we have: H = time = 2000wH / 300w = 6.67H
(48v)(50A)(1H) = (120V)(2.5A)(6.67H) : The 300w device can be ran for up to 6.75H

USING A MULTI-METER TO MEASURE ELECTRICAL VALUES

A multi-meter which is now often a digital multi-meter (DMM) with a digital numeric display rather than a (relatively expensive) analog meter display with a dial or scale and pointer hand, can be used to directly measure voltage, resistance, and current if it has an ammeter or current function. It is still possible to use an individual meter for each measurement. Some of these meters include a (electrical, conductance) continuity function so as to check if a wire is functioning and not broken and having a very high resistance of an open circuit, but rather having a very low resistance. Sometimes a value cannot be measured directly, and a calculation, usually using Ohm's Law, can then be made, especially when finding a value of current and trying to avoid placing the meter in series with a wire and-or component.

Before proceeding, a multi-meter is calibrated to display the effective DC value of the AC voltage or current when the meter setting is for AC waveform, and this value is the RMS value of that AC waveform and-or signal. Vpeak = Vp =~ (1.414) Vrms and mathematically: Vrms = Vpeak / 1.414 =~ (0.707) Vp. Since power = (V)(I), the product of the RMS values of each will give the equivalent DC power. Note also that 0.707 is one-half of 1.414 = sqrt(2). Here are some generalities and considerations of measuring and the measured or measurement values when using a Multi-Meter:

TO MEASURE THIS VALUE , YOU CAN DO THIS

Voltage , Set the meter on a high voltage scale and-or range. Place the measuring terminals or probes across the circuit element or component. Reduce the scale and-or range so as to find the voltage scale and-or range having a good precision and voltage display.

An ideal voltage meter has a very high to infinite internal resistance so as to not draw any current and alter the device or circuit being measured. Many common volt meters have about 1M ohm resistance.

Although a crude estimation of a batteries current state of charge can be determined by simply using just a volt meter, it is better to place the battery "under load", that is, some current is being drawn by the load or device being powered. For this, you can connect and turn on the device to be powered and then measure the battery voltage. An alternative to using the specific devices to be actually used and powered, is to use a resistance such as from a resistor of perhaps in the range of 5 ohms to 10 ohms. An alternative load for a car would be to temporarily turn on its headlights or some other lights. When a battery is under load, its internal resistance can then be accounted for by being in the actual circuit, and this resistance will have a voltage drop or energy loss across and-or through it, and will result in the actual available and lower voltage and measured value or "reading". A battery may have a measured voltage of 12 volts without a load,and 10 volts with a load being powered, and this may be insufficient for it to function properly. An alternative to this problem is to use a voltage regulator designed for a device that was designed for and requires a lower input voltage, say 9v.

Resistance , Set the meter on a high resistance scale and-or range. Do not place the terminals across an element having current through it, hence also having a voltage reading across it. This could damage the meter. Place the terminals across the (unpowered) resistance. Reduce the scale and-or range so as to find the resistance scale and-or range having a good precision and resistance display. Be wary of any other possible resistance in parallel and-or series with the resistance you are trying to measure, for it will then give an unintended measurement reading or displayed value on the meter. In some instances, you may need to unpower the circuit and cut or remove one of the two resistor leads so as to measure its resistance value. Resistors are usually color coded so as to have color bands on them to indicate its rated value of resistance: Black (0), Brown (1), Red (2), Orange (3), Yellow (4), Green (5), Blue (6), Violet (7), Grey (8), White (9), The third band is the power of 10 multiplier to the previous two bands. The fourth band is the "tolerance" code, but it is actually the possible, percent difference in error from the rated color coded value and actual true or measured value: Brown (+,- 1%) , Red (+,- 2%) , Gold (+,- 5%) , Silver (+, - 10%).

An ideal resistance meter has a high internal resistance, and since this resistance will be in parallel to the resistance being measured, it will have a very low (parallel resistance) effect on the displayed value of resistance.

It is very possible to measure the value of a resistance indirectly: From $V = I R$, $R = V / I$

If the current is not known or can not be measured, a form of the voltage divider formula for two resistors in series can be used to determine the value of a resistor, here R2:

$\frac{V1}{V2} = \frac{R1}{R2}$, $R2 = R1\, V2 / V1$, also: $I = V1 / R1 = V2 / R2$: I = same series current

A resistance meter can be used to determine the **continuity** of a wire. If it has a low resistance,the wire is still conducting. If the resistance of a wire is very high, that wire is probably broken, and is non-conducting.

Amps = I = **Electric Current** , Set the meter on a high current scale and-or range. Place the probes in series with any circuit component or element in that circuit branch of which you want to directly find the current for. Reduce the scale and-or range so as to find the current reading having a good precision and display.

So as to not impede the circuit current being measured, a current meter will have a very low internal resistance, perhaps a tenth of an ohm. This resistance is actually a parallel resistance to the coil or sensor within the meter, and is often called a "shunt resistor", and is practically a short circuit to it. Shunt or a shunting resistor diverts ("shunts)" the high current away from the sensitive current sensor so as to not damage it. An amp meter is rated at a maximum amount of current to measure, and if it is exceeded, it may blow an internal fuse, or cause damage to the meter, etc. Some amp meters, sometimes called "(current) clamp or loop meters", have magnetic field sensors that can indirectly measure the current flowing through a nearby wire, and without the need to put the meter in series with the circuit.

Use Ohm's law for any calculations and-or checking needed: $I = V / R$, $V = IR$, $R = V / I$

P = electrical power = $V I$ watts = joules / second

$P = I^2 R = V^2 / R$ = watts = J / s

An indirect way of measuring current is by the voltage across a resistance and then using Ohms law to calculate the current: $I = V / R$. This works will for a pre-made circuit that has a known resistance value, however, we do not want to lower the actual current to the load resistance by introducing a resistor into the circuit to measure its current. A compromise is by using only a very low, calibrated and known "precision resistance value" value such as 0.1 ohms or near that value, and typically a power resistor type of say 10W to 100W power handling capability. The calculated value will be only slightly less than the actual current value without the introduced resistance for the measurement. Please read the following note:

Due to the resistance of the wire probes of the meter, this value will be added to the resistance being measured Typically for values of say 1 ohms or greater, it is a relatively insignificant value, however, when measuring a very low resistance, the value of resistance of the probe is relatively significant and must then be deducted.

To measure the value of the resistance of the probes, simply connect the end points of the probes together, and then simply observe how much resistance is then measured by the meter. Since most inexpensive amp or current meters can only measure about 10A maximum, and only for a few seconds, the above method is a good option when trying to measure current greater than say 10A. For relatively high currents, there are also current measuring devices which simply encircle a wire and measure its flowing current indirectly via the magnetic field that current creates.

Some meters and-or multi-meters can measure other electrical values such as: continuity or low resistance check, diode check, transistor check and-or gain (amplification), capacitance, inductance, temperature, frequency, and battery test.

Another type of meter is a **power meter** that can sense and measure both current and voltage in a circuit. The power value is internally calculated as: Power = (voltage)(current), and this can also be done manually if the current and voltage is known. This device is generally plugged into a home's electric power socket ("outlet"), and then the device being measured is then plugged into the power measuring device or meter. With this meter, you can determine how much power is actually being drawn by a device, perhaps when checking if the device is using a greater amount of power than its rated value. You can also check the power used by each device in a home or building and so as to sum, determine or estimate the total kilowatt-hours (kWH) being used, and to then estimate the corresponding electric bill (fee, price, cost) that is based on the amount of kilowatt-hours (kWh) used. Some electric power utility companies may sometimes estimate the amount of power a home used, and it could be based on the average monthly usage and-or a previous amount for a certain month of the year. A bill or financial charge from the electric company an-or the supplier (ie., [wire, maintenance, service and repair] distribution company) will usually have the number of KWh used, and the cost per KWh of electricity.

To measure capacitors and inductors, you will need a capacitor and-or inductor meter. These measurements are usually performed on the circuit element (here a capacitor or inductor) when it is not in a circuit. Before measuring the capacitance of a capacitor, be sure that it is discharged such as by connecting a low value resistance across its leads. If a capacitor or inductor is in a circuit, please remove all power to that circuit, discharge the capacitor, and take one lead of it out of the circuit so as to the measure that capacitor and-or inductor. Some mult-meters may include a capacitor measuring function and possibly an inductor function. It is possible to measure the value of a capacitor or inductor by using a voltage divider circuit that includes a series resistor, and with AC signal applied across just those two circuit elements or components. For example, solve for the reactance of the capacitor (Xc), and then use the reactance of the capacitor formula and solve for the capacitance (Cf).

Some multi-meters can also measure the **temperature** of something via a temperature sensor probe that plugs into that multi-meter. Some multi-meters can also measure **frequency** within a certain range. As of the year 2010 or so, there are many inexpensive digital **oscilloscopes** available, and which can view the waveform(s) of an electronic signal with respect to time. It is recommended that the measurement sample rate or frequency of a digital oscilloscope be at least 10 times the frequency of the wave being measured so as to construct it reasonably accurate on the display screen.

A COMPUTER PROGRAM TO FIND THE AVERAGE AND RMS VALUE OF A SINE WAVEFORM

An **RMS** value is the Root Mean Square value of a waveform. RMS means the square root of the average (ie., mean) of all the squared instantaneous values of the wave form. RMS is considered because the average of a sine waveform above and below the 0 value has a resultant value of 0, and by squaring the curve values, the result is always positive in value. These positive values are then averaged, and the square root of that average must then be taken or undone so as the resultant value is not left as excessive in value. RMS is generally considered as the equivalent DC (both the voltage and current sine wave forms) power available to a resistive (ie. resistor) load. Power is also the product of voltage and current, hence this is essentially a squared value in terms of the voltage and corresponding current sine waveforms which both have a maximum relative value 1.0 Because of the above facts, the RMS value is slightly higher than the average value of the voltage and-or current sine waveforms, and the RMS value should be considered as the power value.

The two programs below are very similar in construction and with slight mathematical adjustments.

```
/* Sine Average Value.c

   A experiment to find the average sine value, of a sine curve.  I take many "samples" values as the angle
   increases slightly in value up to 90 degrees which is about 1.57 radians, and then divide the growing sum
  of the values by the number of values or samples taken.

   (c) JPA June 8, 2018

-----------------------------------------------------------------------------------------------------*/

#include "stdio.h"
#include "math.h"

/*----------------------------------------------------------------------------------------------------*/
void main(void)
{
double increment=0.0000001;   /* increment a "millionth" = (one-millionth) = (one/millionth) = (1/million) = (1/1,000,000)   */
double angle=0.0;
double sine=0.0;
double sum=0.0;
unsigned long int n=0;

for(;;){

        sine=sin(angle);
        sum=sum+sine;      /* NOTE , If this statement was made to be:  sum = sum + sine * sine;   such as when
                              considering the product of the voltage and current at each instant, the result will be 0.5, and
                              then doubling this for the other half of the wave (180° to 360°) will mean (ie., average) result
                              in 1.  Since squared values were used to create the result, we can take the square-root of
                              this 0.5 value, we have about  0.707  as the equivalent DC value for the voltage and-or
                              current, and this is called the RMS value of the AC voltage.  See the RMS program below. */

        angle=angle+increment;
        n=n+1;
        if(angle>=1.570796326){  break; };     /* 90 degrees ,  if this is doubled for 180 degrees, the average is still the
                                                  same over 180 degrees since a sine waveform is symmetrical about 90°
                                                  and will yield the same average value. */
    };
```

```
printf("\nThe average value of the sine waveform  is:  %lf",sum/n);    /*  Displayed is:  0.636620  , and if it may matter, this
                                                                                     value is close in value to, but slightly greater than:  1 - (1/e)

printf("\n\nPress a key."); fflush(stdin);  getch();

};
/*-----------------------------------------------------------------------------------------------------------*/
```

If the peak voltage of a sine waveform was 9 volts, the average value of that waveform and effective or equivalent dc voltage is then: (9v)(0.636620) = 5.73v

```
/*------------------------------------------------------------------------------------------------------------------------------------------------*/
/* Sine RMS Value.c

   RMS = Root Mean Square  =  Square-Root of the Average of the squared values.

   This program is based on sineaveragevalue.c that does not consider RMS, but the basic values of
    the curve such as for up to 90 degrees, and that average value is also the same value even if 180
   degrees is considered.  To consider the equivalent dc power of the entire wave, and so that the
    positive and negative halves do not cancel or negate each other to 0, the RMS method is done
    where squared values are considered.  Nonetheless, the RMS value of 0.707 is close in value to
    0.637 = 2 / (pi) , as found in the above program to find the average value of a sine waveform.
    1 / 0.637 = 1.57 = (pi) / 2

    If given an RMS voltage of Vrms, the peak (Vp) value of that waveform is (Vrms)(sqrt 2) =~ 1.414 Vrms = Vp
    mathematically then:   Vrms  =~  Vp / 1.414  =  0.707 Vp .   Also note that 1.414^2 = 2   Most AC volt and current
    meters measure the RMS value of that AC waveform and which is the "effective (as like, equivalent)" value in
    in terms of the effective power measurement of that signal, and is therefore not the peak values which would be seen
    on an oscilloscope.  Consider that Pw=(Vv)(Ia) for DC values, now with an AC waveform:
    Pw = (Vrms)(Irms), and so if Vac has a peak of 1Vp  then  Vrms = 0.707 Vp,  and Irms = 0.707 Ip   , and the equivalent
    DC power is:  Pw = (0.707Vrms)(0.707 Irms)  =  0.5W and not 1W as would be with DC.  If the RMS voltage was
    1 Vrms, and the RMS current was 1Arms such as through a 1 ohm resistor, Vp = 1.414 V  and  Ip = 1.414 A , and
    Prms = (Vrms) (Irms) = (1Vrms)(1Arms) = 1W of equivalent DC power.

    Extra considerations:  1 / 0.707 = 1.414 = sqrt(2)      and      0.707 / 0.5 =  1.414  =  sqrt(2)   ,  sqrt(0.5) = 0.707
                           0.5 / 0 .707 = 0.707      and     0.707^2  =  0.5       ,     0.707 (2) = 1.414
                           (0.707)(1.414) = 1
                           (0.637)(0.637) = 0.637^2 = 0.4058      and      0.637 / 0.4058  =  1.57  =  (pi) / 2

   (c) JPA Jan, 2021
 -------------------------------------------------------------------------------------------------------------*/

#include "stdio.h"
#include "math.h"

/*-----------------------------------------------------------------------------------------------------------*/
void main(void)
{
double increment=0.0000001;
double angle=0.0;
double sine=0.0;
double sum=0.0;
```

```
unsigned long int n=0;

for(;;){

          sine = sin(angle);    /* :using the compilers built in ANSI C, sin() function.  There is an extra NOTE below. */
          sum = sum + (sine * sine);  /* squaring each sine value */
          angle = angle + increment;
          n = n+1;
          if(angle>=1.570796326){  break;  };    /* if greater than 90 degrees  = (pi)/2  =~  3.14159265 / 2 = 1.570796325 */
      };                                                   /* 1.570796326 rads = 90 degrees */

printf("\n%lf",sqrt(sum/n));     /* taking the square root of the average value  ,  the result is 0.707107  */

printf("\n\nPress a key."); fflush(stdin);  getch();

};
/*----------------------------------------------------------------------------------------------------*/
```

If the peak voltage of a sine waveform is 9 volts, the RMS value of that waveform is then:
(9Vp)(0.707107) = 6.36Vrms

When a DC signal (direct [non-alternating direction] voltage, current and frequency) such as a power supply is constant, the output power is:

> Po = Pmax = (voltage max.)(current max.). If that power signal is on for a certain amount of time and then off for that same amount of the time, then the power available is clearly half of maximum power possible = Pmax. These facts are part of the concepts known as "**duty cycle**" and (equivalent resistor load) "effective power". On an oscilloscope instrument, the waveform of this would looked like square waves and is usually called "**pulsed DC**".

$$\textbf{duty cycle} = \frac{\text{dc power on time}}{\text{dc power off time}} \quad , \quad \textbf{effective power} = (\text{Max. DC power at 100\% duty cycle })(\text{duty cycle})$$

A power inverter that converts 12vdc to a 120vac, 60hz pulsed dc signal for common household devices that connect to the electric utility power ("grid") supply. The inverter device simply pulses the 12vdc input supply by 60 hz with a 50% duty cycle, and then raises that signal by 10 times with a voltage step-up transformer so as to create 120v pulsed ac. The output of this type of inverter is not very close to being an ideal sine waveform, but is useful for some non-sensitive electronic devices such as basic lights and resistive heaters, etc. Square waves such as pulsed DC can contain and-or cause electronic noise and interference, and can potentially damage an electronic device. For input power signal sensitive devices, a "pure sine wave" type of inverter should be used, and which shapes the output power waveform so as to be nearly sinusoidal (ie. having a smooth curve, sine waveform shape). If a 12Vdc voltage is boosted to 120Vac by using a transformer or inverter, to power a 120W device will require only 1 amp of current. Pw = (V)(I) = (120Vac) (1A).

In brief, a 12vdc to 120vac will boost the voltage by 10 and decrease the current by 10. Due to this, the current needed from the 12vdc battery will need to be 10 times more to result in the same available power. In theory, this will drain that battery 10 times faster, and charging it will take ten longer. A 24vdc, 36vdc, and 48vdc battery system will therefore use less current, last longer per charge than a 12vdc system. The tradeoff is the higher costs.

$$\underset{\text{Pin}}{(12\text{vdc})(\text{A})} = \overset{\text{Pout}}{\frac{(\text{n})(12\text{dc})\ (\text{A})}{\text{n}}} = \overset{\text{Pout}}{(120\text{vac rms})\ \frac{(\text{A})}{\text{n}}} \quad : \text{ here the factor of n=10 for the same amount of power}$$

Ex: (12vcd)(10A) = (120vac)(1A) = 120w

[This space for book edits.]

A general example of a car or automobile battery and (electrical power) inverter system.

The mechanical analogy of an electrical inverter system is a (mechanical) gear system that can alter and-or transfer mechanical (ie., direct, physical contact forces) power. Given a constant value of power = P = (voltage)(current) = VA or VI, the two variables: V and A will be altered by the **inverter**. The physical and mathematical relationship of those two factors of P is that they are **inversely** related. If one increases by (n), the other decreases by that same factor of (n) when the power value is a constant value.

A common 12V, non-deep cycle or drain, car or automobile battery has about a 50 amp-hour rating = 50 aH. This means it can supply 50A maximum for 1 hour, or mathematically 25A for 2h, and an equation for this is:

Rated Discharge Time = aH / a : expected discharge time until the car battery needs to be recharged.
aH = amp hour rating, a = A amps = current.

Rated Discharge Time = wH / w : **wH = watt-Hour rating = (V)(A)(H) = (V)(aH rating)**

After this rated discharge time, a car battery will usually have power still in it, but it has fallen below its rated 12V and is perhaps now just 10v or 11v, and which is enough to power circuits for emergency LED lights and-or other devices that can operate at lower voltages. You may which to then consider some type of voltage regulator and-or circuit for these. It is also of not that the current drawn from a battery during engine ignition is often higher than its aH rating, but its for just a brief amount of time.

Ex: If a device that uses 5A of current is connected directly to a fully charged 12V, 50aH car battery, the expected time of it to function using this battery is: time = 50 aH / 5a = 10H = 10 hours. For this to happen, the device also needs to operate at 12V.

Ex.: While using an inverter: Power in from the battery = Power out to a 20W device
20W = 20W , and:
(12v)(1.67A) = (120vac)(0.167A) : P=VI , I = P/V = 20 / 120v = 0.167A

In general, regardless if the system uses an inverter or not: A 12V, 50aH battery can supply a maximum power of:
Pmax = (V)(Imax) = (12v)(50A) = 600W, and this was tested and rated to last for 1 hour = 60 minutes of time. This can also be expressed as a total safe amount available as: (Power)(Time) = (watts)(Hours) = (V)(I)(H) = 600wH.

For a non-inverter system, using just the battery: A 20W device can be powered for 600w / 20w = 30 times longer than 1 hour, hence for 30 hours = (30h)(60min/h) = 1800 minutes of continuous or intermittent use. If the device is used only for a few minutes at a time, say for 5 minutes, the battery can be expected to provide this 20w of energy for: 1800min / 5min = 360 times. A battery array, either series and-or parallel, will increase the stored energy available and the amount of time a fixed or certain amount of power can be drawn. A 12v, 50aH rated battery would have a corresponding (maximum) watt-hour rating of: (12v)(50A) = 600wH, and therefore it can supply a maximum of 600w of power for 1 hour of time.
If the battery (mass-weighed) 18.1kg = 40lbs, its corresponding **energy density** or **specific energy** would be rated as: (wH / mass) = (600wH / 18.1 Kg) = $33.\underline{2}$ wH / 1 Kg . It is generally easier to weigh a battery than to calculate its volume, but an energy density could possibly consider the volume of the battery as: (wH / volume). The energy density rating of a battery is sometimes expressed in Joules of energy per mass. It was shown in this book that:

Energy = J = VAs = Ws = (Power)(time)

1J = 1 Ws , if the amount of seconds was 3600s = 1h , we have after multiplying each side by 3600:

(3600) J = (1 ws) (3600)
3600 J = 3600 ws
3600 J = 1 w (3600s)
3600 J = 1 w (1h) = 1 wH , or by switching sides:

1 wH = 3600J

Considering the above mentioned battery rating of 33.2 wH / Kg , a proportion type of equation can be created, or by simple multiplication, and so as to find the safe and expected amount of energy in that battery, we have:

(33.2 wH / Kg) (1 wH)
(33.2 wH / Kg) (3600 J / 1wH)
119520 J / Kg : expected or rated energy, although the battery also has more in it

For two batteries in parallel, the amount of time available to draw a certain amount of current will increase by the same factor of two. This is much like two capacitors in parallel that will double the total capacitance and-or maximum charge storage.

To effectively increase the total energy storage for a system, a larger constructed battery of the same voltage can be used, and this can be effectively achieved by placing similar (ie., same voltage, aH, etc) batteries in parallel (P) connection: positive to positive, and negative to negative. Similar batteries in a series (S) connection: negative to the positive terminal of the other battery, will effectively increase the available voltage by the value of each battery. The current value of charge level or state, and voltage level of each battery should be very close to avoid electrical damage such as an inrush and-or drain of a high value of current of which can damage electronics and can be a fire hazard, To help prevent this, charge the batteries so as to have the same voltage or within say 0.1V from a reference or goal voltage. Some systems have what is called "balancing resistors" so as to help maintain identical voltage levels for all the batteries once they are charged up.

A 48vdc system will require a 48v battery or series array of smaller voltage batteries, and a 48v (battery) charge controller, and it helps to keep the input voltage to the charge controller a few volts higher, say by 5v higher, due to the energy requirements and-or voltage drop or loss due to the charge controller circuit. A charge controller prevents overcharging a battery to a higher voltage than its safe recommended voltage, and which can then damage a battery. In general, the larger the battery in terms of its size or volume, the higher its aH rating. When single batteries are connected together, the aH rating of each battery still remains the same, and it is recommended to not exceed the maximum amps of its aH rating because it is the safe rated value of current passing in, out, or through that battery, and the aH rating does consider any other batteries in a system and their energy storage and possible extended time available. The aH rating is both a measure or indication of the amount of charge storage, time available and its safe maximum, continuous current.

For a 12v system, 50A from the battery is required to have 600W of power. For a 48v system how much current will be needed so as to have 600W of power?

From: Pw = V **I** = 600w = (48v)(Ia) and **I** = 600w/48v = 12.5A of current drain from the battery. This is the maximum safe current, and it should not be exceeded. Fuses and-or circuit breakers can prevent this.

Note also that 48v/12v = 4 times increase in system voltage , corresponding to a 50 A/12.5A = 4 times decrease in system current. When the current between the battery and the inverter is lower, thinner and-or longer wires can be considered. If 4 similar , 12v, 50aH batteries are connected in series so to make a 48v battery, the total amount of energy stored will technically be 4 times higher than any one battery, likewise it will also take 4 times more energy and-or power to charge to its full voltage. As mentioned previously, though the stored energy may be higher, the aH rating of a battery cannot be exceeded.

You can always use fuses and-or circuit breakers to prevent high current and-or short circuit damage to your power system, including the energy input and charging system. For example if a battery is rated at 50aH, then use a 50aH fuse - probably a slow-blow fuse, or circuit breaker rated at 50aH or less that is needed for all devices being powered. For extra safety, each device being powered can also have its own individual fuse or circuit breaker.

Typically, inverters are made for 12V, 24V, 36V and 48V battery systems. The 48v inverters are generally cheaper, perhaps half the price than the 12v inverters because in the 48v inverters a smaller step-up transformer (**1:2.5**) is needed, that is, the input of 48dc voltage needs to be boosted by only 2.5 times so as to produce 120vac. 12v systems, such as in a RV or "camper vehicle", will require much more current so as to provide power (P=VI). This can drain the charge in a battery fairly quick. An option to is to then use several, identical 12V rated batteries in parallel. A 12vdc system can also be converted to a 120vac system by using a 12vdc to 120vac inverter, however the current from the battery will still be high, and the parallel battery method will still be encouraged.

The maximum safe and-or available current for a 12V battery having a 50aH or (12v)(50aH) = 600w maximum rated power output is: (Note, the actually result is 600 watt-hours = 600wH.)

P max. in = P max. out : Power = energy used and-or supplied / time , P in = power from the battery
600w in = 600w out
(Vin)(I in) = (Vout)(I out)
(12v)(50A) = (120V)(I out) , after solving for I out:

I out = 5A : this value is one-tenth (1/10) the current drawn from the battery by the inverter. The ratio of voltages equals the reverse ratio of currents: (120 Vout / 12 Vin) = (50 Ain / 5 Aout) = 10

Note that the time of this power usage, either input at the inverter and-or output on the AC line is still the same value for a certain max. safe wattage available. It is incorrect to think that the time of use will be: time = aH / A = 50 aH / 5 = 10h , but the max. time value is rather one-tenth of this value, and is 10h / 10 = 1h, and this corresponds to that from the battery to the inverter as used for this 600W of continuous use and where Pin = Pout: time = 50aH / 50 = 1h . To help overcome the maximum amount of time available at a give wattage, the current drawn can be significantly reduced if the battery system has a higher voltage. Its aH rating will also increase if the batteries are in parallel, and then the time of use of the available power will also increase. If the output device used only half of the 600w max. available or 300w , and-or this could be calculated as 600w/2 = 300w, and-or 600w/300w = 2, and then the time of use would be twice as much or 2 (1h) = 2h. Also, 300w/600w = 0.5 and the time value will increase by the reciprocal of this ratio: 1/0.5 = 2 , As a check:

Energy in = Energy out **:** (Power)(time) = total energy = total Joules
(Power)(Time) = watt-hours in = watt-hours out : Power = joules / s = watts
: **(Power)(time)** = (J / s) (s) = (w)(s) = **J = Energy J**

$\frac{3600J}{1s} = \frac{1J}{s}$ 3600s = 1 w for 1 hour = **1wH** = 1w (3600s) = 3600 ws = **3600J**
1wH (1000) = 1000 wH = **1kwH** = 3600J (1000) = **3600000 J**

600wH in = (600w)(1hr) = (12V)(50A)(1hr) = (300w)(2 hr) = (120v)(2.5A)(2h) = 600wH out

To effectively double the amp hour rating of a battery system, you can connect two similar batteries in parallel. For two similar 50aH batteries connected in parallel, the total aH rating of this battery array and-or system is: (number of batteries in parallel) (aH rating) = (2 batteries)(50 aH / battery) = 100aH. Similar voltage batteries connected in parallel will have the same output voltage as any one battery. To be safe and not permit high currents to flow amongst batteries when they are connected together, please make sure they are at or near the same voltage level. Remember, it is a potential or voltage difference that will cause a current to flow

For **charging a battery**, many consider a fair and safe value of **one-tenth the amp value in the aH rating**, hence 1/10 the maximum input or output rating of current, or less. This reduces internal heat damage in the battery and gives more time for the chemical reactions to take place, and simply requires a relatively low power supply to charge that battery. Ex.: For a 50aH battery, a max. safe value for charging is: 50A / 10 = 5A of current. The theoretical amount of time to charge the battery when considered below its rated value and is "drained", and at this amount of current is: time = (aH rating / A) = 50 aH / 5 A = 10H = 10 hours . The ratio of this charging or discharging current to the rated capacity in amp-hours is sometimes called the **C-rate** or Charging and Discharging rating. This value is essentially a percentage of the aH rating:

C-Rate = current drawn in amps / max current in the aH rating :It is recommended that a C-Rate be less than

1 = 100% of the aH rating of that battery

A typical 100W, 12V rated solar panel can deliver about: from P = VI , we have I = P/V = (100w / 18max open circuit voltage) = about 5.5A maximum of current. The time it takes to charge a battery to its full rated capacity is determined by both the safe amount of recharging current, and how drained of energy the battery is and-or its current amount or capacity of energy. When charging a battery, it is best to monitor its voltage if it is not performed by a charger or voltage regulator device. To do this, temporarily stop charging the battery, and before and while measuring its voltage, temporarily draw an amp or so of current from it, such as for a light and-or other devices, and so as to have its true available output voltage value while being used. A battery itself has an internal resistance of which there will be a voltage drop or loss across and due to it, and this will not take place until it is in a circuit with current being drawn.

As an extra note for a more completeness of the energy conversions mentioned above:

To convert aH to J , it depends on the voltage used because it is the voltage that will give and increase the kinetic energy (J) of each electron in the moving current. More voltage means more (electric, electromotive) force applied to the electrons, and they will then have more kinetic energy and are therefore transferring more energy (Joules).

From: Power = (energy) / (time) = Pw = W = J / s

1 J = 1 Ws = 1 VAs , since 1h = 3600 seconds, and multiplying each side by 3600:

3600 J = 3600 Ws = 3600 VAs = VAh = W (3600s) = Wh : **VAh = (VA)(h) = (V)(Ah) = Wh**

(1V)(1aH) = 3600 J : 1 aH could be for example: 1A drawn for 1h or 0.5A drawn for 2h , etc. , **aH = (A)(h)**
J = (V)(aH) / 3600

Some data about a common example of a disposable or non-rechargable battery, here an AA electro-chemical cell.

These single cell, but often simply called batteries, have a typical voltage of 1.5V, whereas most rechargeable batteries of the same size are usually rated as 1.2V . These batteries are often tested using a 0.050A =50mA drain of current. For example it might take 12h for the battery to not be able to deliver 50ma. The rating of this battery would be:

(Power)(Time) = (watts)(time) = (1.5V)(0.05A)(12 h) = (1.5)(0.05)(12)VAh = 0.9 aH = 900maH

Internal Chemistry	maH rating max, expected, safe rated values at 1A load drain (Typical)	
zinc-carbon	600 maH = 0.6 aH	: "standard duty". Ex. If a device uses 25ma of current, it can function for: time = aH / A = 0.6aH / 0.025a = 24H = 24h
zinc-chloride	1200 maH = 1.2 aH	: "medium duty"
alkaline	2200 maH = 2.2 aH	: "high duty" (high current ability)

Though most rechargeable batteries, such as Lithium-Ion, are more expensive than non-rechargeable batteries, they can be recharged repeatedly and this results in a comparable and significant cost savings - perhaps by 50 times the purchase cost, thereby creating a way for an incredible financial savings over time. Many lithium batteries are rated at 1000 to 2000 full charging cycles, and some as high as 5000 cycles, and if the battery is not drained much, it can be recharged perhaps 10 times more. The energy density of lithium batteries is greater than that of standard disposable or lead-acid batteries, and has an average energy density of about 5 time more by volume.

[This space for book edits.]

Lithium Batteries During Cold Temperatures:

A current (as of 2024) problem with lithium batteries is that their current will decrease as temperature decreases. This is due to the electrolyte becoming not as conductive, and then potentially some lithium being plated on the anodes which will permanently degrade the performance of the battery. Lithium batteries are best used when the temperature is between (15°C = 59 °F) to (45 °C.= 113°F). A lithium battery can be permanently damaged if it is used when its internal temperature is less than 0°C = 32°F. At cold temperatures the electrolyte can expand and damage the internal structure of the battery. Special blankets can help keep a battery warm, and-or a special electric heater for batteries. Some lithium batteries may even have an internal electric heater. Even with all these facts, it is also said that lithium batteries still perform better in the cold air temperatures as compared to lead-acid batteries, but then lead-acid batteries do not have the risk of being damaged so easily by cold weather and this invites the possibility of also including a lead-acid in an automobile so as to start it, and warm the lithium battery. **It is recommended to only charge a lithium battery when the temperature is greater than or equal to 32°F = 0 °C** Some lithium batteries include a battery management system (BMS) which will help keep the battery safe, such as from discharging too much, and then the battery will appear as if it is drained and not working until it is recharged. The BMS also helps from over charging a battery with too much current and-or too high a voltage. If cold weather is approaching, the lithium battery can be removed and stored in a warmer climate, and-or be sure it is charged up. Batteries can "self discharge" slowly, and if they are left sitting too long, their voltage will go so low that the BMS will refuse to begin charging them, and so it is best to maintain the lithium batteries at no less than 50% of its total charge state or greater. Fully charge the batteries when possible when they are in use.

Note that an automobile and-or some electric motors require a high amount of power and-or torque to start the engine, and this requires a high amount of current so as to produce a high magnetic field having much power to rotate that high power electric motor which will "turn-over" or start a gasoline engine or electric motors for an electric car. These **starter batteries** must have what is called as a high amount of **"cold cranking amps" (CCA)**, and can start a petrol (ie., oil or gasoline) engine in cold weather, say at -20°C, and even so, this battery should only be charged when the temperature is above freezing. A typical, average sized car engine will require about 350 CCA (ie., 350A) to start, and larger engines will require about 1 amp more per cubic inch more in engine volume. Note that the rated volume of an engine is usually only for the volume of the empty cylinders in that engine, hence combustion related volume only, and not the engines total volume. These batteries have large internal plates and can then supply a large amount of that current and-or power very quickly, however, they cannot maintain that amount of current or charge being drawn for too long, and the maximum time rating of that current is for about 30 seconds. Then if the vehicle (car, etc) combustion engine has started, that battery can then be automatically recharged by the electricity generator ("alternator") that gets mechanically powered by the engine.

A COMPUTER PROGRAM TO FIND THE AVERAGE VALUE OF ANY CURVE

```
/* AverageValueOfAnEquation.c

   The example equation shown below is "hard coded" (ie., explicitly, constant), here as a parabolic or
   second-degree quadratic equation, and can be changed for any equation you need.

   This method will find the average of y=x^2,  between the user settable upper and lower "bounds" or
   limits of x1 and x2.

   N sample values will be taken and summed together, and then divided by N.

   When the limits are between x=0 and x=1, the average value of y = x^2 is 0.33333...
   This is the case whether the curve is increasing from x=0 to x=1 or decreasing from x=1 to x=0.

```

BASIC CONCEPTS OF INTEGRATION

In the topic of calculus, there is a concept called integration. The basic meaning of integration is the summing of all the small parts so as to find the whole thing of which it came from. In calculus, the small parts are actually infinitesimally (as small as possible) small parts. This discussion and notation below is meant to be very basic so as the reader can gain at least a minimal understanding and to research the topic further if needed. If needed, you can review the topic of Understanding Basic Calculus shown previously in this book.

If given variable x, all the small bits of x are theoretically the infinitely small change or "differentials" (ie., a difference) of x = (dx), and will sum to that variable of x, regardless of any actually value of x. We can consider dx as like a very small first dimensional length amount and is equivalent to a very small change, piece or bit of the entire x or length that is infinitely long, and if each is identical and having a theoretical infinitely small size:

Sum of all the small bits of x = x1 + x2 + x3 + **. . .** = dx + dx + dx + **. . .** = S dx = S 1 dx = x :S means summation
an alt. expression: S 1x^0 dx = x or integration

When the summation symbol does not have any indication of the bounds (boundary) or limits of the summation, it is considered an indefinite, undefined or a general summation and which basically means a complete, full, or infinite summation of all the small parts. When the limits of the summation are indicated, the integral is called a limited, definite or defined integral. Here is a helpful pseudo-example of both integration and the notation used:

1 brick = Sum of all of its grains of sand : for practical purposes, any grain cement substance is not considered here

weight of 1 brick = Sum of the weight of all its grains of sand

weight/brick = S of weight of each piece of sand , If the weight of each same piece of sand is or averages about 0**.**001g and if the sum weight of each brick is 2kg:

$\frac{2kg}{brick}$ = (**n**umber of grains of sand) (0**.**001g) , mathematically , the **n**umber of grans of sand in 1 brick is (2kg / **b**rick) / 0.001 = (2000g/**b**) / 0**.**001g = (20)(10^5) grains / **b**
Expressing the indicated product with summation notation:

weight g = $\underset{x=1}{\overset{x=n}{S}}$ (0.001g) : Here, (0**.**001g) is a constant for the weight of any amount of bricks considered.
: x = term and-or grain number, and (n) is the number of grains of sand considered

If y = a function of (x) = f(x), its derivative with respect to the (x) variable is noted as: y ' = f ' (x) = (dy / dx) = d f(x) / dx .

(dy / dx) represents the (infinitely small) instantaneous rate of change of (y) with respect to (x), and when (x) changes by an infinitely small value. (dy / dx) is mathematically either a constant such as for a linear equation or a derived equation from the given function. In short, a derivative actually represents the slope value of the curve or function at a specific value of the independent variable, location or point, and is therefore is the instantaneous rate of changes in the variables or can be thought of as the equal the instantaneous slope (m), of a very small line segment, at one point on the curve..

$\frac{\text{(instantaneous change in y)}}{\text{(instantaneous change in x)}} = \frac{dy}{dx}$ = derivative = f'(x) = instantaneous slope , mathematically:

(dy) = (derivative) (dx) : though (dx) is a theoretical constant equal to an infinitely small value, we see that (dy) is not and (dy) depends on the product indicated

dy is an infinitely small part of (y) = f(x). The sum or integral of all these small parts of (y) will therefore equal (y) = f(x):

y = f(x) = S dy = S (derivative) dx = S f'(x) dx

Area Under The Curve Of A Function And Between The X-Axis

Given a function and its curve, integration can be used to find the area beneath that curve (See the figure below.) which is bounded by that curve and the (x) or independent variable axis. Since we are not finding an infinite area, but rather a much smaller, defined, definite, limited, or bounded portion along the (x) axis, we will indicate (ie., notation, express) this with "boundary" or "limit" numbers next to the summation symbol. The upper or higher value or limit of (x) will be placed higher near the S symbol, and the lower or smaller value of (x) will be placed lower near the S symbol. Here is a notation for the rectangular Area (theoretically, length times width) that is defined or bounded by the curve and the (x) axis between the values of x=a, and x=b, and it is an example of a "definite integral" with a specific result or sum rather than a generalized integral, sum or result:

First: $y = f(x) = A$, and which could be expressed as A(x) since A is a function which depends on (x). Ex. A=x^2

$$\frac{dy}{dx} = \frac{d(\,f(x)\,)}{dx} = f'(x) = \text{derivative} = \frac{dA}{dx} \quad , \quad \text{mathematically:}$$

$$d(\,f(x)) = f'(x)\,dx \quad , \quad \text{and since } A = y = f(x):$$

$$dA = f'(x)\,dx \qquad \text{summing (S), all these infinitely, and infinitesimally small bits:}$$

$$y = f(x) = A = S\,dA = S_{x=a}^{x=b}\ f'(x)\,dx = \int_{x=a}^{x=b} f'(x)\,dx$$

: The area will have the same units as those of (x) or some other variable being integrated. The term(s) being summed is formally called the integrand.

In the above notation, each bit of Area is an infinitesimally small rectangular area (dA), and each with a base or width of (dx) and a corresponding height of y(x) = f(x).

Area = A = (base)(height) = Sum of each small rectangular, differential area = S dA

For each (dx) or small base length of the small portion of the Area, hence dA and which is not a constant value, (dx) is defined as an infinitesimally small constant value. but the specific, actual or corresponding value of (y) is not defined as a constant value, and is actually variable in value, and essentially is the corresponding value of the function using a specific value of (x), hence the (y) value of the function at that specific value of (x), hence y at f(x) = y(x) = f(x), and the result is the (variable) height of the curve above the (x) axis at that point.

The derivative of a function is the rate of change of (y) with respect to a change in (x) when the change in (x) is infinitesimally small in value, and therefore, the corresponding change in (y) will also be infinitesimally small and it is generally and symbolically not equal to the same value as the change in (x), and this is due to the specific functional equation and relationship of (x) and (y).

Given y=f(x) = "y equals a function of x" (ie., y, the output or result, depends directly upon the value of x and the equation it is in) below is some notation for: "the derivative of y with respect to x", and since the changes are infinitesimally small, unlike that when finding a general slope value, it is more properly spoken as: "the differential of y with respect to the differential of x":

$$\frac{d\,f(x)}{dx} = \frac{dy}{dx} = \frac{\text{change in y --> 0}}{\text{change in x --> 0}} = y\,' = f\,'(x)$$

: notation for the derivative of the function of (x) with respect to x, the independent variable. It is a constant or an expression for the point to point (on the curve of the specific equation, or instantaneous rate of change of (y)=f(x) with respect to (x). Mathematically:

$d\,f(x) = \frac{dy\,dx}{dx} = dy = f'(x)\,dx$: the product of the derivative of the function and the infinitesimally small change in (x) or dx is equal to a differential of the function. The sum of differentials, dy, of a function is equal to that entire function: f(x) If this sum is limited or bounded, the result is not equal to that function, but rather is essentially a defined, limited or bounded area.

Notice that: $dy = f'(x)\,dx$ has the form of a linear or line equation:
$y = m\ x$, and $m = y / x$ = the slope or rate of change of y with respect to a change in x, and:

The sum of all the small bits of y will equal that entire function:

$S\,dy = y = f(x)$, and $S\,dy = y = f(x) = S\,(\,f'(x)\,dx\,)$: as shown above.

$dy = f'(x)\,dx$ = (derivative of the function) dx Note : $\frac{dy}{dx} = \frac{d\,(f(x))}{dx} = f'(x)$ = derivative

Given that: $S\,dy = y = f(x) = S\,(\,f'(x)\,dx\,)$, this clearly shows that to solve for the sum of all the differential bits of the function, we need to take the anti-derivative of the derivative, so as to have the original function = f(x) or= which may be expressed with the notation of F(x) = anti-derivative. Also:

First remember that : d(value) = a very small or instantaneous amount, bit or "differential (amount or value)" of the stated value, and do not consider this as the derivative of a value or function which is actually the value of: dy / dx = d(function) / dx . A differential is actually a very small instantaneous value and should be considered as a constant value for a given function, and not variable in value.

$y = S\,dy = f(x) = S\,(f'(x)\,dx) = S\,(\,(\text{derivative})\,(dx)) = S\,\frac{dy}{dx}\,(dx) = S\ dy = S\,f'(x)$

Also consider: $\frac{dy}{dx} = \frac{d\,(f(x))}{dx}$ = (derivative) , then $dy = \frac{d\,(f(x))\,(dx)}{dx} = d\,(f(x))$

$dy = d(f(x))\,dx = (\text{derivative})(dx) = \frac{d(f(x))\,(dx)}{dx} = d(f(x))$, by summing both sides:

$S\,dy = S\,d(f(x)) = S\,(\text{derivative})(dx)$
$y = f(x)) = S\,(\,(f'(x))\,(dx)\,)$: Shows f(x)) is both the result of the summation and the anti-derivative of the function: f'(x).

$S_{a}^{b}\ f\,'(x)\ dx$ = Area between x=a and x=b = F(b) - F(a). If a=0, F(x) = F(0) = no Area, and Area = F(b)

It could also be said that this bounded or defined area is the difference in areas from or bounded by: ((x=0) to (x=b)) and is the area between or bounded by: ((x=0) and (x=a)).

Consider a line, y=x , with an infinite number of infinitesimally small line sentiments, piratically points side by side. Each segment is a "differential" of that line with a value of dx. The sum of all these segments is that entire line: $x = S\,dx$. If we want to just consider the length of only a portion of that line, hence the length of a line segment (with a length that could be thought of as a multiple of dx, and yet not the full line x), we need to also limit the sum between two selected or boundary values of x, such as x=a and x=b:

length of line from points x=a to x=b = $x_{x=a}^{x=b}$ = x_{a}^{b} = length of bound portion of that line = a line segment

$x_{x=a}^{x=b}$ = (limited multiple of)(dx) = xb - xa : the length of the line segment is the difference between (b) and (a) which is the difference between the upper and lower limiting values.
From: **(a) + distance = (b)** , **distance = (b) - (a)**

x_{a}^{b} = (limited multiple of)(dx) = S_{a}^{b} 1 (dx) = S_{a}^{b} x^0 (dx) = $x\hat{\ }1_{a}^{b}$ = (x^1=b) - (x^1=a) = $x_b - x_a$

= (x at b) - (x at a) = (x=b) - (x=a) = x(b) - x(a) = y(x=b) - y(x=a) = y(b) - y(a)

Also note that: y = f(x) = x = S dx = x^1 = S x^0 dx : x^0 is a constant value of 1, and is the derivative of x^1, and x^1 is the antiderivative of x^0. (dx) becomes automatically included into the sum, and here the sum is x^1

Given a derivative of a function, this is noted as: y ' = f '(x) . When given a derivative, noted here as y ' or= f '(x) , we can find the original function (F) from which this derivative was derived out from.

Consider that F represents a function and its derivative is the function: y=f(x). F is the notation for the anti-derivative of y=f(x). In more symbolic form: F is the anti-derivative of its, or a given, derivative.

The derivative of F is therefore equal to:

d F / dx = F '(x)

In short, the derivative of the anti-derivative of a given function is equal to that same given function.

The derivative of y=f(x) with respect to x is: y' = f'(x) = dy/dx . Given the derivative equation = dy/dx, the antiderivative of this is y=f(x) which is the original given function.

In the notation shown being summed or integrated, all the bits of the derivative of a function which is f '(x) = y '(x) will sum to Y = F(x) which is the "whole thing", the "whole function" and not just a "bit of the function", and it is also the anti-derivative function of the function being integrated.

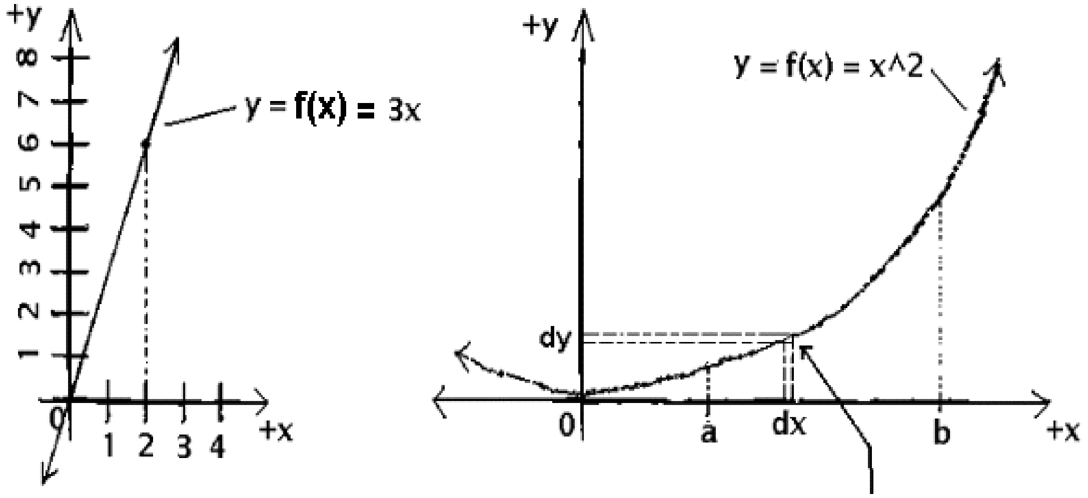
The area (A) beneath both the bounded curves of a line and parabola will be developed below.

In the graphing of the parabola curve on the right, the area (A) to be found is indicated as defined, limited or bounded by the lower bound value of (x=a) and the upper bound value of (x=b). An infinitesimally small "slice" or "differential area" (dA) bounded by dx which is a very small change in (x), and the height=y at that value of (x) is indicated within the total area being found.

Now considering the line graph. The area being found is triangular and is easy to see that it is bounded by (x=0) and (x=2) as the triangles base, and having a height that is equal to: y(2) = f(2) = 3(x) = 3(2) = 6. The area of this triangle is:

At = $\frac{\text{(base)(height)}}{2} = \frac{(2)(6)}{2} = \frac{12}{2}$ = 6 square units

[FIG 275]



Essentially a very small right triangle wth sides (dx) and (dy), and -or a very small (hypotenuse) line with the slope of = (dy) / (dx) at that point, and which is the derivative of the given function, here: x^2

Before proceeding, first notice that for the line, that the slope value = m = dy/dx is a constant value anyplace on that curve (here a line), and that for the parabola curve, dy/dx is not a constant value and is actually an equation. dy/dx is called the derivative when the changes are infinitesimally small and considered at a single point of the curve.

Given this equation of this function (f) = y = f(x) = 3x, and if the derivative of some other function is 3x, that function (F) is:

$$F = \frac{3x^{(1+1)}}{(1+1)} = \frac{3x^2}{2} \quad \text{or=} \quad 1.5x^2 \quad : F(x) \text{ is the anti-derivative of } y = f(x) = 3x$$

We can take the derivative of this function = F as a check:

$$F'(x) = \frac{dF}{dx} = \frac{d}{dx}\frac{3x^2}{2} = \frac{(2)\,3\,x^{(2-1)}}{2} = \frac{6x^1}{2} = 3x \quad : \text{checks}$$

Just for some extra completeness, the derivative of the line equation of: y = f(x) = 3x is:

$$y' = f'(x) = \frac{dy}{dx} = \frac{d\,f(x)}{dx} = \frac{(1)\,3x^{(1-1)}}{1} = 3x^0 = 3(1) = 3$$

: the derivative of a line is a constant, and is equal to the slope=m of that line.

Now consider:

$$f(x) = 3(x) \quad \text{and} \quad F(x) = \frac{3x^2}{2}$$

The derivative of: $F(x) = \frac{3x^2}{2} = 3x = f(x)$: $F'(x) = d(F(x)) / dx = f(x)$: F(x) is the antiderivative of f(x)
f(x) is the derivative of F(x)

A(a to b) = A(x=a, to x=b) = A(x=b) - A(x=a) = Ab - Aa : The bounded area is equal to the difference of two areas

Area of a thin section or slice of the bounded region = A slice = (base of slice)(height of slice) = (dx) (y value at that location of x), however, since y=f(x)=A itself, we would then be trying to multiply (dx) by the entire area (A), and we rather just need an infinitesimal amount of y=f(x) = A at a time, and this value is dA, then sum all these "differential areas" bits:

A slice = dA = (dx)(dy) , dy = dA / dx = A'(x) = f'(x) , The antiderivative of A'(x) = A = y = f(x)

A = Area of all the "differential areas" = dA, and if A found by summing (S) all these (dA):
A = S (area of each slice or differential area) = S dA

y = f(x) = A(x) = S dA = S (dy)(dx) = S f'(x) (dx) = F(x) = Y or = y = f(x) : F(x) is the antiderivative of f'(x) = A'(x)
F(x) = A

Let a limited value of being determined A = the summed area of all the area slices from x=(0 to b) =

$$A_a^b = S_a^b\ dA = S_a^b f'(x)\,(dx) = A_b - A_a = F(b) - F(a)$$

: the Area is limited so as to have a definite sum or integral, rather than an indefinite result of just the function itself. (a) and (b) are the limits or bounds of the summation of the differential areas where each is dA. This general expression is sometimes called the **Fundamental Theorem Of Calculus**.

Another way to consider or look at the derivation and meaning of all this:

$$y = f(x) = \text{function1} \quad , \quad \frac{d\,f(x)}{dx} = \frac{dy}{dx} = (\text{derivative of function1}) = \text{function2}$$

: function1 is the anti-derivative of of function2

y = f(x) , and dy / dx = d (f(x)) / dx = f'(x) , and therefore, mathematically:

dy = d(f(x)) = f '(x) dx : f(x) is the anti-derivative of f '(x) , after integrating (ie., S) each term, we find:

S dy = S d(f(x)) = S f '(x) (dx) , and these terms sum to:

y = f(x) = f(x)

$$\text{Area} = F(x) = Y = S\,dy = S_0^x\ (dx)\,(\text{derivative of function1}) = S_0^x\ f'(x)\ (dx)$$

Note that the infinite sum of all the (bits of x) = S (dx) = (x). To help understand this, consider all the infinite, infinitesimally small line segment lengths or bits (or infinitely small line segments) of a line, and which when put, added, joined or combined together, they will sum up to or create that whole (infinite) line. This was shown previously in this topic.

If we consider the function = f =3x as a derivative of another function = F, then F is the anti-derivative of 3x which is equal to: F = (3x^2) / 2

$$S_{0}^{b}\ f'(x)\,(dx) = S_{0}^{b}\ 3x\ dx = D_{0}^{b}\ \frac{(3x)(x)}{2} = D_{x=0}^{x=b}\ \frac{3x^2}{2} = \frac{3(b^2)}{2} - \frac{3(0^2)}{2} = \frac{3(b^2)}{2} \quad \text{or}= 1.5\,b^2 \quad : D = \text{difference}$$

For the example above when b=2, the area beneath the curve of $y=3x$, from $x=0$ to $x=b=2$ is:

$$\text{Area} = \frac{3(2^2)}{2} = \frac{12}{2} = 6 \text{ square units}$$

For another example, the area beneath the curve of $y=3x$, from $x=a=1$ to $x=b=2$ is:

$$\text{Area} = \frac{3(2^2)}{2} - \frac{3(1^2)}{2} = 6 - 1.5 = 4.5 \text{ square units}$$

For the parabola curve of $y=f(x) = x^2$, Its anti-derivative is: $F(x) = \frac{x^3}{2}$, and for the area beneath this curve curve, bounded by (b) and (a) and the (x) axis:

$$\text{Area} = S_{a}^{b}\ (dA) = S_{a}^{b}\ f'(x)\,dx = F_{a}^{b} = \left.\frac{x^3}{2}\right|_{x=a}^{x=b} = F(b) - F(a) = \frac{b^3}{2} - \frac{a^3}{2} = \frac{b^3 - a^3}{2} \quad \text{: with square units of the (x) axis.}$$

If the limits were: $x=a=0$ and $x=b=1$, the area beneath the function or curve of $y=x^2$ is:

$$\text{Area} = \frac{b^3}{2} = \frac{2^3}{2} = \frac{8}{2} = 4 \quad \text{: with square units of the (x) axis}$$

Ex. You are filling a 100 gallon container with a watering hose. The flow rate (gallons per hour = gal/hr) is constant and it fills the 100 gallon container in 5 hours. What is the flow rate:

$$\text{flow rate} = \frac{\text{volume of water}}{\text{time to move and-or fill that volume}} = \frac{V}{T} = \frac{100 \text{ gallons}}{5 \text{ hours}} = \frac{20 \text{ gal}}{1 \text{ hour}} \quad \text{: rate of filling}$$

From this data, we can mathematically derive a formula for the volume (V) of water in the container with respect to the time (T) variable:

Volume of water = volume = V = (rate) (Time) = $R\,T$: a linear equation with the rate = slope = m = R

$V_{gal} = (R)(T) = (\text{gal / hour})\ (T \text{ hours})$ and for the specific example above:

$100\text{gal} = (20\text{gal / hour})\ (5 \text{ hours})$

From the above equation, the derivative of Volume with respect to Time is:

First: V is a function of both (flow) rate and time. Here, the rate is a constant value of 20gal/hour, and then V becomes a function (relationship) of just the Time variable, and with the rate being a multiplier. Since the rate of change of one variable with respect to another is constant, the equation for V is a linear equation. Expressing V as a function of Time:

$V= f(T) = R\,T^1 = (20\text{gal/hour})\ T^1$

By knowing how to take derivatives as shown previously in this book:

$\frac{dV}{dT}$ = R = (1) (20gal/hour) T^(1-1) = (20gal/hour) T^0 = (20gal/hour) : a constant

If just given the above derivative equation, or constant flow rate with respect to time, we can integrate that constant or equation so as to find the volume equation of which it is from.

First note mathematically from the above expression:

dV = (rate) dT = R dT : extra, since dV and dT are instantaneous values, so is the (rate) or derivative.

S (dV) = S (rate) (dT)

V = (rate) (T)

If the container had some initial volume; (+) of water or deficit; (-) of water, that can be included into the formula as an addition of this constant (C). This will only shift the curve of the volume equation in the vertical direction, and will not change the general shape (ie.. slopes and-or the rate of changes) of the curve This is also a more formal or complete way to write an equation. This initial constant has no affect on the flow rate, and only has an affect on the total volume at negative time vales before the start of time when it is considered as Th=0h:

V = (rate) (T) + C : checking, at T=0h, V = 0 + C = C, the initial or starting amount of water volume

The formula for distance is very similar to the above formula for volume.

distance = (rate) (time) = (speed) (time) = (velocity) (time) = D = V T

In the situation here, V = velocity, and not volume.

$\frac{d\,D}{d\,T} = \frac{V\,T\text{^}(1-1)}{1}$ = V T^0 = V(1) = V mathematically:

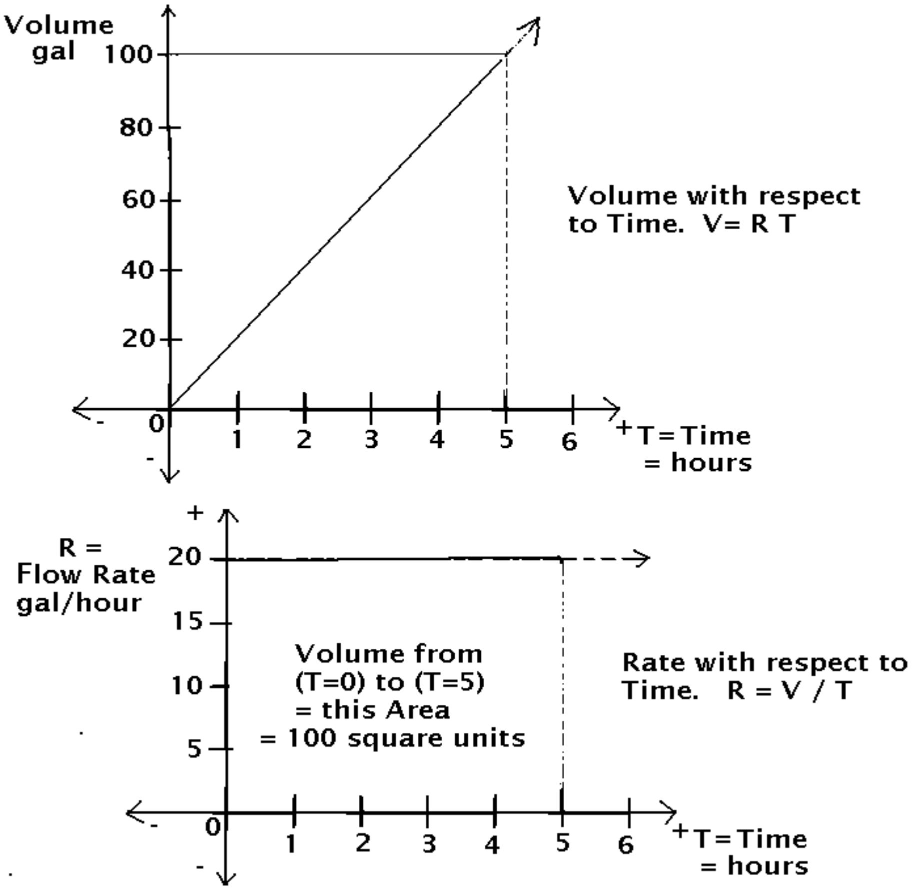
dD = (V) (dT)

S (d D) = S (V)(dT)

D = V T

See FIG 276 below.

[FIG 276]]



Area on the above graph = Volume of water = RT = (base)(height) = (5hr)(20gal / hr) = 100 gal

Above in the first image, consider R = V / T = slope of the line

A COMPUTER PROGRAM TO FIND THE AREA BENEATH A CURVE SEGMENT

```
/*******************************************************************************************************************
  AreaUnderACurve.c

   (c) JPA , April 2020

   This is a program to find the area beneath the curve of a function y=f(x) and the x-axis, and has a width
   that is bounded by a lower limit of (x=a), and an upper limit of (x=b).  This program uses a successive
   approximation method of summing up many smaller areas or thin, narrow "slices" or segments of area,
   and so as to find the total area by summing smaller areas.  This is a nice program to understand, and is
   very useful for when standard methods of calculus are not being used for some reason.

   Adjust the program as needed.  For example, since the function is hard coded or set fixed as:
   y = f(x) = x^2,  and this is essentially a simple parabola curve and you will have to change it if you want
   to use other functions and their curves.

*************************************************************************************************************/

double findarea(double lowerlimit_a, double upperlimit_b);

/************************************************************************************/
void main(void)
{

                  /* findarea(), function use example program:  */

double area=0.0;
double a=0.0;     /* lower limit of integration */
double b=0.0;     /* upper limit of integration  */

printf("\n\nThe function currently used in this program is:  y = f(x) = x^2 ");
printf("\n");
printf("\nInput a = lower x limit of integration: ");  scanf("%lf",&a);
printf("\nInput b = upper x limit of integration: "); scanf("%lf",&b);

if(a>b){
          printf("\n\aPlease use an upper limit that is greater than the lower limit.");
          printf("\nPress A Key To End The Program");  getch();  exit(0);
       };

area=findarea(a,b);

printf("\n\nThe approximate summed area is:  %lf square units.",area);
printf("\n\nPress a key");  getch();

exit(0);
};
/*****************************************************************************************/
```

```
/****************************************************************************************/
double  findarea(double lowerlimit_a, double upperlimit_b)
{
double area=0.0;
double a=0.0;
double b=0.0;

double dx=0.0000001;    /* Increment in the x variable , equivalent to the width of a
                                    slice of area .  Here, dx is hard coded as a constant, and
                                    you can use a smaller value for increased precision in the
                                    result.  This value will give about 6 digits of precision in the
                                    result.   Use a smaller value for more precision.

                               An option is to let the user enter this dx value, OR: modify the
                               program to let the user enter the number of slices, steps, or
                               increments, and then dx can be found from that as for example:
                               Instead of the user entering 0.001 for dx, the increment in x, the
                               user can enter 1000 for the number  of steps or slices of area,
                               and steps would also essentially be a loop counter variable.

                              dx = (upperlimit_b  -  lowerlimit_a) / steps
                              steps  =  (upperlimit_b  -  lowerlimit_a) / dx                              */

double y=0.0;            /* y = f(x) = equivalent to the height of a slice of area */
double x=0.0;           /* current position along the x axis during the summation process */

x=lowerlimit_a;      /* let's start x and the summing at the lower limit */

for(;;){                 /* successive approximation, summing loop        */

             y = x * x;         /* the hard coded function of the curve of which the
                                    area beneath it ant the x-axis is being found.
                                    here: y = f(x) = x^2  and is C coded as:   x * x    ,  if something like
                                    y = ax^2 = a * (x * x) is used, the result or area will be a factor of (a) times more. */

            if(y<0){ y=y*(-1.0); };  /* make y always positive, since area is always a positive value: */

            area = area + (dx * y);    /*  Summing each slice of area to the total accumulated area.
                                                  (dx * y) is analogous to:  Area slice = (width) x (height) */

            x=x+dx;         /* incrementing (x) by the value of dx , and so as to have a new value of (x) for the loop */

           if(x>=upperlimit_b){ break; };    /* break from the summing loop */
        };

return area;
};
/******************************************************************************************/
```

Use ex.: If 0 and 1.0 are input, the result is 0.3333...   : square units = units^2
Use ex.: If -1 and 1.0 are input, the result is 0.6666... : hence twice as much due to the symmetry of the parabolic curve
Use ex: If 0 and 2.0 are input, the result is 2.67

A COMPUTER PROGRAM TO FIND THE ARC LENGTH OF A CURVE SEGMENT

```
/**********************************************************************************************
  ArcLengthOfACurve.c

   This coding is mostly based on the algorithm found in the program
   AreaUnderACurve.c program that is shown in this book.

   (c) JPA,  Dec 11, 2021,

  This is a nice program to understand, and it is very useful for when standard
  methods  of calculus are not being used and-or not known such as for
  when a difficult equation(s) is involved.      This is  very handy when the
  anti-derivative is difficult to find when using a standard calculus method.

   Basically, this is a form of integration by summing up many small distances
   along the entire (arc) length of the curve that was bound or delimited by limits.
   In the sample use program below, the function or curve is y=f(x) = mx, a linear
   or line equation,   and the limits or boundary section or definition, are from x=a
   to x=b.

*********************************************************************************************/
#include "stdio.h"
#include "math.h"    /* : if needed, such as for sqrt(number) and pow(base, exponent */
#include "stdlib.h"   /* : for system() */

double findarclength(double lowerlimit_a, double upperlimit_b, double a);
/*  This program currently uses a hard coded, or constantly defined
     function, y = f(x), and of which needs to be changed for other equations.
     The specific function used is for a liner or line function. */

/*********************************************************************************************/
void main(void)
{
/* Function use example program:  */

double a=0.0;   /* here the slope (m) of the line function:  y = f(x) =ax = mx   */

double x=0.0;

double x1=0.0;      /* : for point1 on the curve, coordinates = p1(x1,y1);  */
double y1=0.0;
double x2=0.0;      /* : for point2 on the curve, coordinates = p2(x2,y2);  */
double y2=0.0;

double distance=0.0;  /* distance between two points on the curve */
double arclength=0.0;      /* total sum of distances = arc length */
int n=0;

x=lowerlimit_a;    /* : let's start the value of x, and the summing, at the lower limit */
```

```
for(;;){
        x1=x;

        y1 = (a * x1);    /* : 1:  The hard coded function of the curve of which the
                                   area beneath it ant the (x) axis is being found.
                                   here: y = f(x) = ax + b ,   and is C language coded as:
                                   (a)( x) + 3   , for a linear equation, b shifts the entire curve
                                   vertically, and the arc length still remains the same, hence
                                   its not used here.  */

        /* : Now we have the first point's coordinates , p(x1,y1) */

                         /*  Three other example functions to consider, and the arclength() should be rewritten as needed,
                             in particular, for any arguments needed to be sent to this function:  */

                        /* 2:   y1 = a * (pow(b,x1));     : such as for an exponential function:  y = (a)(b^x),
                                   and the user could first input the base value (b) and multiplier (a).  */

                        /* 3:   y1 =  sqrt((a * a) - (x1 * x1));     : such as for a circle function:  r = x^2 + y^2 ,
                                   and the user could first input the radius value (r).   */

                        /* 4:  For an ellipse:  This will give 1/4 of the perimeter depending on the limits, hence multiply by 4:

                                    y  = +-  b  \/  1  -  _x^2_          : Note that when x=0, y= +-b as should be expected, and
                                                           a^2

                                    y1 =  minoraxis * sqrt( 1 -  ((x1 * x1) / (majoraxis * majoraxis)) );   */

       x2 = x1 + dx;    /* : increment x so as to find the next close point and its coordinates */

       y2 = (a * x2);     /* 1: Now we have a nearby, second point's coordinates  p(x2,y2)  */

                             /*  2:   y2 = a * (pow(b,x2)); */
                             /*  3:   y2 = sqrt( (a * a) - (x2 * x2));  */
                             /*  4:    y2 = minoraxis * sqrt( 1 -  ((x2 * x1) / (majoraxis * majoraxis)) );   */

        /* For the distance between two close, successive points on the curve:
           This uses the standard distance equation, for the distance between two points on a plane:
            distance = sqrt ( (change in x)^2 + (change in y)^2 )
            In theory, for two very close points, this is an infinitely small distance value
            for that segment or portion of a curve between x1 and x2:                              */

        distance = sqrt( (x2 - x1) * (x2 - x1) + (y2 - y1) * (y2 - y1) );   /* : this is similar to:   hypotenuse = sqrt (x^2 + y^2)  */

        arclength =arclength + distance;  /* : add each distance value to the total distance called arclength */

         x = x + dx;    /* : incrementing x by the value of dx, so as to get the coordinates of the "next point" on the curve */

        if(x>=((upperlimit_b - dx))){ break; };
    };

return arclength;
};
/*****************************************************************************************************************************/

[This space for book edits.]

BASIC CONCEPTS OF VECTORS AND RESULTANT FORCES AND MOTION

Consider an airplane or other object ascending or descending in the sky. For detailed scientific analysis, the airplane can be considered as having two basic types of motion; a horizontal motion and a vertical motion. Each motion has a velocity (ie., speed) and direction. More specifically, it will have both a horizontal (ie., "x") velocity or speed, and a vertical (ie., "y") velocity or speed. These two types of motions can be considered separately over time so as to find a change in either the horizontal or vertical distances traveled. These two motions can also be combined or summed into one resultant (ie., true, actual, apparent) motion that is often called the resultant or effective velocity and direction. These two basic or component motions with both having a magnitude (ie., size) and direction are formally called **vectors**, and their combined or summed vector is called a **resultant vector**. A resultant vector can be considered as the effective vector of several other vectors. Since a plane generally does not just go vertically and-or horizontally upon landing or taking-off, the resultant direction or angle is someplace in-between the horizontal (0°) and vertical (90°) dimensions, and the plane will have a small angle or direction of ascending or descending between those two extreme values.

If an object such as a plane or ball has a horizontal velocity and direction, and a vertical velocity and direction, the resultant velocity and direction is composed (ie., a combination) or determined by those two values, and the actual effective or resultant velocity and direction of that object will be between those two values, hence like an upward rise and-or downward decline.

If two or more forces are acting upon an object at the same time, there is a single, net, effective (as if, or equivalent to a single force or vector) or resultant force that would be equivalent to those two component or vector forces.

Ex. An object is being forced both rightward, and also leftward with the same value of force. The net or resultant force is obviously 0. We can assign direction to the forces using positive and negative signs. For rightward, we will use the positive sign, and for leftward, the opposite direction, we will use the negative sign which indicates a 180° rotation in the opposite direction. Expressing the combining of forces or vectors (have both a magnitude or value and direction) algebraically:

$$F1 + F2 = Fr$$

: General equation for the sum of forces. The forces can have any sign.
Fr = resultant force.

$$+F1 + (-F2) = Fr$$

Since the magnitude of F1 = F2, and using substitution:

$$+F1 + (-F1) = Fr$$
$$+F1 - F1 = Fr$$
$$0 = Fr$$

Since the resultant force is 0, the object will not have any motion due to F1 and-or F2. Even though there is no effective or resultant force that causes a motion for the object, the object can also be considered as being (somewhat, depending on the material) compressed (like a spring) by those forces acting upon or applied to it.

If F1 was 3, and F2 was -5, the resultant force is:

$$F1 + F2 = Fr$$
$$3 + (-5) = Fr$$
$$3 - 5 = Fr$$
$$-2 = Fr$$

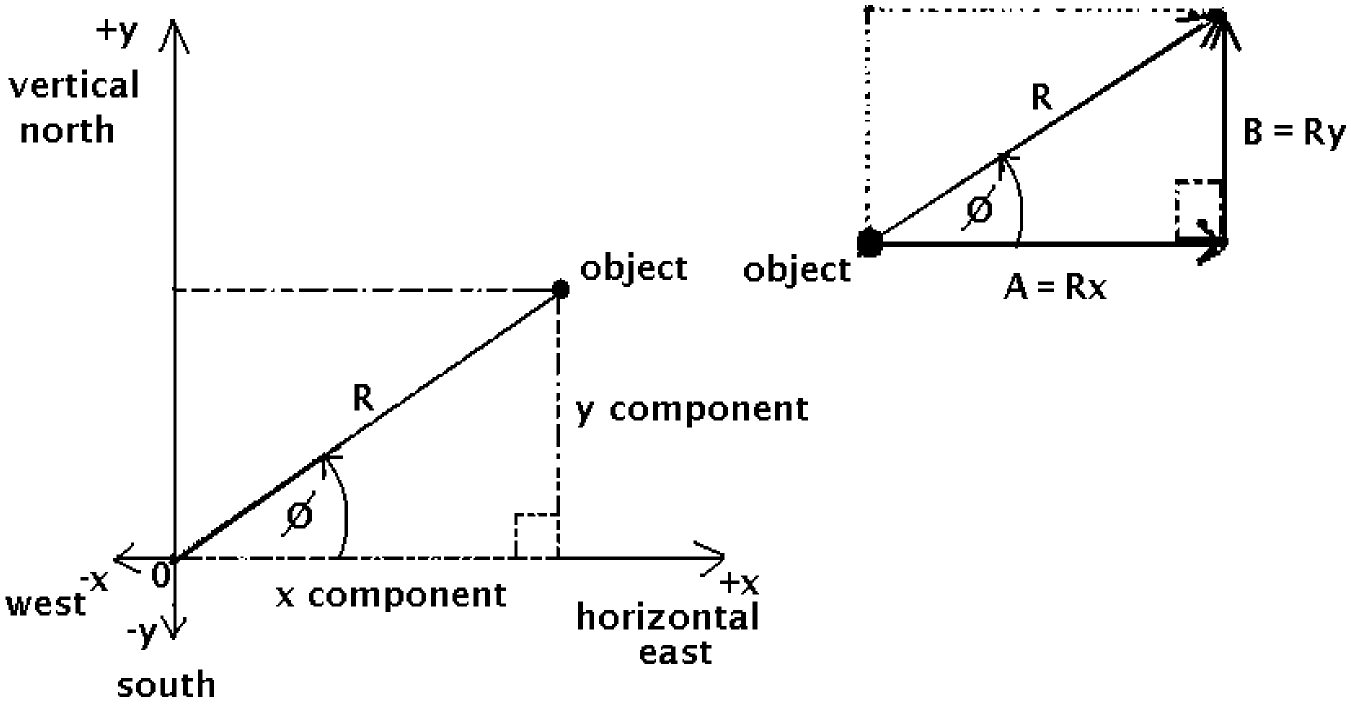
: the object will resultantly or effectively have a force of 2 applied to the object into the leftward direction.

Vectors may be noted (notation, indicated, expressed) as the variable identifier with an arrow "directional" line over it and which does not necessarily indicate the direction of that vector:

Ex.: $\overrightarrow{F1} + \overrightarrow{F2} = \overrightarrow{Fr}$

The following drawing shows two common and fairly similar methods to visualize several component (or "dimensional") vectors and their corresponding effective or resultant vector. The one on the right is generally the methods used to

visualize force vectors acting upon an object, and the resultant (R) force and direction is shown. The length of the vectors indicated by lines and directional arrows is proportional to the magnitude (size, value, amount) of that vector. This method of showing the resultant is often called the "head to tail" method, where one vector starts at the head or arrow of the previous one. The method on the left is very similar and is typically called the rectangular method and it produces the same resultant. Another vector summing method is called the "parallelogram" or "tail to tail" method which starts two vectors at the same position and considers these 2 sides of a parallelogram, and the complete 4 sided parallelogram which often looks like a slanted rectangle, is then drawn. The diagonal in the parallelogram from the starting point is the **resultant vector** that represents the resulting or effective magnitude and direction of something. [FIG 277]



R=real or resultant vector

If A and B are vectors, the resultant (R) vector is the sum of those two vectors. In vector notation form this is expressed as:

$R = A + B$: a special vector expression or notation form for the sum of two vectors. It is incorrect to sum their magnitudes for the resultant magnitude of the resultant "summed", combined, output vector or result.

From the study of trigonometry:

$\sin \text{¢} = \frac{y}{R}$ and $\cos \text{¢} = \frac{x}{R}$

$y = R \sin \text{¢}$ $x = R \cos \text{¢}$

If x and y are two component or vector forces acting upon the object:

$Fy = R \sin ¢$ and $Fx = R \cos ¢$

In a reverse type of manner, if you were given the two component vectors, you can derive the resultant vector:

$\tan ¢ = \frac{\text{opposite}}{\text{adjacent}} = \frac{y}{x}$ and $¢ = \arctan(\tan ¢)$

$R = \frac{y}{\sin ¢} = \frac{x}{\cos ¢}$

$R = \sqrt{x^2 + y^2}$: this has the form of the Pythagorean Theorem

Just as a point can be identified by two values: an x coordinate and a y coordinate, P(x,y), a vector or vector line on a graph is also identified by two values: a magnitude and direction. V(magnitude, direction), where direction could be an indicated angle, often with respect to the horizontal axis. When the direction of the vector is not explicitly given, it can be found from its horizontal (x) component and vertical (y) component vector as indicated above with the trigonometric, triangle or Pythagorean analysis.

Since each vector has a horizontal (x) component, the resultant vector's horizontal component will simply be the sum of those two horizontal components. Since each vector has a vertical (y) component, the resultant vector's vertical component will simply be the sum of those two vertical components. Expressing the notation of the combining or summing of vectors so as to find the resultant vector, and optionally including notation for when there are more vectors to sum or combine so as to find the resultant vector:

R = effective or resultant vector

Rx = effective horizontal component or vector of the resultant vector
Ry = effective vertical component or vector of the resultant vector

A and B are vectors

Ax = effective horizontal component or vector of vector A
Ay = effective vertical component or vector of vector A

Bx = effective horizontal component or vector of vector B
By = effective vertical component or vector of vector AB

$R = (\bar{A} + \bar{B}) = (Rx, Ry) = (Ax + Bx + \ldots, \; Ay + By + \ldots)$

In the above drawing, since Ay=0 and Bx=0 we then have:

Rx = Ax and Ry = By, and that A and B vectors are as legs or sides of a right triangle, and that the Pythagorean Theorem can be used to solve for the value of the resultant vector.

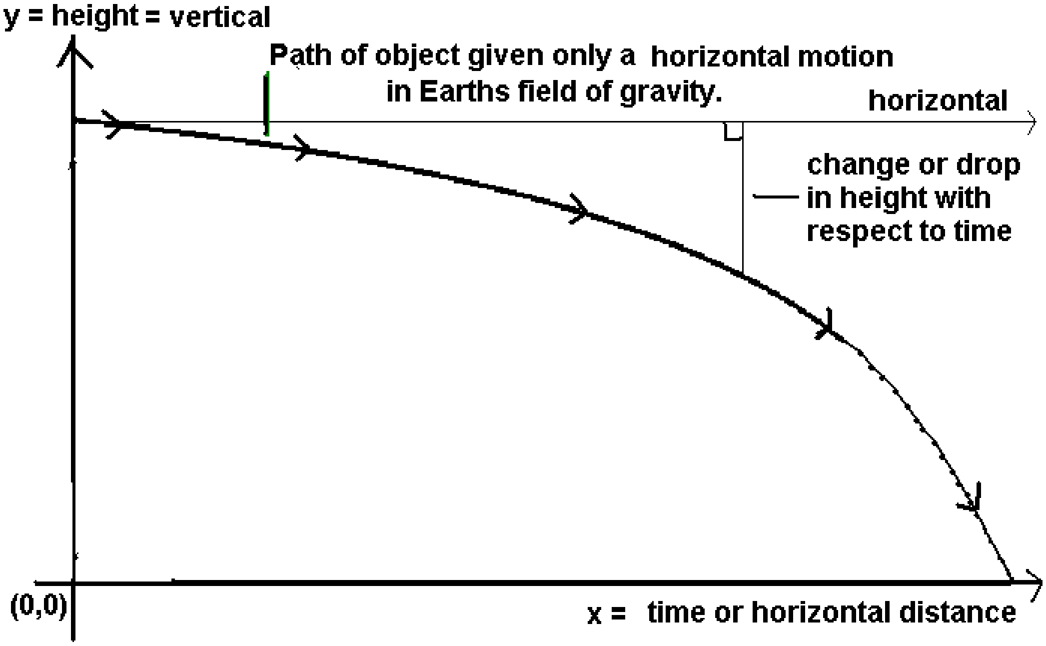
$R = \sqrt{(Rx)^2 + (Ry)^2} = \sqrt{(Ax)^2 + (By)^2}$

With this previous equation, we see that the (right-triangle) legs or component vectors of the resultant vector are the (vector) sum or resultant of all the horizontal component vectors, and then all the vertical component vectors of each individual vector.

A 3 dimensional or spherical reference and measurement system may use coordinates that are something like this:

point = P(radius distance to the point from the origin (0,0,0), horizontal or rotational angle on the x horizontal plane
from the x axis reference line, vertical angle above the horizontal plane from the origin vertex).
Ex. point(r=distance= 5m , 30° h , 45° v)
A linear or non-angular version for a 3 dimensional system was shown previously as: P(x, y, z)

Ex. A ball that is thrown across a field will have both a horizontal component of motion or travel due to the input energy applied to it, and a vertical component of motion or travel due to the force of gravity constantly acting upon it. Its path, locus or curve will be like that of a upside-down or inverted parabola due to that as time increases, its vertical velocity, here downward, is increasing with respect to time, hence it rapidly approaches the surface with respect to time. This increase in vertical velocity is due to that its vertical velocity (v = d / t = at) and acceleration (v / t) is related to a squared variable, here (s): a = g = 9.81 meters / s^2 = 9.81 m/s^2. In short, as time increases, its vertical velocity rapidly increases exponentially with respect to it, that is, the vertical velocity and time are not linear or proportional as would be for a linear relationship and-or equation. The horizontal velocity will remain the same, but it will get less or decrease at a very slow rate with respect to time due to the ball colliding with air and creating a drag force in the opposite direction to its travel where some of the kinetic energy of the ball will be transferred and-or lost to many air particles of which each then gains a small amount of that kinetic energy transferred to it. [FIG 277A]



A COMPUTER PROGRAM TO CALCULATE SOME STATISTICS OF DATA

This computer program will calculate some common statistics of numeric data stored as ASCII text strings in a text file (has the .txt filename extension, and contains readable ASCII text characters. If possible you may even create a program so as to enter numeric values and store, edit and-or append them in a text file. The text file can also be easily edited by nearly anyone, just like any text file. The data can always be edited and-or quickly reused without having to find, calculate, and-or reenter the many values again. In the following computer program, the statistics calculated for the floating point numeric data (ie., signed decimal values with or without a fractional portion) are:

1: Number of data values, elements, instances or samples
2: Average of the data values
3: Average Deviation of the data values
4. Standard Deviation of the data values

```
/*-------------------------------------------------------------------------------------------------------------------------------
DataStatistics.c

(c) JPA,  Aug. 2021

           This will read a text file for text segments that are strings of ASCII numeric values.  The program
            will calculate the average of those data values as:  (sum of values) / (number of values).

           The format of the input data file was kept as simple as could be so as to have a simple program,
           however you can always improve upon it, such as for allowing comments bounded by a delimiter
           character such as *, etc.

           The data is decimal values, separated by a space(s) or new line. The program is written so allow
           up to 10000 data values.

--------------------------------------------------------------------------------------------------------------------------------*/
#include "stdio.h"
#include "stdlib.h"
#include "math.h"     /* : for sqrt() */

/*-------------------------------------------------------------------------------------------------------------------------------*/
void main(int argc,  char * argv[] )
{
unsigned char c;
int n=0;
int t=0;
int e=0;
FILE *file1=NULL;
unsigned char filename1[1000]={ "\0" };      /* the file to either code or decode, the input file   */
double datavalues[10000];
double averagevalue=0.0;
double deviation=0.0;
double deviationsum=0.0;
double averagedeviation=0.0;
double standarddeviation=0.0;
double temp=0.0;
float  x=0.0;

system("cls");
```

```
fflush(stdin);

if(argc==2){ strcpy(filename1,argv[1]);      /*  arg[1] is the second real argument, and is the "input"
                                                   dragged and dropped (with the mouse,) file. */

                printf("\n\nINPUT FILE:  %s",filename1);   /* fflush(stdin);  getch();    test ok    ex.  mydatafile.txt   */
           };

printf("\n");

if(argc == 1){         /* : if no file entered on the command-line argument, and only the program name is an argument  */
             printf("\nPlease enter the text filename with the data values expressed as an ASCII text strings on each line: ");
             fflush(stdin);
            gets(filename1);
            };

/* This will  check if the file even exists */
file1 = fopen(filename1, "rt");      /*  : open the file for access, here reading in text mode */
                                      /* text mode is similar to a viewable screen output mode, where numbers and text are
                                         read and-or written to as readable strings of text characters, and not generally as
                                         binary numeric values such as for numeric data.    Also consider for example that
                                         in text mode, a n indicated (as a string of ASCII text characters) value of 100 will take
                                         three bytes: "1 =49,  "0"=48, and "0"= 48 , however in byte mode it will require only 1
                                         byte and it will be: 100 expressed in binary numeric form as 8 binary bits:  01100100 */
        if(file1==NULL){
              printf("\n\aREAD ERROR --- OR FILE DOES NOT EXIST.");
              printf("\n\nPress A Key To Exit This Program >");  fflush(stdin); getch();  printf("\n"); exit(1);
             };

            for(;;){       /* : a loop to get each number (here, actually a string of ASCII text characters) or data element
                                that is stored in the file  */

                    e = fscanf(file1,"%f",&x);

                     /* fscanf() is similar to scanf() to get keyboard read text input, but is for reading computer files,
                        reads formatted text data. This is a simpler alternative to using fgets() and then having to
                        use a function to convert the text string to a floating point numeric value.  If values are
                        not stored in text or string character, ASCII form in the file, but binary numeric values, then
                        the file should be opened for accessing in binary (pure byte) mode, instead of text mode.
                        Here is a similar example of how to access coordinate values of points stored in a text file
                        and having the format:  x-value , y-value    , and for example:   5 , - 4.2
                        The coding for this would be:        e = fscanf(file1,"%g ,%g",&x,&y);
                        The comma in the format specifier will cause a scan for a comma in between the text values.     */

                    if(e==(-1)){  break; };      /* : The eof = end of file, is a C language defined constant, and is often -1 */

                    printf("\n%g",x);             /* : opt. to display all the input data on the screen */

                    datavalues[n]=(double)x;     /* : store the read values from the file into the numeric

/* Use example:

   Here, the example or test input (plain, ASCII, with no formatting symbols or commands from a word processor) text file,
   as shown below is called (ie., its filename) NumericData1.txt, which contains the string or ASCII text form of the
   numeric data to use in the program.  In this way, a text file is being used as data storage that a program can use.
   A program can be made so as to input and-or create data files, and the data can be stored as numeric a values or
```

readable (and-or easily editable or creatable by anyone, even without the main program) ASCII text values which must then be converted to numeric values so as to be used by arithmetic in the (data) statistic program above.

If you want to make various notes or comments within the data file, you can delimit it or set it apart by using a special character such as * and then keep checking for this character and-or byte so as to find the start of the note or comment. You can then access each byte of the note or comment and build a text string with it if you need to display it, or to simply skip over it until the next * character is found, and then continue accessing the file data as normal.

```

A COMPUTER PROGRAM TO CREATE, SAVE AND LOAD RANDOM VALUES

```
/* -------------------------------------------------------------------------------------------------------------------------------------------------------
randomdata.c

A computer program to generate or make, view, save and load (store, write)
random byte, 8-bit  (0 to 255 decimal, a total of 256 values) or single byte values
to a file.  For this program,  each random byte value is only used once in the array
or list of values.

This minimal or basic C-program was created as an example of several useful
programming concepts which may be adopted, modified and used in other
programs.  If interested about computer programming, such as C-programming,
there are many book, articles, and even some courses available elsewhere.
Depending on what kind of program you are making, knowledge of some math
is a good application of, and can help with computer programming. Seek
assistance from others where necessary.  With just the basics of C-programming,
or any other computer programming language, many useful programs can be
created.  Just like any other topic, computer programming is fun, but can become
an endless cycle of learning and experimentation without a useful result, and
therefore, it is good to put what you know into useful computer program(s) or
ideas so as to have something actually useful to you and-or others.

The compiler used for this C source code program was:  TinyC Compiler

(c) JPA 2018

255  54
```

The average value of all the 256 data values shown above is: 127 , and this is approimately 256 / 2 =~ half of 256

The above data is what is printed or displayed on the viewing screen of the computer used. The binary data was converted to ASCII text characters to be displayed on the screen, but in the computer file or memory, the data is stored as binary values. For example, a (text) screen display of the number 1 is the ASCII text character coded as a binary value of 49d = 0011001b, however the (numeric) binary value for 1 is 00000001b and this is what is saved on disk or memory if it was stored as a binary value and not ASCII or "text values". A file can be opened (ie., for read and write access) in binary mode or text mode. When a data file contains readable characters it may be best to access the file in text mode, but this mode does some extra things such as converting a carriage return (ASCII 13) character to two bytes of data: a carriage return (ASCII 13) and line-feed (ASCII 10) characters, hence it automatically adds a byte to the stream of data. If this is not desired, then open the file in (pure, strict) binary access mode so as to access only the (exact) saved bytes of the file. fprintf() is the usually function for "text printing" to a file. For example a text string (ie. with the %s format specifier) can be printed to a file with fprintf(). If you want to first "build" a string, such as containing multiple variables, etc, one function you can use for this is the **sprintf()** function which will catenate (ie., string catenation, appending or joining) text strings together rather than use the strcat() function and other numeric to text conversion functions, such as itoa() to build a string. Once a string is built, it can then be displayed and-or saved to an opened text file, etc. This function essentially prints or sends the resulting output to a string instead of the screen as printf() would.

Ex. sprintf(mystring,"The Filename is: %s, and the number is %d",string1,n); printf("%s",mystring);

A COMPUTER PROGRAM FOR A COUNT-DOWN AND COUNT-UP TIMER

```
/* -----------------------------------------------------------------------------------------------------------------------
       timer.c

        Some measurements require the time or duration of an event or process.
      . Below is a program that has both a "count-down" and "count-up" timing
        options.  Several instances of these programs can usually be ran
        simultaneously on the same computer.  The precision of this timer is 1s,
        and accuracy is +,- 1s and it is good for many practical applications such
        as for cooking recipes, procedures and processes which require timing.

(c) JPA Feb 2018

A COMPUTER PROGRAM FOR A STOPWATCH TIMER

This is somewhat similar to a count-up seconds timer as shown in the last program: timer.c, but with this program shown below, it allows the user to pause and continue the seconds timer.

```
/*------------------------------------------------------------------------------------------------
stopwatch.c

   A timer with a user pause ability that is started at the press of a key,
   and ended at the press of a key, and then displays the elapsed time.

   (c) JPA September, 2021

  Extra:   A pseudo-type of code and-or steps so as to time a process
           such as a function, etc. is:

           1.  starttime=time(0);

           2.  Some process to be completed.

           3.  endtime=time(0);

           4.  total_seconds = endtime - starttime;

           5.  Display the number of seconds.

------------------------------------------------------------------------------------------------*/

#include "stdio.h"
#include "stdlib.h"

/*----------------------------------------------------------------------------------------------*/
void main(void)
{
unsigned long starttime=0L;

```

A COMPUTER PROGRAM TO ENTER AND DISPLAY A TEXT STRING

Below is a simple computer program (for a PC computer that runs .exe (executable, "runable", working, operational, ready, already compiled to the machine or internal processor code of the computer) data files which are computer programs for it. You can study it, and-or improve upon it, perhaps even writing your own string handling functions. There are computer programs in this book which show how to enter (ie., input, type in) and mathematically work with and-or display numeric values.

A "text string" is also known as a "string of text", repetition or array of text characters, one after the other in succession, and it essentially has the same structure as that of a sentence in a book. On a technical or advanced level of knowledge with computers, when entering and-or displaying numeric values, it is done by visually entering and-or displaying ASCII text characters (ie., a graphic or symbol for each) from the keyboard (the standard input) and screen (the standard output), and of which can then be converted to or from actual binary numeric values. Consider that letter or text character A has a (ASCII) code value of numeric 65. B is 66, and so one. These are small values and can be contained within a single byte (8 binary bits or digits in length) of memory which can hold equivalent decimal system numeric values from 0 to 255. Just the same, there are (ASCII) text characters codes for the text or graphic numbers of 0 through 9. Text character 0 is assigned the (ASCII) code number of numeric 48, and text character 1 is assigned (ASCII) code of numeric 49, and so on. If text character 0 was assigned an (ASCII) code number of numeric 0, this would interfere with the null character of 0 that is often used to signal the end of a string. Also the ASCII codes from numeric 0 to 32 are often used for "control codes" for the display and-or printer system. A sentence is an example of a character or text string. When you enter numeric value from the keyboard, it is entered and-or displayed as a series of individual ASCII text characters, such as keyboard or text characters 1, and then 5 and then 9, and these can be stored as a text string having the ASCII numeric codes of: 49, 53, and 57 respectively, and each can be converted by a premade, standard or built-in computer function so as to be a real binary coded number value that can be used mathematically such as an operand for a mathematical operations in your program.

```
/* -------------------------------------------------------------------------------------------------------------------------------
    StringExample.C

     This example program shows how enter and display a string (ie., several) of
     (ASCII encoded) text characters on the standard output or display (ie., the
     computer screen).  For example, a string could be a persons name, or a sentence
     to display.

    To get a single text character, the "get character" function:  getch() is one of the
    methods that be used.  A single text character is equivalent to a string length of 1.

   (C). J.P.A.  July 2021
---------------------------------------------------------------------------------------------------------------------------------*/

#include "stdio.h"      /* : where the functions used in this program are located in or at */
#include "string.h"
/*------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
int string1length = 0;
char c = 0;
unsigned char string1[129];        /* declaring an array to hold many values, here, the values of
                                      displayable, or entered text characters */

                       /* : above, declares an array (ie., multiple) of char (ie., 8 bit, byte) data type,
                          and the computer will allocate and set aside the amount of memory
                          necessary for it, which can be calculated as:
```

```
                    total memory needed =
                       =  (data size in bytes per element)(number of elements)

                    Here, the memory allocated is 129 bytes, with 128 being
                    used to hold a string, and 1 byte for numeric 0 which is
                    a byte value set to numeric 0,and not ASCII text character 0
                    which is assigned a code value of 48.

                    An unsigned numeric data type indicates that numeric values are to be
                    stored there as an unsigned numeric value, hence the sign is to be
                    discarded when storing a value there, and this allows twice as much
                    positive or sign-less values since the first or most significant bit
                    is essentially not set as the numeric sign indicator for the numeric value.

                    Be sure to always allow 1 extra byte or character of memory in this
                    character or  byte array that will hold, store or contain a text string.
                    This extra byte will ensure there is a null or numeric 0 character to
                    be placed at the end of a (here) 128 byte text string.  The scanf() will
                    automatically do this for you when you press the Enter key.  The 0
                    or "null" byte will be placed in the next byte position past  the last
                    text character of the string.  Using scanf(), once the ENTER key has
                    been pressed, it essentially signals to the scanf function that you have
                    input the completed string of text characters or bytes.  Scanf will then
                    "null terminate" that string, and so as to know when the end of the array
                    and-or string has been reached when displaying and-or processing that
                    string.  There could be a system error if the user enters a string that
                    exceeds the total allocated size of the array.

                    When an array is declared, given a identifier or name, it is also possible
                    to also assign values to its  elements.                              */

printf("\nEnter A String: ");
gets(string1);                    /* : A C function to input a string, and allows space characters.
                                     scanf() will terminate a string when the first space is entered.
                                     Ex.  scanf("%s",string1);
                                     scanf() does allow special modifications to its basic format
                                     specifiers, such as %s, so as to then allow certain characters
                                     such as spaces to be input.  */
 ;
printf("\n\nThe string you entered is:  %s", string1);     /* display the string  */

string1length=strlen(string1);      /* : A standard C function to calculate the length of a string up to, but  not including
                                       the null terminator character of 0 in this character count or length */

printf("\nThe length of the entered string is %d characters or bytes", string1length);

printf("\n\nPRESS THE ESC KEY or CTRL Break,TO EXIT THIS PROGRAM: ");

   for(;;){
         c=getch();                 /* : A standard C function to input a single character from the keyboard. */
                                    /*   Using getch() is also a way to pause any program, such as to read the screen .*/
         if(c==27){   exit(0);   };  /* : Exit the program when the user enters ASCII 27, the ESC key.  */
      };
```

```
return;
};
/*-------------------------------------------------------------------------------------------------------------------------------------------------------------*/
```

How are the text characters displayed on the screen? The ASCII character codes of the desired text characters are first placed into memory for the general program to access. When a text character is to be displayed on the screen, such as with the printf(), it is essentially converted to and placed into the video (display) memory area as an array of bits (ex., an 8 x 8 grid, array ["dot matrix"] of bits, hence 8 bytes per character) that will get displayed on the viewing screen, bit by bit, pixel by pixel, line by line, row by row, across the screen, and then displaying the next row of the text characters, and so on at high speed. This entire process is done repeatedly so as to keep the image available on the screen so the viewer has time to see it.

The computer programs contained within this book can also inspire some mathematicians to be able to find some quick solutions with a computer programs(s), and-or for computer programmers to consider more mathematics in their programs. Both mathematicians and computer programmers can even consult and collaborate each other so as to more knowledgeable and productive, and make something useful.

There is often several ways methods to do the same thing in a computer program, and some are more efficient (quicker). For example, here are some other methods to display this text string are as follows:

1. Indexing the string array or "array indexing" so as to have a desired element or piece of data in the entire array. This is also called "array offsetting", where the array offset is the index or element number into that array. The first element starts at the first byte of the array in memory, and therefore, it has no offset, hence 0 offset.

2. Using a **pointer**, where the pointer variable or identifier contains the address of a memory location being accessed.

   A: "Pointer indexing" by incrementing the pointer to the next memory address so as to access the data there.
   B: "Pointer Arithmetic" where the initial pointer's memory address is held the same.

First, a basic example of a pointer that can be in a program:

```
unsigned char c=65;     /*  :declaring and initializing a char (ie., a byte) data type and variable, here c  */
unsigned char * p;       /*  : declaring a pointer, or declaring a variable (here, p) that has a pointer data type, here
                                 the data type is:  char *  ,  and  which can be read as "a char or character pointer" or
                                 "a pointer to a char data type"  */

p = (unsigned char *) &c;       /* :assigning the memory location or address of variable (c) to the pointer p */
                                /* : & retrieves the address of (c), and (unsigned char *) is a (data) "typecast", where
                                   here the data (here &c) is an address and is being typecast or altered so as to a
                                   pointer data type because it will be assigned to a pointer data type.

                                    &  can be thought of as the "address retrieval operator", and
                                    *   can be thought of as the "data access operator" for a memory location, such as
                                        assigned to a pointer.   Here the access is read (a copy, retrieval) or
                                       write (set, assign value or new value)  */

printf("\n%d",c);     /* : 65 will be displayed */
```

Now that pointer (p) has been assigned the address of (c), you can even access (read, write) the data of (c), for ex:

```
*p = 66;       /* This sets the data that the pointer is pointing to, hence the data at the address it is assigned to access.
                  This will not change the address or memory location that (p) points to.  If you  wanted to change the
```

```
                  address assigned to that pointer, you can increment the pointer, and here fore example to the next
                  char or byte since that is the data type or memory size of this pointer :  p = (p+1);                    */

printf("\n%d",c);     /* : 66 will be displayed  */
printf("\n%d,*p);     /* : 66 will be displayed since the pointer (p) is assigned to the computer memory address of variable
                           (c).  It could be said that (p) points to (c).  *p is used to access the data that (p) is pointing to, hence
                           it is accessing the data held by, at or assigned to variable (c)   */
```

Why use pointers if we can already use variables? When the amount of data and-or possible variables and their identifier names become large, it is then difficult to assign, remember and use so may variable names and identifiers, and it is easier to access data by using an assigned corresponding number or memory address, especially if that data is held in successive memory and is repetitive in its data type and-or structure, such as having any data types and or elements.

A pointer with a FILE data type has been shown previously in this book. This type of pointer is used to access (read, and-or write) computer (binary) files that were stored byte by byte on disk drives. For example: FILE * myfile; When a FILE pointer is first associated to a file and-or filename, that pointer is set to access the first byte of that file that is located on the disk and its memory array of (digital, binary, 8 bit) bytes. When a FILE pointer is incremented by 1 in the program, it will then be able to access the next byte of that file. The C-language also has (ANSI) standard, common and-or required functions for accessing files such as fread() and fwrite(), and these are analogous to those of accessing program, data input from the keyboard such as with scanf(), and accessing program, data output to the display screen (computer "monitor"). More technically, a FILE pointer points to a file data structure (a struct data type in the C language) assigned to a file being accessed and that structure holds information about a desired file on data storage, such as its current access or offset (from its start) location within it. This file data structure is usually "transparent" to the programmer since the FILE pointer itself is used by the file functions that (transparently) access that file data structure, and the functions will appear to be accessing the file directly.

The following methods are shown as portions of a larger program of which you can test and use them within, such as the program shown previously to display a text string:

/* **Method 1**: Displaying the string using string or **array indexing** (ie., numerical amount or offsetting from the start) each element of the array: */

```
/* Some initial program preparation before the loop, hence "loop preparation": */
printf("\n");  n=0;

for(;;){                              /* : a  loop to display the input string, (;;) is used to indicate an
                                           "infinite loop"  that will keep running or executing until
                                            the loop is somehow terminated, and then the next
                                            statements in the program will be run.

                                            Can also use any loop preparation and or termination condition in the for-loop
                                            declaration:

                                                          Format:  for(initialization , do while or until , adjustments)
                                                          The statements are separated by a semi-colon.
                                                           ex:  for(n=0;c!=0;n=n+1){                                    */

          c=string1[n];               /* (n) is used as the index or offset from the start of the array
                                           and-or its starting memory location. */

          if(c==0){   break;  };      /* at the null terminator of the string,  break or terminate the
                                           loop (program repetition),  otherwise:  */
          printf("%c",c);             /* %c is the printf() format specifier to display a single
```

```
                                         character on the screen */
        n=n+1;                  /* increment n by 1so as to have the next array element, here a  char value  */
    };

/* Method 2:   Displaying the string using  pointer incrementing it to point to the next memory location or text
               character in that string: */

/* Some initial preparation before the loop:      */
printf("\n");
n=0;
p = string1;      /* : setting the pointer to point to the first byte of the string1character array  */

  for(;;){
        c =(unsigned char) *p;          /*  :is used to access the data at a memory location or pointer.
                                            Can also use:     c = (unsigned char)  *(p+n); ,orr increment the pointer by 1
                                             below with p=p+1, and use c=*p;                                             */
        if(c==0){   break;  };
        printf("%c",c);
        p=p+1;    /* increment the pointer to hold the next memory value and-or point to the next memory location.
                    Incrementing a pointer that has a certain data type will increment it by the byte or memory size of
                     and allocated for that data type.  The data type of a pointer is that of the type of data it that it points
                     to in memory, and here, it is a char data type which is 1 byte of memory.  Incrementing this pointer
                     by 1 will increment its reference address by 1 byte.  */

      };  /* end of the for-loop */

/* Method 3:   Displaying the string using pointer arithmetic applied to a pointer, where the initial value of the
              pointer remains unchanged:   */

/* Some initial preparation before the loop:      */
printf("\n");
n=0;
p = string1;     /* : setting the pointer to point to the first byte of the string1 character array  */

  for(;;){
        c =(unsigned char) *(p+n);      /* (p+n) resolves or sums to the address of the next byte,
                                           hence this C language expression is a temporary pointer.  */
        if(c==0){   break;  };
        printf("%c",c);
        n=n+1;
      };

/* Method 4:  Displaying the string using an array name or identifier as a pointer to the start or first or starting
               memory location of that array:   */

/* Some initial preparation before the loop:      */
printf("\n");  n=0;

  for(;;){
        c =*(string1 + n);          /* : when n increments by 1, it will increment the string1 pointer by 1 so as
                                       to point to the address of the next byte or character in that array */
        if(c==0){   break;  };
        printf("%c",c);
```

```
            n=n+1;
        };
```

Pointers can even be assigned as having the same address that another pointer is assigned or pointing to. For example, if p1 is a char pointer assigned to a memory location, and say p2 is NULL or 0, hence not assigned to a memory location yet, p2 can later be assigned to a memory address by setting it equal to another pointer. An older saying or equivalent word for the word "NULL" is "NIL"..

Ex.

```
/* initial declarations: */

char c=65;
char * p1 = NULL;   /* NULL means an unassigned pointer, and or 0, or an address of 0 */
char * p2 = NULL;

/* an example of using the variables and or identifiers in the program: */

p1=(unsigned char *) &c;      /* : a (data) type cast of the address of a variable, here (c), is considered here,
                                   so as it can be properly assigned to an actual pointer variable. */

p2 = p1;          /* : setting pointer p2 equal to the same address that p1 is pointing to, or in reference to */

printf("\n%d",*p2);    /* the result displayed is 65  */

/*-----------------------------------------------------------------------------------------------*/
```

In the **BASIC** programming language, the default keywords to access a memory location are: PEEK and POKE. PEEK is used to read or get a byte stored in a memory location, and the general syntax format is:

```
    variable = PEEK (memory_address);
```

POKE is used to set (ie., write) a value into a memory location, and the general syntax format is:

```
    POKE (memory_address, value);
```

The above syntax looks similar to a function call in the C programming language.
For comparison:

```
BASIC language:     value  =  PEEK (memory_address);       : PEEK is analogous to READ
      C language:     value = *pointer;

BASIC language:      POKE (memory_address, value);         : POKE is analogous to WRITE
      C language:      *pointer  =  value
```

The BASIC language was one of the first "user friendly" ways to create computer programs. Programs became fairly or relatively easy to understand, write and edit. There are many **BASIC** language interpreter programs and "dialects" of BASIC - often suited for a particular computer and-or graphics abilities of it. BASIC is called an interpreted language because the program is not compiled into a standalone executive program, but rather each line is executed one at a time. Most of the BASIC interpreters use or require a similar syntax or format of the source program or input language, and there has been an attempt to standardize BASIC and you can research this if you want. There are also some BASIC compilers now available so as to generate a standalone executive program for a specific computer system.

A Computer Program For A Homemade Text String Input Function

```
/*-----------------------------------------------------------------------------------------------------------------------------------------------------
   mygetstring.c

   As a programmer learns more about the C language and-or computer programming, they will eventually consider a
   need for having their own homemade functions such as string function(s).  A text string is a series or string of readable
   text characters.  ANSI C, has several string input functions, and the main ones are scanf() and gets().  The source code
   for the homemade  function show below should also give a programmer some useful ideas to consider when they
   write their own functions.

   (c). JPA 2021
------------------------------------------------------------------------------------------------------------------------------------------------------*/

#include "stdio.h"

/* Here is the function prototype for mygetstring()              */

void mygetstring(unsigned char * s, int maxchars, int display);   /* a homemade getstring() */

    /* 1.  s is a pointer to the string and-or its memory, and where you want to access (read, write)  the input string.
           maxchars is the total number of characters to accept into this string.
           display is 1 to display the input string, and 0 to not display the input string.

       2.  A potential issue is that when backspacing, the cursor won't go back to the previous line on the display,
           hence a max. of 80 characters can be seen so as to be  edited if the string input starts at the beginning
           of a line of the display.

       3.   Allows use of the BACKSPACE  key or ESC key so as to terminate the input early with no valid input.

       4.   Shows a way to determine if a special key such as a function or arrow keys has been pressed.
   */
/*----------------------------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
unsigned char c;
unsigned char string1[129];        /* declaring an array to hold many values, here, the values of
                                      displayable, or entered text characters */

printf("\nPlease enter some text up to 128 maximum characters. ");
printf("\n:");
mygetstring(string1,128,1);      /* call mygetstring() with two arguments,
                                    the string indentifier, and the max. number of input characters */
if(string1[0] != 0){  printf("\n:%s",string1);  };   /* or use NULL for 0, see if an input string exists  */

printf("\n\nPRESS THE ESC KEY or CTRL Break,TO EXIT THIS PROGRAM: ");

LIST OF ASCII TEXT CHARACTER CODES

ASCII is the American Standard Code for Information Interchange (communication), and is used as a standard for machine and computer programming and display screens. These are essentially 1 byte values, hence 8 bits of which can be sent over 8 parallel wires, all at the same time. ASCII was standardized in the early 1960's by what would later become the ANSI which is the American National Standards Institute.

7 Bit ASCII Standard Text Character Codes: (0 to 127), and 8 Bit ASCII Extended Text Character Codes (128 to 255):

ASCII codes 0 through 31 are usually non-text display codes that are used to control (ie., send basic commands for various functions of) a machine such as a printer or computer display screen. The table below was printed using a C language computer program.

```
 32       33 !     34 "     35 #     36 $     37 %     38 &     39 '     40 (     41 )

```

Common ASCII machine control and-or formatting control characters and-or values:

0 = NULL
7 = A = Alert and-or a bell sound. To consider people with hearing problems, you can do something such as displaying the word "alert!" or "error!" on the screen.

In C, you can use the escape (from the normal text displaying, display and-or machine system control)character symbol followed by letter b so as to have access to, and signal the system to use the bell character, and from within a printf() statement. These control characters are also called an "escape sequence (of characters)" The backslash character is used first, so as to signal an escape sequence. For example:

```
printf("\a Did you hear a bell sound?");  This is equivalent to:
printf("%c Did you hear a bell sound?,7);
```

Note, to display a backslash character and-or the quote character, use for ex.

```
                 printf("   \\    \"   ");
```

8 = BS = Backspace = Go one text position "back" or leftward on the current line.
10 = LF = Line Feed = New Line = Go to the next display and-or text line.
13 = CR = Carriage Return = Return to the start of the current line of text.
27 = ESC = **Esc**ape Character = Typically used to start a special process and-or hault in the program, or to control the display.
32 = SP = Space, "blank" Character, "word separator", the absence of any visible char.

Pressing the Enter key usually generates both a CR=13 and LF=10 characters or commands.

The ASCII characters can optionally be entered by pressing and holding the ALT(Alternate) key and then entering the text character code on the numeric keypad, and then releasing the ALT key. The Windows ((t) Microsoft Co.) computer operating system may redefine the look of the extended characters and-or depending on the font being used. Note for example that given a capital or upper-case letter such as character A = 65, the corresponding lower-case version is 32 higher, hence character (a) = (65 + 32) = 97.

ASCII Images or Art is term used to describe images composed of ASCII text characters, either for graphics or photos. This is an actual method that can be used for communication systems without dedicated graphics ability, but still having text ability to work with. The result is a mediocre image if viewed from a few feet away or more, but it is much better than nothing. Today, with modern computer systems, ASCII art is generally unnecessary, however computer programs are available to convert (.bmp, .jpg, etc.) images to ASCII art and with color ability, and which can then make something such as interesting and artful posters. Many of the first electronic computer games before programmable, pixel graphics and colors were developed used ASCII text characters to display things such as values, locations, and (movable) objects on the screen. It was common before about 1985 to purchase a book containing BASIC language (text) source code programs that you could type in yourself and run on a personal computer(PC).

More ASCII Control Characters   (generally for communication to send ASCII text files)

1 = SOH = Start Of Heading
2 = STX = Start Of Text
3 = ETX = End Of Text
4 = EOT = End Of Transmission
5 = ENQ = Enquirer (ie., a question, find)
6 = ACK = Acknowledge
9 = HT = Horizontal Tab (ie., several spaces such as for making columns, indentation)
11 = VT = Vertical Tab   (ie., insert blank lines)
12 = FF = Form Feed   (ie., eject current page, prepare for next page to be printed)
14 = SO = Shift Out   (typically for printer color selection)
15 = SI = Shift In
16 = DLE = Data Link Escape
17 = DC1 = Device Control 1 (the control depends on the device and how it was programmed)
18 = DC2 = Device Control 2
19 = DC3 = Device Control 3
20 = DC4 = Device Control 4
21 = NAK = Negative Acknowledge
22 = SYN = Synchronous Idle
23 = ETB = End Of Transmission Block
24 = CAN = Cancel
25 = EOM = End Of Medium   ,   26 = SUB = Substitute

28 = FS = File Separator   ,   29 = GS = Group Separator
30 = RS = Record Separator   ,   31 = US = Unit Separator

Extra:

On a Window's © operating system computer ALT 0169 is the copyright symbol: © and(c) can be used.

On a Window's ® operating system computer ALT 0174 is the registered symbol: ® and (R) can be used.

Why the ASCII standard uses 7 bits instead of a complete 8 bit byte.

The basic answer to this is that the 8 bit was used for error checking. For example, if the 8th bit was set it could mean there was either an even number of set bits (ie. "1's") transmitted. If the receiver counted that an odd number of bits were received after counting them, then there was an error in the transmission of the data, and a request to resend that data again could be sent to the transmitter device. Though this will not find all the possible errors, it is still practical. It is even possible to send the received data bact to the sender so as to compare the data and-or compare the unique checksum value of all the data send and received, and which surely will indicate if there was a data error. A slower method to find transmission errors would be to send each byte twice and compare those, and even send it back to the sender for comparring. If there was an error, the two same bytes could be sent again and comparred again.

Besides encoding the control characters into the standard set of ASCII printable characters, it is possible to make a special byte value (say 1, 127, etc.)to signal or indicate that a control value or control character (here, still a byte value) follows.

USING COMMAND LINE ARGUMENTS AND-OR DATA WITH A COMPUTER PROGRAM

```
/*-------------------------------------------------------------------------------------------------------------------------------------------
    CommandLineArguments.c

    This program shows an example of how to send optional and-or various argument data (such as text and-or numbers)
     to a program when it is first ran on a personal computer (PC) having a  DOS (Disk Operating System) command line,
    and then how to access those arguments from within the program so as to be used within the program.  The
    command-line is sometimes called the computer's operating system input and display (ie., typing, basic input and
    screen output) or (access or system) "terminal", and or the "DOS (Disk Operating System, of commands and access)
    command-line".

    Format example:   myprogram.exe  argument1  argument2 . . .

                             Examples of the arguments:   a word, sentences (ie., words with space between them)
                                                           bounded by quotes (ie. "word  word  word"), numbers, a
                                                           filename, etc., and these are input as ASCII text characters

   Each argument should be separated by a space character.  Extra spaces will be ignored unless they are
   within quotes such as for a string of text characters.

   Using (mouse, left-click) "drag and drop" of an icon or filename onto the programs icon or filename, is also
   a way to send a filename and-or the file as an argument.  The file can then be accessed within the program
   without asking the user to type in or select what file to use.   With the Windows operating system (technically
   a program itself), you can place a program in the SENDTO folder so as when you mouse-right-click on a
   filename, one of the menu options is "send to" so as to directly send that file to your program(s), and without
   needing to find and enter long directories, etc. To open the SENDTO folder or directory, press the START
   button the screen, select RUN, and then enter Sendto, and then drag and drop, or copy, your program to be
   in there.   To RUN or execute an .EXE format computer program, simply double click on it, or enter its name
   on the computer system's (DOS) command-line.  To see a list of files in a folder or directory, enter DIR on the
   command-line.  To see a list of DOS commands available for that computer system, enter:  HELP, and for
   help with a specific command, enter:  HELP command.   If possible, try to always make backup copies of
   your programs and-or data, for these devices tend to fail, can get damaged, hacked, lost or stolen.  Put these
   in a safe and protected place.

  The arguments are considered as null terminated (0), text strings, and you may then need to, for example,
  convert a ASCII text string to a binary numeric value that can be assigned to a variable, etc.  One common
  C function for this is the atoi( ) which is the "ASCII text string to numeric integer" conversion function, and for
  converting an ASCII text string to a floating point value, use the atof( ) function.  The return value is a double
  precision floating point number.  Leading spaces will be ignored, a sign and decimal point can be used, and
  the last character accepted will be either a space or a text character other than a number.  strtod( ) is a similar
  function.  To convert a string to a long double floating point number, use strtold( ).

  Since main( ) function is the default or required entry point of a C program, the arguments are passed
  or sent to argument holders described in the main().  Just like for any function with arguments, each
  argument to a function has a data type and an identifier, and here they are also specific C keywords and-or
  variables and their identifiers (identifying names) that need to be used so as to access that data.  Still,
  you can always assign these values to your own variables used in the program.

  The first argument is always the program name itself, and is identified with an offset of 0 as:
  argv[0].   argv[ ] means "argument vectors" array  which essentially means text strings for the arguments.
  argc = argument count, will hold the number of total arguments sent to the program on the command line.

                                                initialize the string with some data.  This here is initializing mystring[ ]
                                                array with a string that is just a null terminator (0 , byte value) character,
                                                but it could also be initialized with a complete string within quotes.    */

printf("\nTotal Number Of Command Line Arguments = %d",argc);
printf("\n\n");

            for(;;){
                      strcpy(mystring,argv[n]);      /* : using the string copy function, here argv[n] is copied to mystring */
                      printf("\nArgument %d = %s",n,mystring);     /* : display each command line argument */
                      n=n+1;
                      if(n>=argc){  break;  /* break or exit from this loop or repetition */  };
                   };

printf("\n\nPress A Key To Exit This Program: ");  fflush(stdin);  getch();  return(0);

exit(0);    /* : can also use:   return;  or something like return or return(0);
               0 is usually used to indicate everything was ok, no known errors or issues   */
};
/*---------------------------------------------------------------------------------------------------------------------------------*/
```

FOR PROGRAM USAGE SECURITY, YOU CAN USE A PROGRAM ACCESS CODE

Perhaps you want to use a **program access code** to be entered on the command line or at some point during the program once started to run. This can be used so as to help limit the access to that program you are making. It is possible to do this in a varitey of simple ways, such as with the code used in the above program to display the command-line arguments to the computer system and program to be run or executed (.exe). For exampe, you can use the string compare function strcmp(), and compare say the first word, or the program access text (including numbers) or words surrounded by quotation marks, and which follow the program name on the comand line. For example:

```
myprogram.exe  1397abz              : there the program access code entered on the command line is 1397abc
```

To Learn To Program A Computer Device

A computer is a machine that can be programmed to have certain steps, and modernly it is a electronic machine that is often based on digital or binary data rather than some physical switch, cog or voltage level. It is of note that binary data can also be used for switching something on or off, and or to store data such as a number or letter. A computer that can be programmed (ie., "told what steps to do") is often used to then control another machine of which may be called as a "computer controlled machine".

To learn C programming, you can take a course or two and-or obtain some books about it. The computer programming books by **Herbert Schildt** are a good purchase to make. Some of these books also include the basics of the C programming language and with many programming examples to consider. Some of these books also include some general computer science topics which are a great aid for any programmer. Schildt's books have made formal computer science and programming into a practical reality for the average person, and so as to consider making some useful programs without a costly formal education in computer science. Another very good learning tool is the **Learn C Now book** by **August Hansen** which includes examples programs and a fast C editor and compiler to test your programs, however. note that it does not create the .EXE programs for standalone operation without the compiler, and is rather used for quickly testing and finding errors in programs you make. The author of Mathization has bought and used this specific book required a local college course about C programming, however, it is also good for any person interested in the fundamentals of the C language, and without the need to take the course, but it does help. People new to a programming language need to "keep it simple" and focus on the keywords and-or commands and syntax used for that language, and what they mean and how to use them. Learn by writing simple test programs that use a specific keyword(s). This book here, **Mathization**, tries to give the programmer a general or practical math education, and with C programs related to math that are generally not found in most computer programming language books and-or courses. These programs are also a good example to reference so as to create your own programs.

Some may desire to also take a course in computer science. For learning C, you will need a C source code compiler such as TinyC . This book considers the TinyC compiler which is generally an ANSI standard, C compiler with no specific computer system (such as Windows (R)) and-or its own specific programming functions to then consider, and which then tends to complicate learning the basics of any computer language. Other compilers may include many other specialized functions to be used for a certain or unique computer system, and such as for basic graphics to put a pixel, line or circle on the screen, or to make some sounds. These compilers must also be compatible with the specific computer system being programmed, but the ANSI C standard is generally compatible with any computer, and you generally will not have to learn or relearn C programming for general programming (creating computer programs) on any ANSI C compatible compiler for any computer system.

With programming, and much like math, just the basics of it can go a long way and be most useful or practical. Rather than make exquisite and specialized programs that take much knowledge and years to develop, it is sometimes better or more practical to make many relatively simple, useful and practical programs or even functions( ) that can calculate some numeric values of which others, such as at a factory, group or business, can utilize. Writing your own homemade functions is a good learning experience. **Writing functions** or the programming code or steps to do a certain task(s) in a program, and of which can be reused in many of your programs and possibly by other programmers, is a very useful way to become an experienced computer programmer. Strive to learn the ANSI C standard keywords and functions first, and before trying to write programs for a specific computer system that requires a specific and capable C compiler which also has some non-ANSI C standard functions for that computer system. Learning how to program or work witih a specific computer operating system with its own non-ASCII requirements with a given computer language such as C is another programming issue and challenge that you may or may not encouonter.

As a computer programmer, you are generally not expected to be initially proficient in the science and-or math necessary for any certain program or company, however you may need to research what is necessary and-or collaborate with other employees and those knowledgeable, such as other programmers, so as to make a specific and customized computer program. Please keep a written record so as you and-or others may need this data later. You may even be designated to do other things such as making the morning coffee and-or sweep the floors so as to be a multi-tasking employee with several useful and valued abilities. This book contains many programs for the common math functions found on a scientific calculator, and these are generally already part of the C language standard and available as prewritten math functions, and hence you do not need to be a "math programmer" to do much general programming in terms of those, but it would benefit any programmer if they know some math so as to make more advanced programs and-or to understand or edit programs written by others.

Many of the computer programs and-or functions shown in this book are relatively uncomplicated, and they may even be overlooked by many when scientific calculators and-or prewritten math computer functions are available in the C compiler. The set of ("scientific") fundamental math functions shown in this book, such as for those found on a scientific calculator or a program compiler, seem to be very rare, and should therefore be of general interest to computer programmers who are oriented to writing mathematical calculations. What is also important and shown in these functions is how to create some specialized loops, such as for performing successive approximation to "zero in on" or to get as close as possible to a numeric result in terms of a certain precision needed.

It is best to make a study of the available C keywords, syntax and functions available in the plain ANSI C current standard. You will find that it is not too difficult, and due to the fact that certain functions like printf() and scanf() are used rather extensively, and that test programs and-or functions to see the results can be made relatively short. You can always make programs as complex as you want from just using the basics, interest, practice, program testing and editing.

[This space for edits.]

A COMPUTER PROGRAM TO DISPLAY THE BITS OF A BYTE

```
/*----------------------------------------------------------------------------------------------------------------------
    BinaryToDecimal.c

    There are many ways to access (read, write or set) the bits of a byte, below is
    one example of doing so in a functional form or coding.  The C programming
    language has several "bitwise" operators that work with the bits of bytes, and
    of which you may wish to reasearch and learn.  For example the leftshift (<<) and
    rightshift (>>) operators:

    Format example:  bytevalue1 >> number of bits to shift rightward, to produce bytevalue2
                             Ex.  10000010  >> 1 would become 01000001

    Note, for example, that the rightshift operator will actually shift the least significant
    bit off the byte and it is lost unless it was first saved before that operation, and perhaps
    then placed after the operation into the most significant bit, and the operation essentially
    becomes a rotate_right operation that ASNSI C does not actually have.   Note that (>)
    and (<) are conditional operators.

    To invert each bit in a byte from 0 to 1, or from 1 to 0, the complement operator (~) can be
    used.  This is also called inverting the bit value or state.  This requires only one operand:

    Format example:   bytevalue2 = ~bytevalue1     : ex. ~10000001  would become 01111110

    The C programming language has many bitwise logical operators such as:

    & for AND        : Note that && is for logical (decision making) AND for two conditions.
                     : example format:  bytevalue1 & bytevalue2 to produce bytevalue3
                       This "ANDing" works on corresponding bits of the two bytes.  If both
                       bits are set to 1, the result is 1, otherwise the result is 0.

    | for OR         : Note that || is for logical (decision making) OR for two conditions.
                     : example format:  bytevalue1 | bytevalue2 to produce bytevalue3
                       This "ORing" works on corresponding bits of the two bytes.  If either
                       bit is set to 1, the result is 1.

    ^ for XOR        : example format:   bytevalue1^bytevalue2  to produce bytevalue3
                       This is "eXclusveOR", it is similar to the binary OR function, however it excludes one extra truth,
                       and that is if both bits are set to 1, the result is not 1, but 0, since this condition is to be "excluded".

   When working with numeric values, a programmer generally does not need to convert a
   decimal value to its binary equivalent, and vice versa,  since the compiler will do this so
   as the computer can work with binary values behind the scenes or transparently.  For
   example, when you enter a decimal value of 5, the compiler will convert this to its
   corresponding binary value of 00000101 so as the computer electronic circuitry can
   work with it such as in mathematical operations.

    There may be times when you explicitly want to enter and convert and-or display these
    binary values.  Some calculators have similar conversion functions available.  In the
    example program below, error or input checking is kept to a minimum,and may be
    improved upon.  One example of error checking is to determine if any other characters
    other than 0 or 1 have been placed in the string, and then signal an error.  It may be
    best to put any error checking in the function itself, since any programmer who desires
```

```
    to use the function does not need to worry about the program coding to do so, and
    can simply concentrate on what the function is supposed to do.

    This program example below is to demonstrate using the following homemade functions:

    btod()   : binary to decimal conversion of an ASCII text string containing 1's and 0's
               ASCII text characters, hence a string of text, and the return values is a
               numeric integer.  Programmed to work with up to an 8 bit unsigned byte value
               only,  however, you may wish to include a function parameter for the sign, say
               0 for unsigned, and 1 for signed.

               unsigned char btod(char * binary_text_string);

    dtob()  : decimal to binary ASCII text string
               Programmed to work with 8 bit byte values only.

               void dtob(int number, char * binary_text_string);

Three extra homemade bit functions are included:

   rotateright()    : rotates the bits of a byte left, and does not loose any bits or data
   rotateleft()     : rotates the bits of a byte right, and does not loose any bits or data
   complement()  : C already has a built in complement function, for example: ~byte , and
                     this will invert or change the state of each bit from 0 to 1, or 1 to 0.
                     Ex:  Using common decimal values :   254 = complement(1)    ,  1d = complement(254)  , and:
                     Binary equivalents are:  11111110 = ~00000001   ,   00000001 = ~11111110

   The C programming language has standard ANSI, C functions to shift the bits of a byte,
   but either the LSB (Least Significant Bit)  or  MSB (Most Significant Bit) is lost unless its value is saved first.

```

Example of program use and screen output:

```
Enter A Binary Value Up To 8 Bits of 0's and 1's, or press ENTER: 10000001

10000001 = 129     : or=  10000001b = 129d

Enter A Decimal Value (1 to 255) or enter 0 to exit loop: 130
130 = 10000010

Enter A Decimal Value 1 to 255, or 0 to Exit Loop:  3

The corresponding binary value is:  3 = 00000011
The rotate-left value of this is: 6 = 00000110
```

```
The rotate-right value of this is: 129 = 10000001    : rotate is like a byte or bit location shift, but does not loose any digits

Press A Key To Exit The Program:

--------------------------------------------------------------------------
```

A homemade way to left shift a binary value is to multiply it by 2, and for a right shift, divide that binary value by 2. When this is done the most significant bit or the least significant bit will be lost if its value (ie., 1 to 0) or some indication such as a toggle or flag variable (ie., set to 1 or 0) was not stored before the mathematical operation.

Ex. A computer byte or char value of 145d = 10010001b , multiplied by 2 is: 00100010b = 34d
The MSB was lost after the left shift operation.

In a similar manner to the above reasoning, for example, when working with single byte or characters(char) values only, they will "roll over, to zero" like an automobiles mile counter when the highest count is reached, and that value is 11111111b = 255d. When 1 is added to this value, the leading carry is lost unless it was somehow saved first, and that binary value will then become 0000000b = 0d. So that this does not happen when you need to consider higher values, you can first define the variables as integers which are often 2 bytes ("wide" or "width") and have a maximum value before rollover of: 11111111 11111111b = 65535d. By having various data types or byte sizes available in a compiler and computer, it can help increase speed and saves memory for other things.

USING THE #DEFINE , C LANGUAGE COMPILER DIRECTIVE FOR TEXT SUBSTITUTION

```
/* ---------------------------------------------------------------------------------------------------------
define1.c

    A basic test of using the #define , compiler preprocessing directive or for text substitution.
    This can be used to redefine keywords, mathematical operation symbols, constants , etc.
    # indicates a certain compiler directive or instruction follows, much like a command or
     option for the compiler program, and usually for how to process the source code.
    The #define data_used   is commonly called a macro.  They are much like program
    "global constants".

Ex.  #define ROWS 50
      #define COLUMNS 80             /* : can change the values as needed for the program, etc */
      #define PI 3.14159265
      #define cube(x) (x * x * x)         /* : this is a inline, function-like macro  , here x can be a integer or float  */

   (c) JPA , June 4, 2025
------------------------------------------------------------------------------------------------------------*/
#include "stdio.h"

#define  rightshift  >>      /*    perhaps make:   leftshift <<   */
#define RS  >>               /*   : an alternate example,  and   perhaps make:   LS <<     ,  ffor left shit  */

#define cube(x) (x * x * x)

/*--------------------------------------------------------------------------------------------------------*/
void main(void)
{
unsigned char c = 128;      /* 128d  =  10000000b  */

printf("\n%d",c);               /* displayed is:   128     */
```

```
c = c rightshift 1;               /* : the compile will convert this to:  c  = c  >> 1   , and 1 is the number of shifts */
printf("\n%d",c);                  /* 64d  =  01000000b  */

c = c RS 1;                      /*  : the compiler will convert this to:  c = c  >> 1  */
printf("\n%d",c);                  /* 32d  =  00100000b  */

printf("\n\n"The cube of 2.5 is %.15g",cube(2));  /* : 15.625 */    /* Can use %lu for unsigned long values only */

printf("\n\nPress A Key :"); fflush(stdin); getch();

};/*-----------------------------------------------------------------------------------------------------------*/
```

A COMPUTER PROGRAM TO CONVERT A DISTANCE BETWEEN THE METRIC AND ENGLISH MEASURING SYSTEMS

```
/*-----------------------------------------------------------------------------------------------------------------
   conversions.c

   A C language computer example program showing several functions to convert
   from the English system to the Metric system.  Functions such as this are
   very helpful and convenient to computer programmers either good with math or
   not so good, and-or don't want to be bothered creating such functions.  These
   functions  are somewhat unique and can be used as an example to create many
   other functions and-or programs for conversions.

1.011 meters = 3.31692924 feet

3 Feet + 3.80315088 inches =
3 Feet + 3 inches + 12.85041408  16ths of an inch =
3 Feet + 3 inches + 25.70082816  32nds of an inch

Press A Key To Continue With This Function or ESC For The MENU:
```

Also of note, for example, in the above program to convert feet to meters, you may also initially ask the user if they want to convert a decimal value of feet to meters, and-or if they want to convert the number of feet and-or fractional parts of feet to meters.

[This space for book edits.]

A COMPUTER PROGRAM WITH SOME HOMEMADE MATH FUNCTIONS

This computer program shows some examples of homemade math functions that can be used within any C program that needs them, and-or rewritten for other computer programming languages.   In particular, here they are some trigonometric functions. Also shown after this program, is how to create the header (.h) file with these functions so that it can later be included in any C program that needs them; such as the computer program shown here.   This header file is called HomemadeMathFunctions.h. To reduce program sizes, you may also place each pre-made function in its own header file, and you can then easily include that function(s) in your program(s) so as to make a shorter source code for editing.

```
/* ---------------------------------------------------------------------------------------------------
    myprogram.c

    This program is to test including a header file called:
     HomemadeMathFunctions.h that contains some homemade
     function prototypes and functions.  To reduce program size,
     it is a good idea to perhaps make each function into its own
     header file and include only that when it is needed by the
     program.

    A programming topic you may wish to research, is that of
    creating object files, (dynamic and static) linking, and libraries.

```

A COMPUTER PROGRAM TO CONVERT A TEXT STRING TO A LONG INTEGER

Below is a homemade string function that will convert a numeric value input as a readable text string of ASCII text characters and convert it to a numeric data type that can be used for a mathematical operation. The standard or an ANSI compatible C language already has some standard functions to do such conversions, but knowing how to make your own functions is very useful for a programmer.

```
/*----------------------------------------------------------------
stringtolongint.c

stringtolongint()  converts a text string to a
signed long integer numeric value. This function
is similar to the standard C function of atoi() and atol().
There are several ways a user could make such a
function, and the one shown below is one example.

A string null value or decimal point will signal the end
of the conversion.  Leading spaces are allowed in the
text string using scanf(), but other spaces signal
the end of the string input using scanf(). You can also
try gets() to allow spaces if needed.  You can also
use commas in the number, for example, -2,000

A more genereal text to numeric function would be
to write one that accepts a double float text input
and converts it to a double float, numeric data type.

So far, the program can display about:
+/- 2,000,000,000,  about  +/- 2 billion
The actual values are:
-2,147,483,648 to 2,147,483,647 for signed values and
unsigned long int, max.  is  4,294,967,295

(c) JA Oct. 2013, updated for the Mathization ebook on
                       Nov. 24, 2022
----------------------------------------------------------------*/

#define start main     /* an example of a compiler directive or
                          command, define is used to define a text
                          alia or substitution in the program */

#include "stdio.h"
#include "math.h"   /* used for sqrt() in the example usage program */

long int stringtolongint(char * string);
```

```
/* It is quite possible to use this function twice so as to construct a
    double float numeric data type.  Enter the string and break it into
    two parts, the whole part and the fractional part.  Send each string
    part to this similar function, say from within a function called
    stringtodouble(char * string) ,  but for the fractional part , the
    weights or powers of 10 will be divided by 10.  A double float
    variable being created will be the sum of both of the whole or
    integer part, and the fractional part of 1.
*/
/*-------------------------------------------------------------------------------------*/
void start(void)   /* example program to use the function */
{
char string[20];
long int n;

printf("\nEnter an integer value: ");
scanf("%s",string);

n=stringtolongint(string);
printf("\nThe integer part of the value you entered is: %ld",n);

printf("\nThe square root of %ld is %.15g",n,sqrt(n));

/* printf("\nOn this computer the size of a long integer data value is:  \n%d bytes",sizeof(long int)); /*
          /* usually 4 bytes , for testing */

printf("\n\nPress A Key");  fflush(stdin);  getch(); exit(0);

return;
};
/*----------------------------------------------------------------------------------------------*/
long int stringtolongint(char * string)
{
char ch;
long int n=0;
int sign=0;
char digits[10]={ 0,0,0,0,0,0,0,0,0,0,0 };  /* :This is actually a string, and with each byte initialized to 0 */
unsigned long int powerof10=1;
int l=0;

while(1)              /* Lets get each numeric digit into an array for processing. */
{
    ch=*string;     /* : Read the char or byte value at the address that string contains and points to. */
```

```
    if(ch==0){  break; };     /* null terminator */
    if(ch=='.'){  break; };     /* decimal point, or to skip over use:  string=string+1; continue  */
    if(ch=='-'){  sign=-1; };  /* negative sign */

    if( (ch>47) && (ch<58) ){    /*  If the text character is a numeric digit:
                                       0=ascii 48,  9=ascii 57  */
       digits[l]=ch-48;              /*  convert ascii letter to a number */
       l=l+1;                        /*  essentially the number of digits also */
      };

    if(l>9){  break; };     /* : for if there are 10 or more digits, and could also use return -1 here
                                 for an error signal indicating the entered value is to big. */
    string=string+1;      /* point to next character in the text string  or char = byte array */
};

    /* Create the decimal number value from the array of numeric digit values. */

   while(1)      /* : Any value other than 0 is considered a truth, and 1 is used here and is constant, and
                      will create an infinite loop until it is broken out of, such as with a break statement.  */
          {
            n=n+(digits[l-1] * powerof10);  /* create the positional sum ,
                                               used [l-1] since first digit is at offset 0 */
            l=l-1;   if(l==0){ break; };
            powerof10=powerof10*10;      /* create the decimal weight of the next digit leftward. */
          };                              /* In a float, the digits rightward of the decimal point
                                               have a digit weight value that is divided by 10. */

if(sign==-1){  n=-n; };    /* :For if the input was to be a negative number.  Can also use:   n  * (-1)   */

return n;;
}
/*-----------------------------------------------------------------------------------------*/
```

Here is an example of using the above program and-or function:

```
Enter an integer value: 100.234

The integer part of the value you entered is: 100
The square root of 100 is 10

Press A Key
```

COMPILING A C PROGRAM WITH A C-COMPILER APP AND-OR MAKING A PHONE APP

The following are some basic and helpful notes about compiling a C program on a phone system and-or making a phone app (ie., application, a [computer, phone program] as of March 2022. The operating system of the phone must be a version of the Android Operating System, and does not consider iOS (ie., the iphone operating system) and phones developed by the Apple Co. There are several C and-or C++ compilers available and they usually can be found on the Google Play ("App Store") website. The author will only discuss two such apps available that he has tried in a minimal manner, and for the following minimal discussion. Be sure to use an APK extractor so as to save any apps that you may need to have again if the phone is damaged and-or needs to be reset or "cleared" via a factory reset or software re-installation selection in the phones settings, and if so, any data stored on it will be erased, and therefore, you will first need to consider saving that data onto a computer, memory card, etc. As for the apps mentioned below, they may or may not still be available, but there is usually some similar apps available.

In your internet (ie., "web") browser such as the Chrome browser, search for Google Play and go to that website.

1. **For the Mobile-C Compiler App**

   This is a easy to use basic C compiler, and is similar to the TinyC compiler in terms of simplicity and speed, however Mobile-C does not make Apps. It will run a C source code program, and is great for learning and-or editing programs. There is a free version and a pay version available. There are other compilers available in the app menu, such as: C++, Javascript, Python and Lua.

   On the Google Play search bar or input, enter: Mobile-C
   Choose to install the Mobile-C App.
   Open the Mobile-C App.

   In the settings menu, there are several default compilers to use. New programmers should select the (basic) C compiler. This compiler seems to be a version of the TinyC compiler (TCC).

   Your C source files can be accessed from the Mobile-C folder (ie., directory) or the external storage directory which is often where most of the user files for the phone are placed. You can press on the filename to load (ie., move, place) that source file into the C program editor, or press Run so as to compile and run (ie, execute or perform the program code or instructions) the file without editing.
   If you choose to edit the file, there is a Run button in the editor.

   To allow the Mobile C app to access to the External Storage to the app, and which is the phones main storage location, directory or folder, select your phone settings, and then select the Mobile-C app, and in its permissions, allow access to the phones storage.

   This app can also edit a .txt (ie. a text) file much like editing a .c file. This app can also view .jpg images when you press on its filename.

   The reader may also read the C4droid section below for some relevant information.

2. **For the C4droid Compiler and App maker App**

   This is an easy to use App that can edit a C source code files and also make an APK file which can then be installed as an runable or "executable" App on your phone.

   Press the Google Play Store App/Link on phone. On the Google Play Store search bar or input, enter: C4droid (ie., C For the Android operating system on the phone). Choose to install the C4droid App. The price of it was about $4USD as of March 2022, and is a good deal. This can be paid for using a Google Pay account having your bank account and debit card assigned to it. Open the C4droid App. You may also want to download and-or install from the Google Play Store (ie. Google's certified apps website location) the free GCC, and SDL (Simple Direct media

Layer Software , and is sometimes called a Software or Graphics Defined Library). SDL contains premade graphics functions for a certain electronic device such as a computer or smartphone. SDL is used as a "plugin" or addition to the C4droid compiler, and so your programs can call these functions(). It is possible that OpenGL might be a fancier option to the more basic SDL, but you will have to check with this.

With this app, there are several compilers available in the Menu. Select Compiler option, such as: TCC (TinyC compiler), or GCC (such as for some graphics with the SDL plugin, and for C++), or the G++ compiler to compile C++ source code programs. For some of these to function, you may need to install GCC and SDL form the Google Play Store if they were not already included with the C4droid App. In the Preference menu menu, you may also select the "Close shell after program exit" option. Shell is essentially the command-line and program input/output environment, and is sometimes called the "terminal". If you are programming using only the ASCI C language, then select the TCC compiler in the compiler preferences.

When you compile and run the Your C source files or accessing other files with C4Droid, you make will usually be found and accessed in the device (ie., such as a phone) memory storage which for an android phone is usually the /storage/emulated/0/ folder or directory. This directory may be sometimes noted as being "external storage" on some apps. A more complete file path of your user stored area is: file:///storage/emulated/0/Download/ of which can even be entered on your internet browser (such as Google Chrome) so as to view and-or access the files in your memory. On some Android system phones using Google Chrome: file:///sdcard/ can be used to view the files in the phone storage. When accessing a file using a C4droid program, note that scanf() will stop the string input at the first space, and so you may rather need to use gets().

The Android system comes with an app to display the files in memory storage: Settings App ---> Storage ---> Files . Google Files is another app made by the Google company, and which can be used to view what files are in memory. There are various ways to save your files on your phone to an external device(s) for file safety, backup and storage: file share via the internal Bluetooth (radio, communication, transmitter) system, USB cable to a computer, between two phones, phone to USB data storage. Some may require specialized cables for data transfer, such as for computer to computer and you will have to research this. One such cable is called an On-The-Go (OTG) cable such as for saving files directly to a USB data storage device or another phone. To save a file on your phone to a computer drive (including any attached USB drive) plug the phones USB charging cable into the computer USB port. In the phones settings/notifications select FILE TRANSFER mode. On your computer, you should now see the phone installed as like a storage drive to access, then locate the file on your phone and copy it and then paste it where you want it to go.

I set the "Buttons" location to "move all to the menu" (in the upper right of the editing screen). Select the Open menu button to access the files and to click on it to load it into the C editor/compiler. When done entering a C source file, it is good to Save it, and then you can then compiler it to check for errors. If there are no errors to fix, then you can Run and test it.

If you are satisfied with the C program, you can then choose Export so as to make an **APK** file from your compiled C program. Most of the default data there can be used, but it is best to enter a application title (ie., name) so as you know what it is about and does for when the memory about the specifics of and making it are slowly forgotten, and-or you share your app with others to use. The name of the APK file will still be that of the C source file, except that it will have the .APK filename extension. The APK file created will be placed in:

Ex: Filename: /storage/emulated/0/myprogram.apk

Note that on an "Android phone": /storage/emulated/0/ can be thought of as your phone's main directory or folder of the phones internal storage. A file may be for ex. located at: /storage/emulated/0/myfolder/myfile

Package name: com.myprogram : This associated, app data folder will be located in the directory: /storage/emulated/0/android/data

Application title: MyProgram

The APK file created will be placed in the same directory mentioned. You can press or click on this APK file so as to install it. You will get a warning about installing unknown (here, "homemade") Apps, and not from the popular App sites such as Google Play Store which tries to verify all apps that they have available as being safe for the device and free of bad things like malware. You may also be asked about the App not requiring or not-requiring any special (phone, system) access such as file access permission. Install the App and, if no special device access such as files for media and-or photos is needed, then select "Deny" as a safety measure. The created app will usually be found in your main App folder, and you can then press and hold on its icon and then "drag and drop" it to one of your phone's screen pages for easy access. The APK file that was made by the C4Droid compiler can be shared, traded and-or possibly sold. C4Droid will access files in the main internal storage memory > android > .com.app_name > files directory. You can select and copy a file into this directory.

Here is a basic example of how to access a file called myfile in the main Internal Storage directory or folder of the phone:

```
FILE *fp;       /* Creating a pointer to a file */
.
.
fp=fopen("/storage/emulated/0/myfile.txt,"rb");      /* Setting the file pointer identified as fp to a certain file. */
if(fp==NULL){  printf("\nFile Error , Press A Key");  fflush(stdout);
                fflush(stdin);  getch();  exit(0);
               }
```

Often by pressing on a file and selecting "File Info" from the menu, you can see what directory it is in, for example:

The phones main storage folder is:	/storage/emulated/0/
Camera photos are often in this folder:	/storage/emulated/0/DCIM/Camera/
Screenshots are often in this folder:	/storage/emulated/0/Pictures/Screenshots/
Downloads are often in this folder:	/storage/emulated/0/download/

Often a phone will come with a Google App called Files By Google, and this can be used to view the files in your phones internal storage. Most phones using the Android operating system also have a method to access your phones internal files, and that is to select: Settings menu or button > Storage > Files , and you can select to display it with the Android's Files App. Note that a "folder" is analogous to the older terminology of a "file directory" or location.

When running your app program, you can select Menu , Preferences, and (Shell) Terminal type. For simplicity, select either the "screen" or "screen-256color". The default is usually Linux. You may also wish to select the Close Window On Exit, and this will fully terminate the app.

There could be issues with some functions, etc, such as with the system() function. For example to clear the screen: system("cls") might not work in the resulting exportedl app. An alternative is to try using just this: clrscr(). Check the menu options and-or uses GCC instead of TCC. You could always print several blank lines to effectually or crudely clear the screen. Be sure to include all the header files needed by the functions in the program. Sometimes there are known solutions to try for certain issues, such as using fflush(0), for to process and clear all buffers, or fflush(1) instead of fflush(stdin) of which can be used before a user input such as: printf("\nPress A Key"); fflush(0); getch(). Also consider using fflush(stdout) so as to be sure text is displayed on the screen. Avoid using the ASCII bell sound character, such as in printf("\a"); ,because it may not work and-or cause issues with the Android phone operating system and cause the program to crash. Instead of using something like #include "stdio.h", rather use: #include <stdio.h> . Seek assistance from people and-or websites more knowledgeable if you need more help. Often, a solution is relatively simple.

The c4droid compiler wants the main() to have an integer return value, rather than void. So use something such as: int main(void) , and at the end of the program use something like: return 0 , or some other integer value.

There are special apps to create APK files from a list of the applications already installed on your device such as a phone. These files can be used for backup reinstalling, and-or for sharing when needed. This type of special app is called an APK extractor, and there are several available from the Google Play App Store. When you share an app, or need to reinstall it, you will need the APK file for that defines a specific App, and then you can install that App by pressing on the APK filename. You phone will process the .apk file in a program called a process installer.

Note that an .exe formatted program for a pc (personal computer, having the Intel Co. type of processor) will not work on another system such as the Android operating system for some phones. It is possible to obtain a third-party app that can simulate a pc, DOS system and run some .exe programs. Look up or search for DOS simulator apps. Likewise, some pc programs for the Windows operating system may be able to simulate the Android phone system and so as to create/edit phone apps. I, the author of this book have recognized C++ as being a superior programming language to (plan, basic) the C language in terms of capability, however, its syntax seems awkward, but there are also many similarities also. If you are learning and-or building simple programs, then knowing C++ is generally not needed, and may in fact complicate the issue of learning a practical programming language by its greater capabilities and-or complexities. **I recommend a new programmer begin with the C language.**

First, learn a computer language such as C and-or C++ before trying to make programs for the "Windows" or Android (ie, phone) operating system which have an increased complexity to learn and use for making even simple programs and-or apps, however, those do make a fuller use of those more robust, modern systems and to have the benefits and practicality of them such as graphics, mouse, sound and on-screen buttons ability for your programs and apps, and lets the users interact (ie., inputting, controlling) with them. For most people, just knowing C programming (ie., its syntax and structures) fairly well and being able to create some simple computer programs and-or phone apps is practical and enough for them.

The Android operating system began its creation in about 2003. It is based on the Linux kernal (core, main) operating system that was designed in about 1983 to be a new alternative to the Unix operating system, and so as to be used for personal computers (PC). By 2007, Android was being used in ("smart", ie., computer, mobile, "cell") phones, and these versions are said as being owned by Google Inc. of which currently owns the YouTube .com website. As of 2021, Android 12 is the latest version of the Android operating system. Some non-proprietary portions of the Linux and Android operating systems software are said as being "free, and open source (ie., publicly accessible)" software, and which can potentially be used and-or modified as needed.

Because programming a machine such as a computer to do useful and-or fun things is imaginative and-or beneficial, it can become not only a habit, but an addiction of which is not needed , and it may interfere with your health, your well-being, your friends, family and relationships. Much thinking can be stressful, and you need to be aware so as to be in a preventative state. Many get addicted to endless cycles of learning things and without actually having a goal of doing something with what they learned, and that is to create some useful programs for others, and rather than "figure-out" every possible detail of a computer system(s) and which is generally unrelated to most programs. An example of this would be a carpenter or auto mechanic who endlessly studies tools, parts and their design, practical tricks and how be a master at multiple choice exams, and yet never fixes or makes anything useful for others. Consider how much a person studies to learn, and then doesn't or can't even remember much of it, and to then apply it well. "Keep things simple" is a helpful concept wanted by most users of programs who just want them to be simple to learn and use, of which is often spoken as being "user friendly" and rather than full of a programmer's most complex and artistic programming skills possible.

Many computers, even the ones that have the Windows operating system, still have a "DOS mode" of programming where it may be called a "shell mode" and-or a "terminal (input, output, system accessing) mode" where commands such as: DIR and COPY, are typed and entered on the "command line" shown on the screen. There are several compilers still available so as to make computer programs on and for the older "DOS system" [technically a program in itself, like the Windows system is] computers. These compilers might be for example, C language compilers, and which the non-ANSI C ones have more functions to access the more advanced, modern computer systems. These functions can be used to access many of its system hardware and-or functions such as graphics, video, mouse input, and sound output, and without any Windows programming involved.   These programs you create may be called "DOS" or "terminal" programs.   Many of these older types of computers and-or systems also came with the BASIC language installed and-or on disk.   Today, we can download a BASIC language compiler so as to still use BASIC.   I believe the C computer programming language was created to overcome some limitations of the BASIC computer language which itself was a giant leap from the more difficult to read, edit, and-or program machine or assembly programming languages.   The DOS (Disk Operating [ie., accessing and control] System is user accessed by typing in special DOS commands which are technically a type of (system command and control) programming language or tool.   A BATCHFILE is simply a plain text file, much like a C language program, but with the .bat filename extension, and is essentially a list of DOS commands which may include some decision ability such as the Basic-like IF and GOTO commands. The commands are generally processed from the top of the file to the bottom, one by one just like regular computer programs. Modern forms of DOS seem to have less commands available to the user.   A batchfile is a program of DOS or system commands. To see a list of the DOS commands, enter: HELP on the command line.   To see the specific HELP data about a particular command, enter the commands name followed by a space character and-or then: /?

For much information about programming a device with the Android operating system, please visit: https://developer.android.com   There is also a link to this website and it is given on a page that is called something like: "Browse All Of Googles Produces And Services", and it was currently: https://about.google/products   , and then select the menu selection called: Android OS (ie., Android Operating System). There are also many websites and-or webpages throughout the internet that offer many tips and-or answered questions about programming any well known language and-or program.   Some other search words for Android programming are: Android App Development Kit, Android SDK (Software Development Kit) and Android Studio. There are also various websites that have associated programmers who can make apps for you for a fee, and just let them know what you are considering and negotiate a fee. You may need to first copyright your idea(s) or be able to somehow verify you were its creator, perhaps in a previous email to yourself and-or to a friend to save, or perhaps a published (ie., publicized, offered to the general public) video, and before letting others utilize them for their own control and benefit.   Even if you let others use your ideas or app and-or a version of it freely, you still need to have some type of copyright or verification so as others will not claim and-or independently create the same general type of idea, and then they may say that you and-others using it can no longer use their idea or need permission and-or a fee to use it.

After making the C source code for a program with C4Droid, I have noticed that this file was not displayed right in Windows, Notepad program. In particular, it was missing some new lines and was seen as jumbled together.   **Windows Notepad** program is supposed to be a pure/only ASCII text editor. I put this .c source code into the DOS EDIT.com text editor and it was displayed right, and could then be saved and then displayed in Windows Notepad. An option to correct the .c source code for proper display in Notepad is to make a copy of the file using a homemade program as shown in this book, and when a byte value of 10 (ASCII for LF = Line Feed) is read, then first write a byte value of 13 (ASCII for CR = Carriage Return), and then write the byte value of 10. In short byte 10 will then effectively become a byte 13 and then followed by 10. The overall resulting sequence then becomes CR, LF.

89.8	1.567305668291	0.9999939076578	0.003490651415238	286.4777340104
89.9	1.569050997543	0.9999984769133	0.001745328365913	572.9572133495
90.0	**1.570796326795**	**1**	**0**	**[infinite, undefined]**

Note that for example: 1.745329251994e-005 = 1.745329251994 (10^-5) = 0.00001745329251994

To find the trigonometric values of angles greater than 90°, convert the angle to its corresponding trigonometrically equivalent acute reference or corresponding angle that is less than or equal to 90°.
Ex. Sin 100° = Sin (180° - 100°) = Sin 80°

Here is an example of how to find the trigonometric values of angles that are between the table-list entry values.
A non-proportion method of interpolation is used.

Ex. Find SIN 37.5°

Here is a method that uses a common type of linear (line-like) interpolation using proportions:

$$\frac{\text{SIN } 37^\circ}{37^\circ} = \frac{\text{SIN } 37.5^\circ}{37.5^\circ} \qquad \text{after using substitution and solving for SIN } 37.5^\circ$$

$$\text{SIN } 37.5^\circ = \frac{37.5^\circ \ \text{SIN } 37.5^\circ}{37^\circ} = \frac{37.5^\circ\,(0.60181502315205)}{37^\circ} = 0.6099476586000507$$

For the angles in the method above, you can use it's degrees or radian equivalent and get the same result.

The true value of SIN 37.5° is 0.6087614290087208. The calculated value has a difference of: +0.001186229591329968 from this true value, or about: +0.001

Here is a slightly better linear interpolation method that uses the "point slope" form of a line which will consider a more correct slope value for those close points or area of the (sin) curve, here, points close to the known sin 37° Since the slope value of a line is a strict (ratio) numeric value, it is unitless, therefore, use radian (unitless, strict numeric) angle values.

$m = \dfrac{(y2 - y1)}{(x2 - x1)}$: slope of a line, between two points (locations) on it

$(y2 - y1) = m\,(x2 - x1)$: "points and slope" for m of a linear (line) equation

The slope of a tangent line (ie. between two close points on the curve) at a point on the SIN curve is not a constant value as for lines, since the SIN curve is non-algebraic and non-linear. The slope value on a line or curve is equal to the derivative of the curve at that point or location. The derivative of the SIN curve at any point, hence also the entire curve, is equal to the COS curve.

Here, the (x) values are the angle values, and the (y) values are the corresponding SIN values:

$(y2 - y1) = m \quad (x2 - x1)$

(SIN 37.5° - SIN 37°) = COS 37° (37.5° - 37°) After some simplification and transposing:

SIN 37.5° = COS 37° (0.5°) + SIN 37° 0.5° = 0.00872664625997165 (radians):

SIN 37.5° = 0.79863551004729 (0.00872664625997165) + 0.6018150231520484

SIN 37.5° = 0.6087844327388832 : a calculated ("close" mathematical estimate-approximation) interpolated value

This calculated value differs from the true value by only: 0.000230037301623964, or about:: +0.0002

This above table, and many others in the book, were made with the assistance of a computer which is essentially a fancy automatic calculator machine with a typing (letters and numbers) keyboard input screen. This electronic machine can process what are called programs which are composed of smaller steps of the desired calculation, and for its input and output such as on the screen and-or printer. In the old days, tables such as this were calculated by hand and pen, usually with many people involved, and some to compare or check the work of the others. But once it was done, it was treasured and distributed in books to be used for many years and even till this day.

To calculate a value that is not listed in the table above, we can use a method that is similar to that previously described above for calculating a value that is not listed in the SIN x table.

Since the slope of the e^x curve is equal to e^x we will use:

(y2 - y1) = m (x2 - x1)

(y2 - y1) = e^x (x2 - x1)

Here are two entries from the table, and we need to find the value of e^0.5405:

e^0.540 = 1.7160068621849 and e^0.541 = 1.7177237273365

The result should be a value that is someplace between these to values, of about 1.7165.

(e^0.5405 - e^0.540) = e^x (0.5405 - 0.540) After some simplification and transposing:

e^0.5405 = e^0.540 (0.0005) + e^0.540

e^0.5405 = 0.000858003 + 1.7160068621849

e^0.5405 = 1.7168648651849 : a calculated ("close" mathematical estimate-approximation) interpolated value

This calculated value differs from the true value by -0.00085822, or about:: -0.0008, which is less than a thousandth.

To calculate a value that is not listed in the table above, we can use a method that is similar to that previously described above for calculating a value that is not listed in the SIN x table, or e^x table.

Since the slope of the natural logarithm of x curve is equal to 1/x we will use:

$$(y2 - y1) = m \ (x2 - x1)$$

$$(y2 - y1) = 1/x \ (x2 - x1)$$

Here are two entries from the table, and we need to find the value of e^0.5045:

$\ln 0.504 \ -0.68517901091077$ and $\ln 0.505 \ -0.68319684970678$

The result should be a value that is someplace between these to values, of about -0.684

$(\ln 0.5045 - \ln 0.504) = (1/0.504)(0.5045 - 0.504)$ After some simplification and transposing:

$\ln 0.5045 = 1.984126984 (0.0005) + \ln 0.504$

$\ln 0.5045 = 0.000992063 + (-0.68517901091077)$

$\ln 0.5045 = -0.68418694791077$: a calculated ("close" mathematical estimate-approximation) interpolated value

This calculated value differs from the true value by +0.000,000,492, or about: +0.000,000,5 , or less than a millionth.

1.000	1						

$\sqrt{10} = \sqrt{10^1} = 3.1622776601684$

$\sqrt{100} = \sqrt{10^2} = \sqrt{(10)(10)} = \sqrt{10}\ \sqrt{10} = 10$

$\sqrt{1000} = \sqrt{10^3} = \sqrt{(100)(10)} = \sqrt{100}\ \sqrt{10} = 31.622776601684$

$\sqrt{10{,}000} = \sqrt{10^4} = \sqrt{(1{,}000)(10)} = \sqrt{1000}\ \sqrt{10} = 100$

$\sqrt{100{,}000} = \sqrt{10^5} = \sqrt{(10{,}000)(10)} = \sqrt{10{,}000}\ \sqrt{10} = 316.22776601684$

$\sqrt{1{,}000{,}000} = \sqrt{10^6} = \sqrt{(100{,}000)(10)} = \sqrt{100{,}000}\ \sqrt{10} = 1000$

Ex. Use the table above to find the square root of 57:

$$\sqrt{57} \;=\; \sqrt{(0.57)(10\hat{}2)} \;=\; \sqrt{0.57}\;\sqrt{100} \;=\; 0.75498344352708\;(10) \;=\; 7.5498344352708$$

Ex. sqrt(6.35) = sqrt((10) (0.635)) = sqrt(10) sqrt(0.635) = (3.1622776601684) (0.79686887252546) =
= 2.51992063$\underline{2}$

To calculate a value that is not listed in the table above, we can use a method that is similar to that previously described above for calculating a value that is not listed in the SIN x table, or e^x table.

Since the slope of the square root of x curve is equal to $1/(2\sqrt{x}\,)$, we will use:

$$(y2 - y1) \;=\; m\;(x2 - x1)$$

$$(y2 - y1) \;=\; (1/(2\sqrt{x}\,))\;(x2 - x1)$$

Here are two entries from the table, and we need to find the square root value of: 0.5045

square-root of 0.504 = 0.70992957397195 and square-root of 0.505 = 0.71063352017759

The result should be a value that is someplace between these to values, of about 0.7103

$(\sqrt{0.5045} - \sqrt{0.504}\,) = (0.5/\sqrt{0.504}\,)\,(0.5045 - 0.504)$ After some simplification and transposing:

$$\sqrt{0.5045} \;=\; 0.704295212\;(0.0005) \;+\; \sqrt{0.504}$$

$$\sqrt{0.5045} \;=\; 0.000352147 + 0.70992957397195$$

$\sqrt{0.5045} = 0.71028172097195$: a calculated ("close" mathematical estimate-approximation) interpolated value
The true value is: 0.71028163428319...

This calculated value differs from the true value by about: +0.000,000,086, or about: +0.000,000,1 , or less than a millionth.

A CUBE ROOT TABLE

The following table is for three decimal point places. A fourth place would require a table having ten times more values.

0.000	0	0.001	0.1	0.002	0.12599210498949	0.003	0.14422495703074

1.000	1						

$\sqrt[3]{10} = \sqrt[3]{10^1} = 2.1544346900319$

$\sqrt[3]{100} = \sqrt[3]{10^2} = \sqrt[3]{(10)(10)} = \sqrt[3]{10}\ \sqrt[3]{10} = 4.6415888336128$

$\sqrt[3]{1000} = \sqrt[3]{10^3} = \sqrt[3]{(100)(10)} = \sqrt[3]{100}\ \sqrt[3]{10} = 10$

$\sqrt[3]{10{,}000} = \sqrt[3]{10^4} = \sqrt[3]{(1{,}000)(10)} = \sqrt[3]{1000}\ \sqrt[3]{10} = 21.544346900319$

$\sqrt[3]{100{,}000} = \sqrt[3]{10^5} = \sqrt[3]{(10{,}000)(10)} = \sqrt[3]{10{,}000}\ \sqrt[3]{10} = 46.415888336128$

$\sqrt[3]{1{,}000{,}000} = \sqrt[3]{10^6} = \sqrt[3]{(100{,}000)(10)} = \sqrt[3]{100{,}000}\ \sqrt[3]{10} = 100$

Ex. Use the table above to find the cube root of 57:

$\sqrt[3]{57} = \sqrt[3]{(0.57)(10^2)} = \sqrt[3]{0.57}\ \sqrt[3]{100} = 0.82913443418497\ (4.6415888336128) = 3.8485011312768$

To calculate a value that is not listed in the table above, we can use a method that is similar to that previously described above for calculating a value that is not listed in the SIN x table, or e^x table.

Since the slope of the cube root of x curve is equal to $1/(\ 3\ (\sqrt[3]{x}\ )^2\ )$, we will use:

$(y2 - y1) = m\ (x2 - x1)$

$(y2 - y1) = 1/(\ 3\ (\sqrt[3]{x}\ )^2\ )\ (x2 - x1)$

Here are two entries from the table, and we need to find the cube root value of: 0.5045

cube-root of 0.504 = 0.79581144157928 and cube-root of 0.505 = 0.79633742417892

The result should be a value that is someplace between these to values, of about 0.7961

$(\sqrt[3]{0.5045} - \sqrt[3]{0.504}\ ) = 1 / (3\ (\sqrt[3]{0.504}\ )^2)\ (0.5045 - 0.504)$ After some simplification and transposing:

$\sqrt[3]{0.5045} = 0.52633031850481\ (0.0005) + \sqrt[3]{0.504}$

$\sqrt[3]{0.5045} = 0.00026316515925241 + 0.79581144157928$

$\sqrt[3]{0.5045} = 0.79607460673853$: a calculated ("close" mathematical estimate-approximation) interpolated value
The true value is: 0.79607451976095...

This calculated value differs from the true value by about: +0.000,000,087, or about: +0.000,000,1 , or less than a millionth.

Table Of Fractional Powers Of (e)

For using this table, see the article on: Calculating Powers Of (e) Using A Small Table Of Constants.

EXTRAS AND LATE ENTRIES

These topics and-or articles are either not specifically math oriented and-or late entries in this book, but they may be interesting and useful for many people. The word "maths" now seems to includes all useful things of science. Distribution and access of knowledge can sometimes be a problem due to a variety of reasons, and it is therefore practical to just include what I could in this one book, and that is why it has a generous amount of pages.

SOME TIPS TO TYPE EASIER

This discussion is about typing better so as to record your thoughts, data, and communicate better via typed messages. Many have never learned to formally type and rather "chicken pluck" each key with one finger rather than use both hands and most fingers. The notes below will help you use and-or remember the keyboard, key layout or positioning.

Standard key layout or positions:

1 2 3 4 5 6 7 8 9 0
Q W E R T Y U I O P
A S D F G H J K L ;
Z X C V B N M , . /
(space key)

People who do much typing should place their hands on what is called the "home row" of keys. These keys are:

Left Hand   Right Hand   : excluding the thumb finger

A S D F   J K L ;   ,   :   **;** = semicolon   and   **:** = colon, press shift and semicolon for colon

Once you place your fingers on these keys, you may feel a slight bump on the F and J keys on most modern keyboards. This will help ensure your fingers are positioned correctly on the "home row" of keys. The home row is also called the middle set or row of keys. The row above it is often called the upper row. The row of keys below the home row is often called the lower set of keys, or simply the bottom row.

All the other keys are pressed by moving a "home row" finger up, down, left or right such as for the G and H keys. The finger used is usually the one of closest to the key and-or the one most comfortable.

Key or finger	The other keys typically used or pressed by that same finger.
A	Q , Z
S	W , X
D	E
F	R , T , C , V , G , B
J	H , Y , U , N , M
K	I , **,** (comma)
L	O , **.** (period)
;	P , / (forward slash) , **"** (quotation marks , **?** (question mark)

By using the above method, all 26 letters of the English alphabet can be typed. The shift keys which are just left and right of the bottom row are usually used to type in a capital or uppercase letter by first pressing a shift key with a "pinky" or small finger that is most opposite from your thumb finger, and then also pressing the desired key. If the letter key to press is with the right hand, the left hand will first press its corresponding side shift key. If the letter key to press is with the left hand, the right hand will first press its corresponding side shift key.

The space bar which is below the bottom row of keys is used to enter a blank space or letter such as using one space between words, and two spaces between sentences. The space bar is usually pressed using a thumb finger.

Here are some ways to remember where the keys or letters are located on the keyboard:

1. Remember the home row of keys: A S D F J K L ;
   The F and J keys often have a small bump on them so you can feel if your fingers are positioned on the home row.

2. Notice how the first letter A and the last letter Z are next to each other.

3. Notice the vertical-like arrangement of the letters: C , D , E

4. Notice the close, horizontal arrangement of the letters: F , G , H

5. Notice the close arrangement of the letters: I , J , K , L

6. Notice the close arrangement of the letters: M , N and O , P

7. Notice in the upper row of keys and the infamous: QWERTY set of keys

8. Notice in the upper row for the right hand, the letters of: Y , O , U and I

9. Notice in the upper row for the left hand, the letters of: W , E

10. Notice the arrangement of the letters: T , H , M as for the word: T , H , E , M

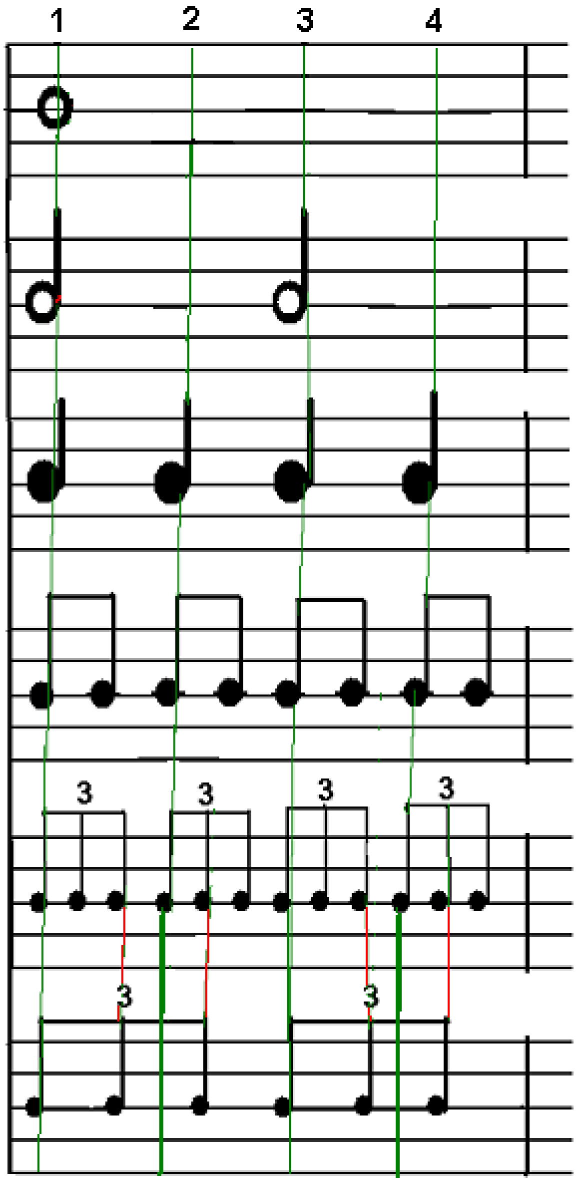
11. Besides the vowel of A, all the other vowels are in the upper or top row: E , I , O , U , Y
    The last four of these vowel letters are near to each other.

12. After reviewing the above tips, try typing the alphabet (letters A through Z, usually the lower case versions first) and some words. You can look at where the keys are located at first, but later after a few weeks, you many not have to look as much. Typing speed is generally unimportant, but rather efficiency or few mistakes is what matters most.

COMMON MUSIC NOTATION OF THE TIMING AND DURATION OF NOTES

FIG 281]

A music symbol can represent a duration or beat, a note, or a rest where no note is played. The green line is used to indicate the timing of the start of one of the 4 beats in a measure.



: beat number

Whole Note, has the duration of the entire or whole measure.

Half Notes
Half of a 4 beat measure.

Quarter Notes
There are 4 beats in a common measure of music.

Each quarter note has a duration of 1/4 = 0.25 = 25% of the measure.

Eighth Notes

An eighth note has half the duration of 1 beat. There are two eight notes in one beat.

Quarter Note Triplets

A triplet puts three notes or durations in the count or duration of two notes.

For two notes, each will have 1/2 = 0.5 = 50% of the beat.

Half Note Triplets

For three notes in a beat, each will have just 1/3 = 0.333 = 33.3% of the beat. The timing of each note of a triplet is at 0%, 33.3% and 66.7%

Though there are usually many notes indicated on "music staffs" which are a notation system for representing music, I have only used the "B" note here so as to keep things simple

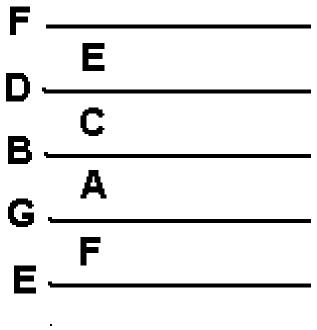
In your mind, you can count the eighth notes as: 1, 2, 3, 4, 5 , 6, 7, 8, however, they are more commonly counted as two sets of 4 as: 1, 2, 3, 4 , and 1, 2, 3, 4.

The quarter note triplets, and where each triplet set of notes starts on the beat, can be counted as: 1, 2, 3.

A half note triplets can be counted when considering the timing of two sets of quarter note triplets as being:
1, 2, 3 for one beat and 4, 5, 6 for another beat, and each note of a quarter note triplet will correspond to: 1, 3, 5

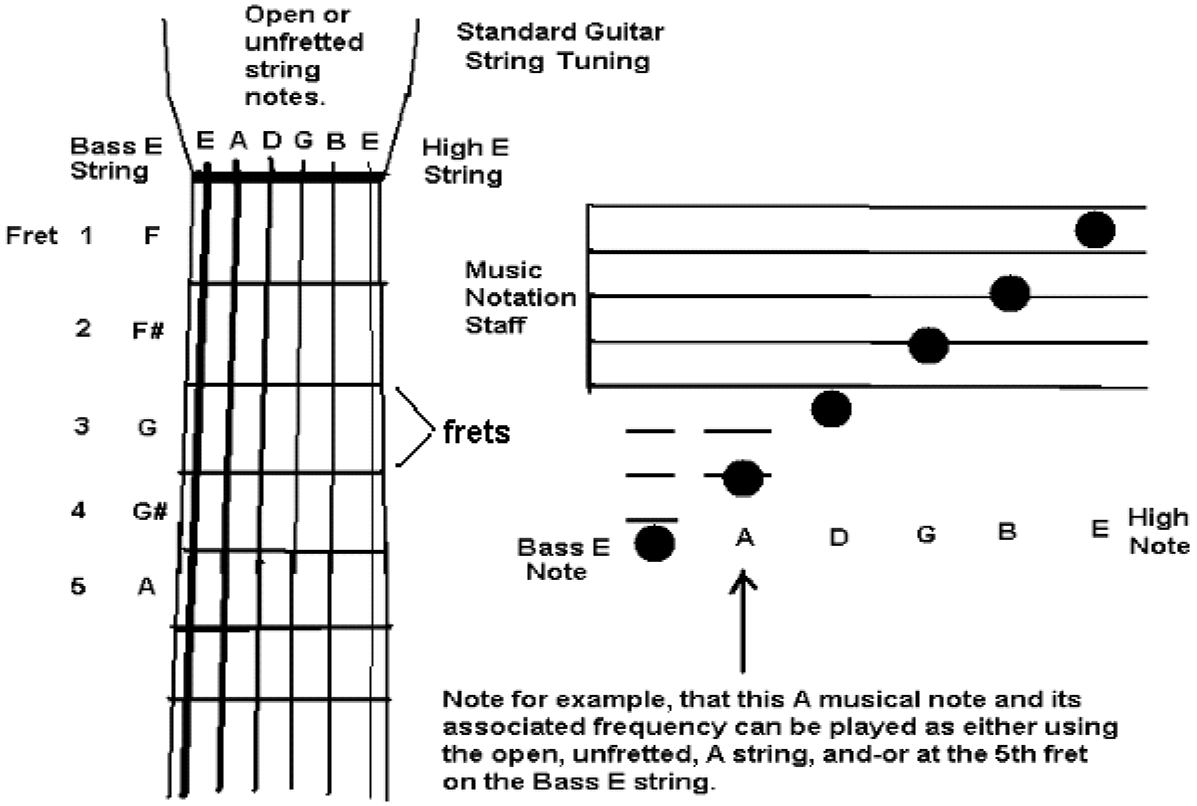
NOTES OF THE LINES AND SPACES OF THE MUSIC STAFF NOTATION

[FIG 282]



STANDARD NOTES, NOTATION, AND TUNING OF EACH GUITAR STRING

[FIG 283]



Note for example, that this A musical note and its associated frequency can be played as either using the open, unfretted, A string, and-or at the 5th fret on the Bass E string.

The right side of the above figure shows the music notation for each of the six strings of the guitar. Beginners will generally first learn the higher frequency, thinner strings on a guitar. Being familiar with music notation helps people quickly learn songs, a guide, and-or how they were intended to be played in a formal manner. Guitarists and or other musical instrument players can improvise by just finding or knowing the chords of a song, and then playing some pleasing sounding notes in the scale associated with the known or indicated chord. A guitarist may even play, or need to play, each chord and-or note of the song using a certain number of half-steps higher or lower on the fretboard so as to change the entire pitch of the entire song, perhaps so as the singer can sing it easier.

EXAMPLE GUITAR CHORDS

A chord is two or more sounds or notes played at the same time. The notes chosen to be played are usually those that have a pleasing sound.

A C major chord includes these notes in the C major scale: **1**, **3** and **5**.

Note #:	**1**	2	**3**	4	**5**	6	7	8
Note name:	**C**	D	**E**	F	**G**	A	B	C

Ex. C major chord = C, E, G : For this chord and or scale, C is called the "root note". here, root = initial or base note. C is the basis of that chord, and the starting or initial note of that scale.

The notes of any chord can be played and-or noted with musical notation as any combination or order of the notes associated with that chord. For example, and with the first note being lowest in frequency and on the music staff:

Ex. C major chords = Cmaj = (C, E, G) and-or (C, G, E) and-or
(E, C, G) and-or (E, G, C) and-or
(G, C, E) and-or (G, E, C)

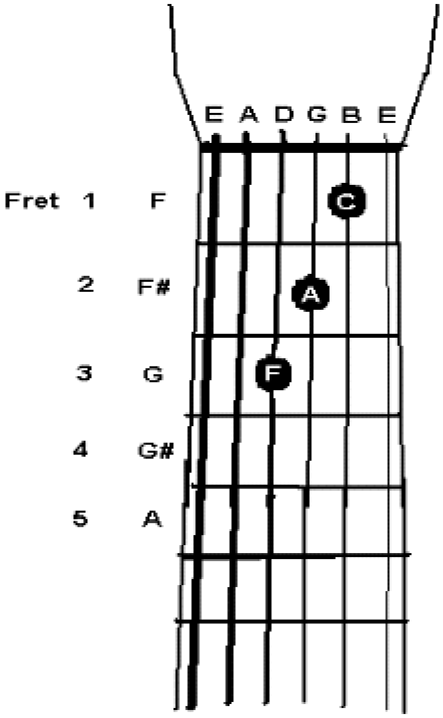
A C minor chord includes these notes in the C minor scale: 1, 3b and 5.

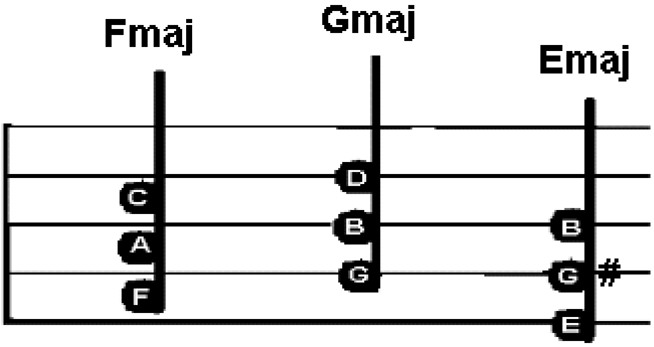
In relationship to the major scale, a minor scale has a flatted third note, and this means that it is one fret lower on the guitar fretboard. It also means that the third note is a half-step (or "1 chromatic step") less than the corresponding note in the major scale.

Ex. A C minor chord = Cm = (C, Eb, G)

A major chord can be thought of as having a direct or powerful sound and feeling, whereas a minor chord can be thought of as having a soft, moody or serious sound and feeling.

[FIG 284]





In the above image, shown on the left is the 6 guitar strings, and with the fingering shown for an F major chord. The other strings are either to be muted and-or not played, and this is sometimes shown with an x symbol at the end of the string. An open or unfretted string that is to be played or included in a chord is usually shown with a O symbol.

Beginner guitar players often develop sore fingers,and it will take several days to a month of casual use so as to develop a callous (harder skin) on the tips of your fingers so as to play more easily.

Once you can play the F major chord indicated, if you move and-or slide your hand 2 frets and-or 2 fret positions up or higher along the guitar fretboard, you can play the G major chord which is indicated on the music staff shown.

Once you can play the F major chord, (F, A, C), indicated, if you move and-or slide your hand 1 fret and-or position lower along the guitar fretboard, you can then play the E major chord, (E, G#, B) which is indicated on the music staff shown above. If you were to play these note positions of the F major chord just one whole step (= two half-steps or frets) higher along the fretboard, you can play the Gmajor chord = Gmaj chord (G, B, D). While playing the Gmaj chord, if you were to rather include Bb, instead of B, and which is one fret and-or half-step lower than the B note, you can play the Gminor = Gmin = Gm chord (G, Bb, D). The minor chord is sometimes said as having a "flatted-third note" (with respect to the major scale). You can then try to play Am, Fm and Em chords and-or notes. Clearly, there are many patterns to position your fingers and to then play chords and-or play individual notes in a chord scale.

While playing the F chord, you can also include the F note on the first fret of the first string which is the high E string. This F note is an octave higher and-or twice the frequency of the F note shown on the music staff. You can play this F note, and the C note at the first fret on the second or B string by using the flat part of your index finger to play both of these notes together at once, and this is called a bar-chord when a finger is used to fret several strings and-or notes at the same time.

If you were to play the open strings of (D, G, B), this is a Gmaj chord. And then moving this up two frets and-or half-steps, the chord would be Amaj (E, A, C#).

Notice for example that of the F chord shown starts on a blank space between the lines of musical staff, and that the next two notes of that chord are also on the next consecutive spaces. It could be said that from space to space is a "third note higher" or three steps in the scale, and that from a line to line is a "third note higher" or three steps in the scale.

There is another system of music notation for guitar playing and it is called Guitar Tablature or Guitar Tab. This notation is similar to a combination of both the standard musical notation system as shown in the above image on the right with a five line music staff, and also similar to the 6 strings of the guitar as shown on the left. The combined result is a 6 line music staff where each line is the string, and the note to play on that string is indicated by the fret number and-or fret position on that string. A bass guitar is similar to a guitar, and it has the 4 thicker strings as that of a guitar: E, A , D, G, of which for the bass guitar also thicker and usually longer so as to produce a lower frequency sound.

The "(musical) key of C" is often used for teaching what notes are on the musical notation staff. The key of C does not have any sharped or flatted notes. Other keys will have at least one sharped note or one flatted note. For example the scale or key of G has these following notes: G, A , B , C , D , E , F#, G. We see that the scale contains an F-sharp note. Still there is a pattern as with the C scale or key:

root note (1), whole-step (2), whole-step (3), half-step (4), whole-step (5), whole-step (6), whole-step (7), half-step (8).

A whole-step is two semi-tones higher in frequency, and since each fret is a half-step or semi-tone in a scale, a whole-step is two semi-tomes and-or frets higher on the guitar fretboard. The key or scale of F has one flatted note, and that is Bb ("B-flat"): F, G, A Bb, C, D, E, F.

Here are the approximate frequencies of the standard guitar tuning based on a standardized A note being 440 hz.:

String	**Approximate Frequency in hz.**	Some types of tuners: reed, tuning fork, electronic, frequency counter
Bass E	82	
A	110	:The A string on a guitar may sometimes be noted as 220 or 440 hz. such as on some "reed tuners".
D	147	
G	196	
B	247	:this is practically 250hz, and which is two octaves lower than 1000hz...500hz..250hz..125hz...62.5hz
High E	330	: This is two octaves higher than the Bass E note. 82hz...164hz...328hz

These frequencies shown above can be verified by the discussion about string length and frequency in the book.

Here are some of the common major and minor chords and their notes.

	Major Chord Notes	**Minor Chord Notes**	**8 Note Of The Common "Western" Major Scale**	
	(1 , 3, 5)	(1 , b3, 5)	**1** 2 **3** 4 **5** 6 7 8	
C	(C, E, G)	(C, Eb, G)	**C**, D, **E** , F, **G**, A , B , C	
D	(D, F#, A)	(D, F, A)	D, E , F#, G, A , B , C# , D	
E	(E, G#, B)	(E, G, B)	E , F#, G#, A , B , C#, D# , E	
F	(F, A, C)	(F, Ab, C)	F, G, A , Bb , C , D , E , F	: Bb = A# , "B flat equals A sharp"
G	(G, B, D)	(G, Bb, D)	G, A , B , C , D , E , F# , G	
A	(A, C#, E)	(A, C, E)	A , B , C# , D , E , F# ,G# , A	
B	(B, D#, F#)	(B, D, F#)	B , C# , D# , E , F# ,G# , A#, B	
C	(C, E, G)	(C, Eb, G)		

As shown above, the major chord has the following notes of its major scale: (1, 3, 5). As shown above, the minor chord also has the following notes of its minor scale: (1, 3, 5). In reference to the major scale, this 3 note of the minor scale is equivalent to a flatted or minor third (ie. 3b) note of the major scale.

To play a major-7 chord, play the major chord and also include the 7th note of that major scale. For example:

Fmaj7 = (F, A, C, E) : This is the F chord shown above, but also includes the open (e) string and-or note.

Cmaj7 = (C, E, G, B) : for example, this C note can be played at the third fret of the A string. The E note can be played on the second fret of the D string. The G note can be played as an open G string. The B note can be played as an open B string.

To play a "7th chord", flatten the 7th note of the scale by a half-step and-or fret. This is technically a "flatted maj. 7th" chord.

For example, here are the formalized notes of some chords, of which are more playable on a piano instrument, and a guitarist needs to consider how, what notes and where to play a chord and any significant sounding special note(s) in it.

C7 = (C, E, G Bb) = (1, 3, 5 , 7b) : sometimes a flatted note is called a diminished note

To play a "6th chord", include the 6th note of that scale. For example:

C6 = (C, E, A) = (1, 3, 6)

C9 = (C, E, G, Bb, D) = C7+9 = (1, 3, 5, 7b, 9)

Cadd9 = (C, E, G, D) = C+9 = (1, 3, 5, 9)

Csus4 = (C, F, G) = C+4 = C4 , : C chord with "suspended" 4th note. This chord is often then followed by the corresponding major chord: (C, E, G) so as to have a "resolving" sound or change.

Caug = C augmented = Caug. 5th = C+ = (C, E, G#) = (1, 3, 5#) = C+6b , This chord is often followed by the corresponding "6 chord": (C, E, A).

Cdim = C diminished = (C, Eb, Gb, A) = (1 , 3b , 5b, 6) , C dim = Eb dim = Gb dim = A dim
, diminished basically means reduced

The most common chords used in a song:

Root note chord (**1**) , Ex. C maj
Fourth note chord (**4**) , Ex. F maj
Fifth note chord (**5**) , Ex. G maj

Some other chords occasionally included in a song based on a C major scale:

Second note minor chord (2m) , Ex. D min , such as (D, F, A), and these are also notes in the C major scale.
Third note minor chord (3m) , Ex. E min , such as (E, Gb, B)
Sixth note minor chord (6m) , Ex. A min , such as (A, C, E)
Flatted seventh note chord (7b) , Ex. Bb , such as (C, E, G, Bb) , although not all notes need to be played at once

Of any chord played, it is not uncommon to find the flatted 7th note (7b) of the scale occasionally being included. The chords and-or their corresponding note number in the scale of a song may be called as the chord progression of the song. If you are able, obtain a basic guitar "chord book" that shows where to place our fingers on the fretboard so as to play a certain chord, and observe what musical notes are to be played. It may take some amount time to get used to the feel of a guitar, chords, etc., and then the guitar will be easier to play.

Observe the patterns of the position of notes in a particular scale on the fretboard so as to help play the notes in scale. Improvising and-or "playing along" with recordings is a way to get involved with the music. Often a player may need to play both chords and single notes of a scale, and of which are could located near or at the chord being played.

On a scientific level, it is possible to create reference sound frequencies. If you had a wheel with say 60 bumps (protrusions, raised surface area) and-or gear teeth equally spaced around its circumference, rim or edge, and then spun that wheel at 1 revolution or rotation per second while holding a rod against that wheels edge or circumference, you would hear a 60hz sound tone. This is due to the 60 bumps and-or sound pulses per second created when the rod collided with the edge of the wheel and some of that energy from the collision was converted to sound energy. More bumps and-or a faster rotation can be used to create higher frequencies. This method discussed here was actually the method used to create the various notes and their corresponding frequencies with the first electronic organs, but instead of a stick against the circumference of the organs various diameter sized, spinning tone-wheels, a electro-magnetic transducer (ie., energy converter) or "(energy) pickup" was used near the circumference edge of each wheel, and its construction was essentially a coil of wire wrapped about a magnet. The varying or AC signal output from this pickup usually had a (smooth, undistorted) sine waveform, much like that from a bell. These organs were not completely electric like modern organs which use only electronic oscillators, but they were both partly mechanical, and partly electrical, hence being electromechanical. The initial invention of the **tone-wheel** is credited to **Thaddeus Cahil** in 1896, and the organ was called the Telharmonium. Because of its large size and cost, only a few Telharmonium organs were built. When electronic signal amplification was made practical after the invention of the vacuum tube amplifier, electronic organs would become smaller and more practical, such as the electromechanical organs produced by the Hammond Co. in 1935. Hammond organs were relatively affordable and were often installed in church buildings that had limited space, and since a full sized pipe organ was very large and very costly. The sound of an electromechanical Hammond organ can heard within many popular musical recordings, particularly from the 1950's through the 1970's.

Ex. To make a 1000hz tone, a large diameter wheel with 100 bumps about it will need to spin at 10 revolutions per second = 10rps:

Each physical bump or vibration on the tone-wheel will produce 1 electrical pulse or vibration.

Frequency = (revolutions per second)(number of bumps on the wheels edge for one revolution) =

Frequency = (10 revolutions / second) (100 bumps, pulses or vibrations / revolution) =

$$\text{Frequency} = \frac{10\ \cancel{\text{revolutions}}}{1\text{s}} \times \frac{100\ \text{bumps}}{\cancel{\text{revolution}}} = \frac{1000\ \text{bumps}}{1\ \text{second}} =$$

Frequency = vibrations per second = bumps per second = waves per second = cycles per second = 1000 hz

Note that this wheel has a rotational frequency or "angular velocity" of 10 revolutions per second, while the outputs sound of this system has a frequency of 1000 cycles per second. Each note on the organ's keyboard had a corresponding tone-wheel.

The "pickup" in an electric guitar is essentially a small electricity and-or signal (ie.,having a frequency part) generator. It is usually made by winding a coil of wire around a permanent (no electricity and-or current needed to produce the magnetism) magnet. When the string made of metal moves and-or vibrates near the pickup, the magnetic field will move slightly and produce an electric signal in the coil, and which is then sent to an electronic amplifier so as to make it a stronger signal with more power, particularly current, so as to move and-or vibrate an audio speaker.

The first assigned note, the A-note and its corresponding frequency is most likely due to the standardized 60 seconds in a minute. The multiples of the 60 hz frequency, musical note and-or its octaves (double the frequency) are then: 60, 120, 240, 480 and 960hz. Through the years, the frequencies of the standardized notes have slightly varied due to various reasons. Today, 440hz is the modern, standardized frequency of the A-note and-or tone, and 55hz is a lower frequency octave of the A-note. Musicians are generally not concerned with the actual frequency of a note(s), but are rather concerned about being "in tune", or tuned to having the same tone or note as that of any reference tone or note available, and particularly so when more than one instrument is being played at the same time by a group of people. It is recommended that musicians obtain a calibrated pitch-pipe (a small (vibrating) metal reed instrument which a person can blow air into) and-or a (metal) tuning-fork designed for tuning their instrument. Today, it is possible to also tune an instrument by using audio recordings of frequencies and-or notes, and-or by using a frequency meter. Some instruments cannot, and-or should not, be tuned, such as having certain metal lengths like a xylophone, various wind instruments, or tubular bells, and rather the entire orchestra must be tuned to these instruments so as every instrument is "in tune".

It is quite possible to construct a tone wheel that will interrupt a beam of light from reaching a light sensor, and so as to create electric pulses that way instead of using an electromagnetic pickup sensor.

COMMON GUITAR SCALE LENGTHS AND FRET SPACINGS

These tables were made by using a computer program made by the author of the Mathization ebook.

In general, the longer the scale length, the more the tension upon the strings is needed for standard tuning (EADGBE). This is due to that the length of the open or unfretted string is then longer which lowers its natural or fundamental frequency and when at the same standard tuning tension, and then more tension will be needed to raise it up to the desired frequency and-or note. An alternative to raising the tension on the strings so as to obtain a higher frequency and-or note is to use a mechanical device called a capo, and which is like movable clamp that can be set by the player and it is used to simulate the nut of a shorter scale length stringed instrument. New players and-or people with small hands may wish to use a capo and-or obtain a short scale guitar which usually has a thinner neck. A problem now with a very short scale length guitar is if the strings will have enough tension to feel right when tuned to standard tuning, but it is not usually an issue for many. With a capo, another less used option is to tune each string of the guitar a fret (ie., half-tone) or more lower than the standard tuning and place the capo up from the nut at the same number of steps of lower tuning, and so as to obtain a standard tuning. Using this method will also reduce the tension of the strings. The author of this ebook has a computer program to calculate the fret location and-or spacings given an input scale length. Shown below are the fret spacings for a 24.75" (regular) and 23.0" (medium) scale length guitar, and a 30.0" "short-scale" bass guitar. A standard bass scale length is 34", a medium bass scale length is 32", and a short-scale base length is 30". Generally, the shorter the scale length, the neck thickness and width is also thinner.

```
SCALE LENGTH  =  24.75 inches =  628.65 millimeters  = 62.865 centimeters  =  62 cm + 87 mm   =~  63 cm = 0.63 m

1 inch = 1" = 2.54 cm = 25.4 mm

SCALE LENGTH = **30 inches** = 762 millimeters = 76.2 centimeters : For a short-scale length bass. An example is the Hofner violin shaped bass.

A short-scale electric bass guitar is well suited for beginners, people with small hands, and standard guitar players since the neck feels almost like a guitar neck. The short scale means less tension on the strings to tune it to standard tuning (E, A , D, G, like the thicker four of the guitar strings), and therefore the sound is slightly deeper, perhaps having a tone more similar to that an old upright orchestral bass that is shaped like a giant violin.

```

HOW THE MUSICAL SCALE WAS FIRST DETERMINED

It is thought that **Pythagoras**, a great mathematician from ancient Greece who is credited to have made the famous Pythagorean Theorem for finding the longest side of a right triangle, conceived a definition of the pleasing musical notes in a range of all possible frequencies in one octave (ie., from a given or starting frequency, to double or twice that frequency) . Before this, it was possible to make a scale by finding the pleasing notes found on a string by just listening to the sounds and marking their positions. If two or more strings are being used, then two or more notes can be played at the same time, and which is called a chord of notes, and in particular, when sounding pleasing (ie., in harmony) together. These strings can also be tuned to different starting or fundamental notes so as to make some chords more available and-or easier to play. Many instruments have a standardized and-or common tuning or notes available.

Pythagoras wanted to formalize a music or sound scale as being geometric in nature, and by using strict integer fractions of a string length. This was during a time that the "equal tempered" and-or geometric ratio scale of notes was not yet known, and this scale ratio was discussed previously in this book. This book derived the relative value of about **1.06** in terms of ascending frequencies of the notes of the chromatic scale and about **$0.944\underline{9}$** for the relative value of the string lengths of each successive note in the chromatic scale. These values are actually reciprocals in value.

Pythagoras realized that if a string length or object was twice as long or big, that the tone of its sound or "pitch" was similar but deeper. Today we would say that its frequency and-or vibrations would be half. In a reverse type of manner, he realized that if the string length or object was half as long or big, that the tone of its sound was the similar, but higher in pitch (ie., frequency as we call it today). Pythagoras thought the harmony of the universe and sound was geometric-like and of "pure numbers" such as fractions containing only integers in the numerator and denominator. With what could be called his math of sound concept, he conceived of a scale containing 7 notes and with the 8th or "octave" (a word created from an 8, equal-sided polygon, called an **octa**gon) note or tone being the next "pitch" or degree higher in tone than the first tone. For some other notes of the Pythagoras octave, major scale:

Note Of Scale	Note Location Along The String Length (Lm) from the nut or string support opposite to the bridge support.
1	L/1 = L , full length of the string, an "open string" = a non-fretted or lessened string length
3	L/5 = (1/5) L , hence (4/5) of the string will be left and-or vibrating , A flatted third, such as used in the minor scale, is at: L/6 = (1/6) L
4	L/4 = (1/4) L , hence (3/4) of the string will be left and-or vibrating (1/4) of L is halfway to (1/2) L which is the first octave note.
5	L/3 = (1/3) L , hence (2/3) =~ $0.66\underline{7}$ of the string length will be left and-or vibrating
8	L/2 = (1/2) L , hence at half the string length, and (1/2) L will be left and-or vibrating

In comparison to the modern 12 note equal "tempered" or ratio scale, the Pythagorean 7 note scale is close in value(s) to it. The Pythagorean scale has a maximum difference from the more modern scale of less than 1%, and is actually just 0.5%. This could be said as being amazing, and that both scales actually help reinforce or verify each other in some way.

Pythagoras found each note and-or length by considering the corresponding length of the 5th note in the scale. For example, if the first note is considered as C, the 5th note is (after skipping over 2=D, 3=E and 4=F) G. He found this note very pleasing or harmonizing to the first note, and so he simply based the other notes and string lengths on this value of (2/3) of the string length, and in the hope of finding the correct values of some other pleasing or harmonizing sounds to the first note or sound of the scale. He figured if (2/3) of the string length gave a pleasing and harmonizing note, then considering this string length as a new string length, then at (2/3) of it, there should be another pleasing note. When he went past the first octave positions with his idea, he shifted the result into just the first octave by doubling its string length, hence an octave less, and the result was the 5th tone or note of his G scale, and which is the D note, and this is also the 2nd note in the original scale of C. The next note he considered was the 5th note in the scale of D, and this is the A note.

The 5th notes of any octave and-or scale were found in this order: C , G , D , A , E , B , F , C , and which then also gave us the 8 notes and locations of a complete octave range of a scale such as: C , D , E , F, G , A , B , C

If we have (2/3) of a string length considered as G, and then take (2/3) of it, we then have a string length of just (2/3)(2/3) = 4/9 of the original string length. 4/9 of a string is 0.444... , and if we double it to get an octave lower, we will have **0.8888....** of that string length, and this is where the D or second note of the C scale would be. This will be less than the full (100% = 1) string length by the relative (ie., percentage, fractional) value of : (1 - 0.888888888) = 0.111111111 = =~ 11.11% The equal ratio chromatic music scale has a value for the second tone of being at **0.890898718 L** , and which is close in is very close in value.

Where are the octaves or twice the frequency located on a string?

This is probably where Pythagoras started his musical scale.

Octave	Location Along A Length (L) Of Vibrating String Producing Sound Vibrations
0	1 / 1 = 1L = 100%L
1	1 / 2 = 0.5L = 50%L : after taking half of the above length
2	1 / 4 = 1 / (2^2) = 0.25L = 25%L : after taking half of the above length
3	1 / 8 = 1 / (2^3) = 0.125 = 0.125%L : after taking half of the above length

We see that these are fractions composed of a simple integer in both the numerator and denominator. For any string length (L) ,the octave is always located at half its length. From the above pattern, we see that the denominator is equal to octave (n):

$$Ln = \frac{L}{2^n}$$

: the higher the octave, tones and-or frequencies, the shorter the string length and string length corresponds to the wavelength of its fundamental or natural frequency.

Pythagoras surely then reasoned that given any string or "scale length", then the octaves of any similar, but different "pitched" note, for example note A , will always be located at the same relative distance along its length from the start of the entire octave (ie., the 8 accepted, common or main tones of a musical scale, and before the concepts of the 12 note chromatic scale was used so as to create a scale of tones when any note is considered as the starting note). An example of the 8 common notes of a complete octave scale are: C=1, D=2, E=3, F=4 , G=5, A=6, B=7 , C=8

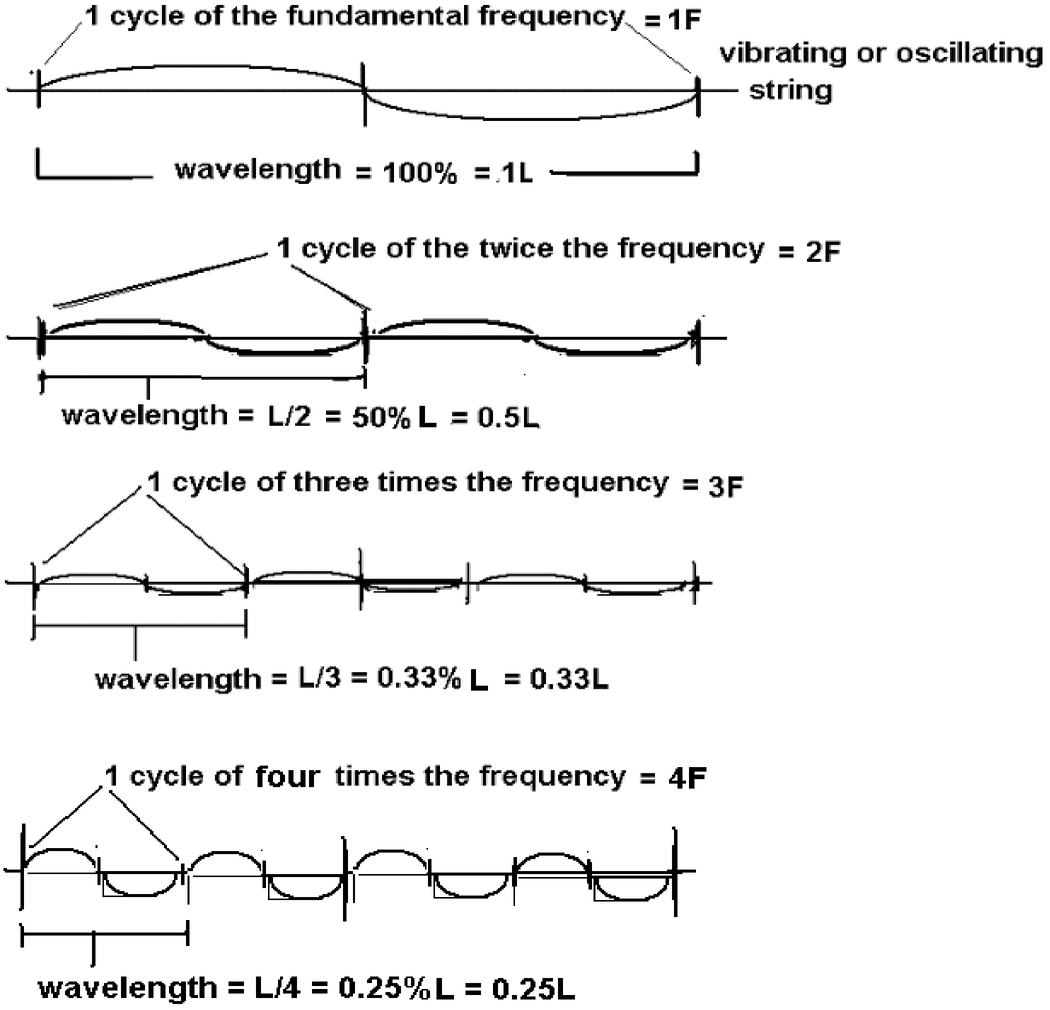
Pythagoras reasoned that if the octave note, a pleasing sounding note, is located at 1/2 of the string length or 1/2 up from the first note, then other pleasing notes should be located at 2/3L or 1/3 up from the first note , 3/4L or 1/4 up from the first note, and 4/5L or 1/5 of up from the first note. These are series of whole number fractions: 1/2 , 1/3 , 1/4 , 1/5

Ex. A musical string is 25.5 in long. The first octave higher in tone from the end of that open string is at 25.5 / 2 = 12.75 in = 12 in + (12/16)in . This considers notes 1 through 8 of a complete octave scale. Halfway on this length segment of the string, there is the 8th note / 2 = 4th note, and this will be located at: 12.75 in / 2 = 6.375 in = 6in + (6/16) in. If the string was tuned to a C note, the 4th note in that scale would be F. Considering this position as the start of a new length of a string, it would be a string length of: (25.5 - 6.375) = 19.125, and at half of this would be the 4th note in the F scale, hence note B. Pythagoras is said to have used the 5th note of every scale for his notes and positions analysis.

Each length of string will have a natural (resonant) frequency associated with it. When it is plucked to vibrate, it will develop peaks and valleys or highs and lows in its vibration or wave shape. The places where the vibration is at minimum, null or 0 is called a node. The first node will be in the middle of string, and then another node between that node and the end of the string, and so on. The amplitude or energy and-or height of each successive vibration between each node will get reduced as the number of nodes and frequencies (called [natural] harmonic frequencies) of vibration increases. For the first node and each successive node, these corresponding and smaller in amplitude vibrations are one octave higher in pitch and-or having a frequency corresponding to the previous node frequency and increased by the value of the fundamental frequency of the string.

If you were to shorten the length of the string to its half-length value at the node, the fundamental frequency of that length of string will be twice in frequency.

[FIG 285]



Note in the above figure, that at half the string length is 2F, and this is where the octave or twice the frequency of the entire string and-or first (or "root") note is located. Now note that 3F does not mean the frequency of the 1 cycle of the three total waves or cycles indicated would be an octave of that entire string and-or note. If that length of string was played (ie., vibrated, sounded) by itself, it would not be an octave note of the original string and its note (ie.,pitch, frequency). Only where the string length is successively halved in length, at that length will be the next octave note and location. For 4F, the length of the 1 cycle shown would actually be the next octave if it is the only segment or portion of the (or a) vibrating string. 3F is considered an "odd harmonic" in relation to the first or fundamental frequency. Likewise 5F, 7F, etc, are also odd harmonics of the fundamental or main frequency. Odd harmonics can give a "richness" or "brilliance" to chords, and in fact the main notes of any chord are the 1st, 3rd, and 5th notes of a scale of a fundamental frequency being considered. 2F if both twice the fundamental string frequency and is the length of the next octave of it. 4F is four times the fundamental string frequency and the length of that once cycle would be the length of the next (higher in pitch) octave or four time the fundamental frequency of the entire string.

Pure and-or theoretical sine waves do not contain any harmonic frequencies, that is, those waves are not composed of, and not combined with, and-or do not contain any other frequencies. When energy waves such as audio or sound waves contain other frequencies, the sound is heard and is said to have a certain "character", "quality", "color", "uniqueness" or "**timbre**", and of which may be subjective to a listener, but will have a "common sound" to most people. A music tone can have a frequency (ie., pitch), and amplitude (ie., loudness, energy intensity), and timbre (ie., tone or color). Tuning-forks can produce pure sine waves, that is, having 1 fundamental output wave. A flute can sometimes produce a pure sine wave. It is possible to create pure sine waves using an electronic circuit such as an LC oscillator circuit. Other than what mentioned, most instruments do not commonly produce pure sine waves, and not even many bells, and of which are often made or designed so as to have a somewhat strange, yet pleasing mix of output frequencies so as to have a unique sound or tone. The sound of a rung or struck bell can still be heard in some quite, low noise communities.

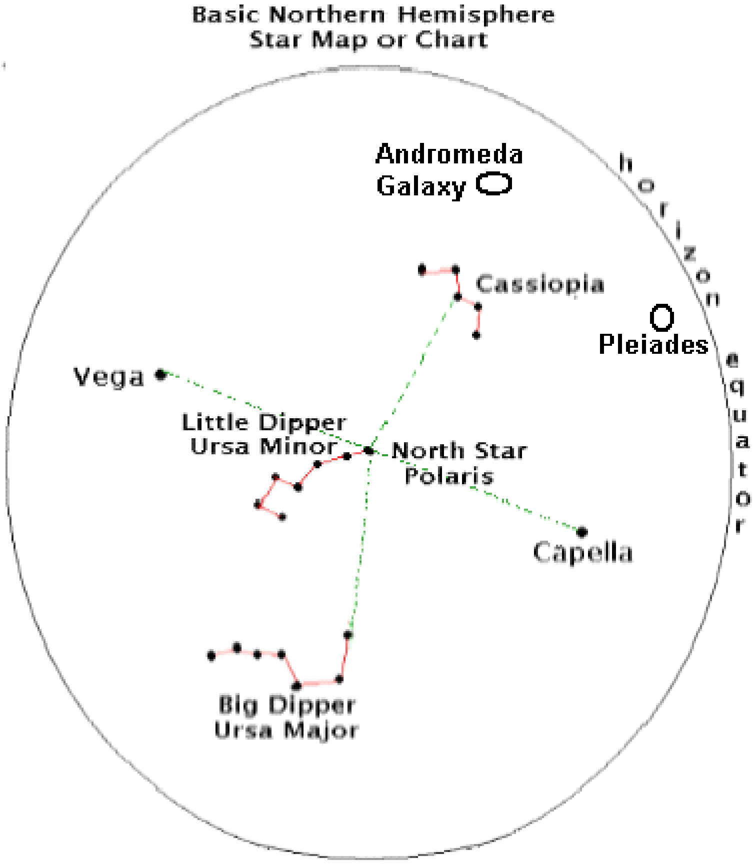
A BASIC STAR MAP OF THE NORTHERN CELESTIAL HEMISPHERE

This is a star chart or map of a few of the most helpful, significant and-or brightest stars in the night sky. Planets and the Moon are not shown because they move from their locations in the sky fairly quickly throughout night and year as compared to the (apparently) constant or fixed relative star positions. Note that astronomical things appear "upside down" in the southern hemisphere than that of the northern hemisphere view. For example, if you live in the northern hemisphere and notice a star on the southern horizon, that same star will appear on the northern horizon as viewed from the southern hemisphere. Of particular importance for people in the northern hemisphere to know is the location of the pole-star called the North Star or Polaris. Using this, you can deduce the directions of north, south, east and west on the Earth. The axis of the Earth constantly, throughout the year, points directly to the North Star, and it would be located directly overhead of a person at the true, geographical north of the Earth. People living in the southern hemisphere can find the true south direction by first locating the stars called the Southern Cross or Crux. Star charts are available, and a popular, portable, and casual version is called a planisphere or "star wheel", and this takes into account Earth's yearly orbit about the Sun, and the apparent tilt of the Earth throughout the year. This circular map system with a "viewing window" of the current visible portion of the sky is rotated to align it with your directional view.

Viewed from Earth's north pole, Polaris will appear about 0° offset from being directly overhead at 90° with respect to the local horizon line. The latitude of the north pole is defined as 90° from the equator line. At the equator region, Polaris will appear along the horizon, hence it will appear at 0° above the horizon. 0° is the defined latitude of the equator. People living southward of the equator may not be able to see the North star, Polaris, except for when the apparent tilt of the Earth takes place and it allows them to see it from locations as far south as about 23.5° latitude during certain times of the year.

Polaris can be found in the night sky by facing in the direction of the north pole (and generally, not the magnetic north), and Polaris will be found at an angle upward in the sky that is equal to your defined, local (north, south) **latitude** on Earth, and with respect to your local horizon line, With an angle measuring instrument, you can also measure this angle if you know where Polaris is located. If you want to calculate your local (east, west) **longitude**, there is a mention of it in this book in the article called: **How to find your local longitude**

A wonderful thing a new amateur astronomer may wish to do, is to first create their own star chart of the brightest stars visible to their own eyes. The star positions can simply be approximated when drawn, or actually measured with an (horizontal and vertical) angle measuring device. After that step, they can look up on a star map what the star names are. The map below shows a few constellations (a star grouping) and some bright stars. [FIG 286]



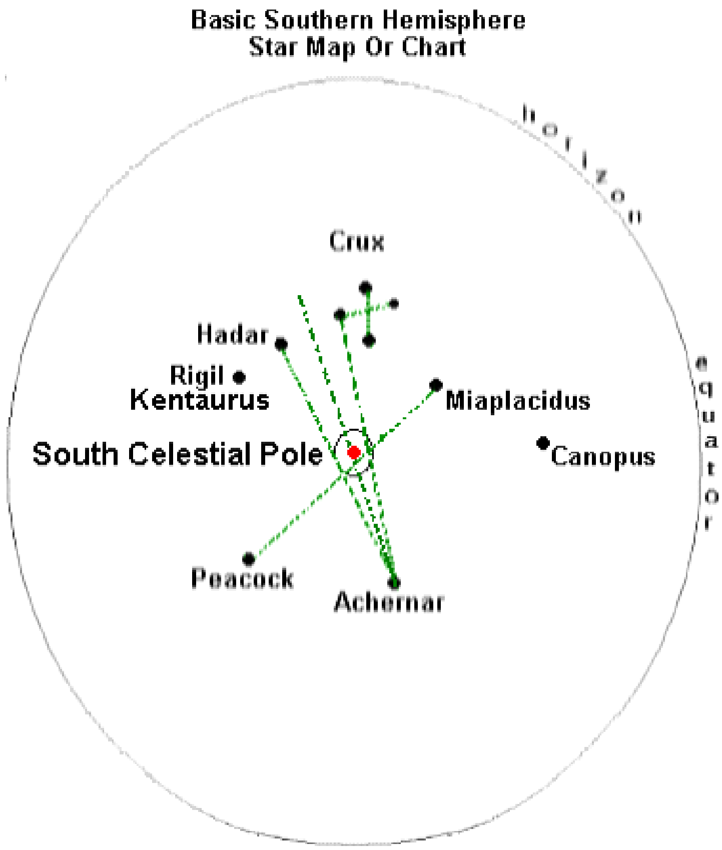
Vega and Capella are indicated due to their positions and easy to find brightness. These two stars are nearly on a line with each other which includes the **North Star** called **Polaris**. In brief, there are several celestial or astronomical coordinate or location systems in use for one reason or another, and all use a reference location and or plane. The distance to each star or planet is generally not used or needed in these basic location systems where direction is more important - such as where to aim a telescope to view a particular star, planet or galaxy. Considered in these systems is the solar or ecliptic plane of which the planets and their orbit travel are relatively near to within a few degrees. The North star to the South star (ie., Earth's polar axis) plane is used in some of the systems. One common term often used in these concepts is "azimuth", and this is simply an angle value such as to a star.

Since astronomical observers may be at different latitudes on the Earth, the apparent angle to a particular star will not be the same as that of another observer, and hence why a common (0°) reference plane(s) must be used so that all may properly locate an object. For example, the Sun may appear as directly overhead to a person near the Equator, but it will appear as say 45° above the horizon (at local noon, 12pm time) to an observer located halfway to the north pole between the equator and the north pole, and while both are located on the same longitudinal line.

A simple astronomical location system for people in the same geographical area, within a few hundred miles of each other, would be the angle rotated clockwise from the north-star's horizontal direction or plane, and the angle to the object above the local horizon. Even so, the planets and stars appear to change celestial position by 15 degrees per hour, and therefore, the same observation time should also be considered for these coordinates or position. Because of the Moons relatively slow orbit about the Earth, the stars will appear to travel across the sky slightly faster than the Moon, and the stars appear near its widest part will appear go behind the Moon and will appear to "come out" at its opposite side in about 20 minutes, hence appearing to travel faster than the travel speed of the moon.

The visible angular width of **Cassiopeia** constellation that seen as the "W shape" in the sky is nearly 30° wide in terms of the North Pole (circumpolar) celestial coordinates (ie., angles) and-or along the celestial horizon.. Vega is about 25 light-years from Earth. Capella is about 43 light-years from Earth.

[FIG 287] **A Basic Star Map Of The Southern Celestial Hemisphere**



The star constellation called **Crux** is also commonly known as the **Southern Cross**. With binoculars (ie., two small telescopes connected side by side, one for each eye) or a monocular (ie., a small, portable single lens telescope), you can see the south pole star called **Sigma Octantis** that is very close to the geographical location of the south celestial pole.

People who live in the high latitude areas, near a pole or axis of the Earth, say greater than 47° latitude, will not always be able to see the stars around the other pole region due to the bulge of the Earth at its equator blocking their view of those stars. First consider that if the Earth was not tilted at all on its axis. Anyone living south of the equator would not be able to see the North pole star region, and anyone living north of the equator would not be able to see the south pole star region. The further from the equator, the less of those stars indicated will be visible. Due to that the Earth's axis is tilted by about 23.5°, then at certain times throughout the year, more of those stars indicated will be visible. Throughout the year, the maximum apparent change in Earths apparent tilt is 47°. It is therefore possible for people living at latitudes as high as 47° to see the pole star region of the opposite hemisphere of the Earth. At any one time of day throughout the year, only 180° of the sky and-or stars is visible from a location on Earth, and "from horizon to horizon". As the Earth turns 180° on its axis for 12 hours during the night, then in theory, a total of 360° of the sky and-or the overhead stars will be visible at some particular time during one day, but not all at once, and rather just 180° worth at a time. At anyone instant of time, Earth's bulge always blocks the view of 180° of all the available stars in the universe since half of them are effectively located below your local horizon line and can not be seen.

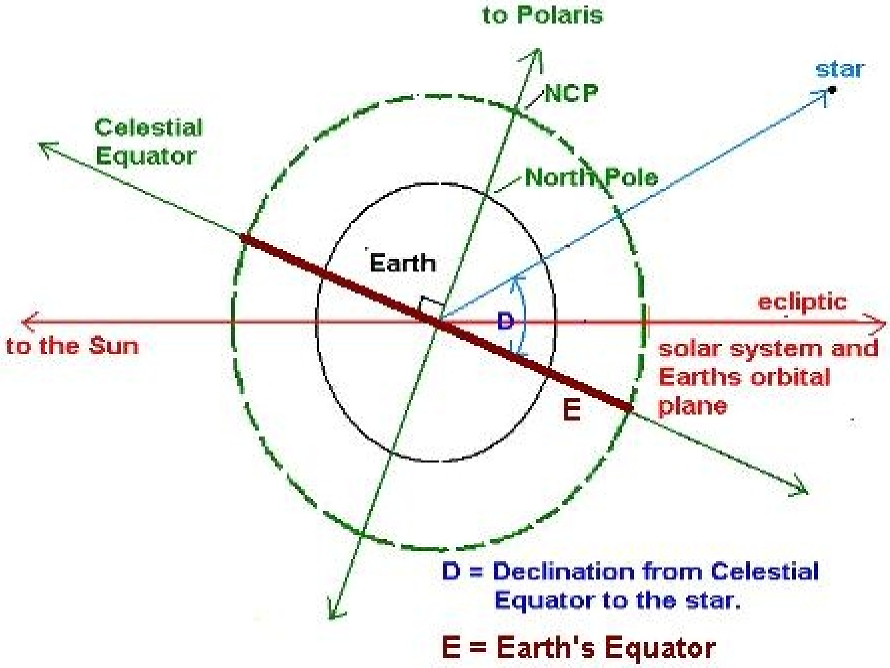
The star in the image above called **Rigil Kentaurus is also commonly known as Alpha-Centauri or A-Centauri** since it is in the Centauri star constellation or formation along with the other stars such as B-Centauri and C-Centauri. This Centauri star system and-or constellation has the closest stars to Earth and are about 4.4 Light-Years away or distant. **Hadar is also called Beta-Centauri or B-Centauri** and is actually a three star system. The star **C-Centauri** is commonly called **Proxima Centauri** which is a relatively small red-dwarf star, southward and slightly eastward of Alpha-Centauri, and here where the (s) letter is located in the word Kentaurus as shown in the above firgure, and it was found using a telescope in 1915, and is the closest star known to our solar system, and is "only" about 4.25 light-years away - a relatively very small distance as comparred to the other stars in the galaxy and universe. In the above figure, Proxima Centauri is located about where the letter (s) is located in the word Kentaurus as shown in the above figure. As of the year 2022, three exoplanets (external planets out of our solar system, and are orbiting another star) have been found to orbit Proxima Centauri, hence they compose the closest exo-planetary solar system. Due to the relative closeness of stars in our Milky-Way galaxy, all of the exoplanets found have been in it. In the above image. Proxima Centauri is located just south-east of Alpha-Centauri, and at about the 5 o'clock position relative to it. By using the apparent visual effect called parallax. and taking two observations of Proxima Centauri at 6 months apart and a distance of (2)(distance to the Sun) = (2)(93 million miles) = 186 million miles as Earth orbits about the Sun, its distance can be found using right-triangle trigonometry to a relatively high accuracy since it is relatively close to us as compared to all the other stars, and where the parallax effect is more apparent. Throughout the year, at most latitude locations in the northern hemisphere of Earth, Proxima Centauri cannot be seen and is effectively below the horizon.

If you are able, a neighbor or friend can show you their telescope for a short amount of time so as you can view the night sky or local area. - of course try not to focus it on the neighbors, etc. for it can cause privacy issues. **John Dobson** (1915 - 2014), from the USA, is generally given credit and name for the Dobsonian Telescope designs and mount. He often encouraged people with telescopes to let other people without telescopes to look through their telescopes so that all may have at least a chance and experience of viewing some of the amazing universe surrounding them in a new and helpful way. It is recommended that a beginner purchase a low power, relatively inexpensive refactor telescope, binoculars or monocular for viewing the local area, and so as to become familiar with a telescope and the night sky. The magnification power of many binoculars is about 20, and for an inexpensive telescope, the magnification power is about 100. As the power and objective (lens or mirror) increases, the cost of the total telescope increases rapidly, and so does the weight of the telescope system (telescope, tripod, mount to connect the telescope to the tripod, etc). It may take a year or more of occasional viewing for a beginner to become familiarized with a telescope and astronomical things, and then the process will be easier if they obtain another telescope for more advanced viewing. Dobson was also a well known (Newtonian) telescope designer and (reflector telescope) mirror maker who educated many others as how to do these things if the are able. The "Dobsonian Mount" is essentially a homemade, inexpensive (usually wooden) Alt-Azimuth (altaz) telescope mount, and this design was practical for very large diameter telescopes to have a relatively inexpensive mount, hence it also helped encourage building telescopes having a large objective mirror. A Dobsonian telescope mount basically has a (hand rotatable) "turntable" or disk mount so it can rotate 360° about its center point when placed level with the horizontal ground, and a pivot mechanism placed onto that turntable so as to adjust and-or aim the telescope vertically above the horizon. Although Dobson was the first to make this mount very practical for telescopes, he mentioned that the basic mechanical and-or design concept was not new at all.

About The Celestial Coordinate System

One way to describe the location of a star in the sky is by using two values: a **Declination** (DEC) value, and **Right Ascension** (RA) value. Right Ascension essentially means how far right and-or eastward will the star will then be located via its declination value. The Earth travels rightward and-or eastward about the Sun each year. Viewed form above the Sun's north pole, the Earth travels in a counter clockwise direction about the Sun.

The north star, and which is directly above and-or inline with the north pole and axis of the Earth, is named as Polaris, and it is also considered as the north celestial pole of the celestial coordinate system. At 90° to the celestial pole is the celestial equator or plane, and is defined or standardized angle of 0° declination. The celestial equator plane is also co-planar and passes directly on and through Earths geographic equator plane that is centered between the north and south poles. The solar plane and-or ecliptic (path of the Sun, and planets in general, across the sky) of the Earth is actually tilted about 24.5 degrees from this celestial plane. Declination is the angle to an object and needs to calculated with respect to the latitude of the observation so as to be in reference to the celestial equator instead of the observers specific latitude. Various sightings of the object, say a star, and seen at different latitudes will all observe it at a different angle above the horizon and the solar plane, but using the celestial declination value will be the same value for all latitudes. Declination then essentially becomes the celestial latitude value from the celestial plane. Declination is usually expressed as a degrees angle or as: Degrees, ArcMinutes, ArcSeconds. [FIG 287A]



The declination of the star Polaris is about 90°. The latitude of the north pole on Earth is defined as 90°. The RA of Polaris is abut 2h , 31m , 49s. Since each hour = 60 min = 3600s corresponds to an angle of 15°, this angle and-or time value corresponds to an angle of about: 30.6833°

The astronomical first day of spring is called the spring or vernal equinox, and it occurs on about March 21 each year, give or take a day. This can be used as a reference position of the visible stars (most being in our Milky-Way galaxy) as viewed from Earth during its yearly orbit about the Sun. On this day, the 0° reference longitude will be in the constellation of Pisces. This reference position in our orbit is called the Right Ascension (RA) value of the celestial coordinates or the "imaginary sphere of celestial coordinates". A Right Ascension value is essentially the celestial longitude value from the reference value of the spring equinox which is considered as 0° Right Ascension of Earth orbiting about the Sun. Each day, the Earth will travel about: (degrees of circular orbit / days of orbit) =~ (360 ° / 365.25) =~ $0.9856\underline{3}°$ =~ 1° / day around the Sun, and also through the 12 months and-or zodiac of star constellations at night time. This orbit of the Earth about the Sun will make the stars shift by nearly 1° each night at the same time of day than the day before. Here, 1° corresponds to 4 min of time earlier. Since the Earth rotates daily on its axis, the stars will constantly appear to also move throughout the night and day, but this RA value is a standardized and-or a calculated and-or constant value for all latitudes and-or locations of Earth. The RA value is usually expressed in Hours:Minutes:Seconds units.

15° of the celestial coordinates and-or apparent star movement corresponds to 1 hour = 60 minutes of time. (1 min. = (1/60) 1 hour , and sec. = (1/60) 1 min. = (1/60) (1/60) hour = (1 / 3600) hour.

1 hour = 60 min = 3600s = 15° , and 15° / 1 hr = 15° / 60 min = 1° / 4 min = 0.5° / 2 min
0.5° = (1/2)° is the apparent diameter of the moon in the 360° complete sky
1 min = (1/60) hour = (1/60) 15 ° = 0.25° : 1 min = 60 sec

1 sec = (1/3600) hour = (1/3600) 15 ° = $0.00416\underline{7}$ °

Since the celestial equator is perpendicular to the celestial pole and axis of the Earth, the celestial equator will be in the true or "due" east and west directions to the observer. Since Polaris essentially remains in he same direction and location (ie,, angle of elevation) in the sky for a given latitude, the stars near the ecliptic plane (solar plane) will appear to travel in an east to west direction parallel to the ecliptic line, and throughout the night and year, the ("circumpolar") stars will also appear to slowly orbit about the north star which is also called Polaris, and which is said as being very close to the true north polar axis of the Earth and-or the true north celestial pole (NCP).

Due to the celestial sphere concept, the RA lines will travel from the celestial equator and meet together at the celestial poles, and the right ascension value can then also be thought of as hour and-or (24 , hour) clock lines about the star Polaris, and where each hour line represents 1 hour of time and-or 15° of location and-or offset from the 0° reference line. Where is the 0° RA reference line defined and-or standardized? It is a line from Polaris and passes near (just right of) to the star **Caph** which is the rightmost star in the constellation **Cassiopeia** which resembles a W shape. The RA or Right Ascension of Caph is not actually at 0°, but nearly, and is rather 9 minutes and about 10.7 seconds. The declination of Caph from the celestial equator is nearly 59° and 9 minutes. Note that an azimuth (ie., along the horizon from true north) angle value depends upon the local location of the observer on Earth, and therefore it is not a constant value.

The constellation called Orion which is easily recognized by the 3 bright stars in a row called **Orion's Belt** is located near to the celestial equator. Note that although the apparent tilt of the Earth changes with respect to the solar plane and Sun throughout the year, the celestial equator does not move in position, and this is similar to how Polaris is (very nearly) the celestial pole throughout the year. The upper-rightmost star called **Mintaka** in Orion's Belt is nearly, directly at the celestial equator 0° reference line At the equator of Earth the celestial equator will appear directly overhead, and this imaginary line is 90° perpendicular to the celestial poles. Mintaka will rise due (ie., directly) east above the horizon and will set due west after 12 hours of time, and it will be directly overhead after 6 hours of rising above the eastern horizon as Earth rotates toward the eastern direction during the night. The celestial coordinates of Mintaka are: (RA = 5h, 32m, 0s and Dec = - 0°, 17 min , 57s = -0°, 17', 57"). Looking rightward from center of the imaginary line of stars in Orion's Belt is the bright star Rigel, and looking leftward from Orion's Belt is the red-giant star called Betelgeuse.

The celestial coordinate system is also called the celestial equatorial coordinate system.

A somewhat more simple coordinate system for perhaps people in the same region on Earth having about the same latitude and longitude is the ALT-AZ , **Altitude and Azimuth coordinate system**. It is also called the horizontal coordinate system since the angles are in reference to horizon directions. Here, altitude is the angle ("elevation angle") from the horizon to the star in the sky. The azimuth value is the angle along the horizon between the true north direction (considered as the 0° reference angle) and the direction of the star. True east would be a 90° angle. True south would be an angle of 180°. True west would be a 270° angle. Since the stars will appear to move across the sky in the night, their ALT and AZ coordinates will be changing constantly, and therefore, it would be a good idea for future reference to also record the date and time of the observation with those coordinates: ALT : AZ : DATE : TIME

For more information about celestial coordinates and-or astronomy, it can be researched elsewhere or learned via an astronomy course, and which may include a visit to a local planetarium which simulates celestial objects, their locations and-or paths via a light projection and display onto a curved ceiling.

Today, with high powered, legal lasers for astronomy use, stars in the sky can be indicated using a (usually green light) laser. It is very possible to make a portable "pointing stick" on a tripod stand. This pointer can be used to indicate objects on land or in the sky. It should be able to move horizontally and vertically and the be set firmly into the desired position. Very small and dim red lights can be used to help align the pointer at night. This pointer system can then even be improved so as to indicate the horizontal and vertical angles of the pointer at your local location and to the objects or stars, and it would then be very possible to draw a more detailed star map(s) and-or to locate stars, especially if the pointer's 0° line is aligned to the north pole direction (horizontal and-or vertical), and either the celestial or alt-az coordinates can be recorded and used to indicate the stars on a paper map being drawn.

Types of telescope (tripod, etc) mounts:

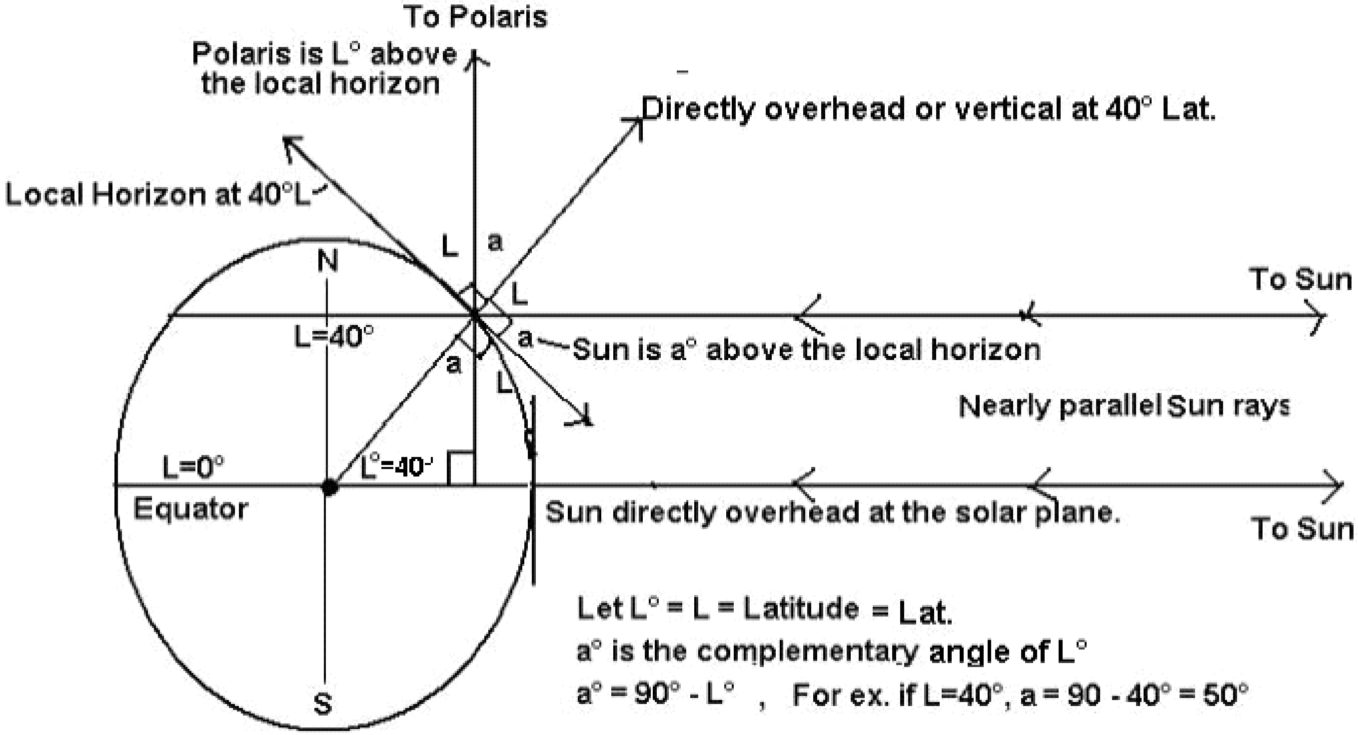
1. **Manual** or "free hand" - Aim the telescope at what you want as needed. Many Dobsonian telescopes and inexpensive are manually aimed. This makes the cost of the system cheaper, and or easier to use for some people just "looking around". Even if a telescope has another type of mount, manual mode is often possible.

2. **Altaz** mount - or Alt-Az mount. This mount can rotate horizontally (azimuth) and-or vertically (altitude above the horizon).

3. **Equatorial** mount - This mount is aligned to be in parallel to Earth's polar axis, hence very close to the star Polaris. As the Earth rotates, the telescope aiming will be adjusted to rotate about this correctly aimed pivot point on the telescope. This mount, and if motorized tracking is used, allows for better long exposure photography.

ANGLES TO POLARIS AND THE SUN AT YOUR LOCAL HORIZON AND LATITUDE

In the figure below, it verifies the angles to both the North-star Polaris and the Sun at your local latitude and-or location on Earth. [FIG 288]



If you live in the Northern hemisphere of Earth, and at 23.5° Latitude, North of the Equator, the Sun will always appear to be slightly southward in the sky throughout the year, and more-so as the more North you are and-or the higher the Latitude on Earth that you are. At the north pole or axis of the Earth, the Sun is very close to the horizon, a very low angle, and sometimes below the horizon, such as during the winter season. Because the Earth turns westward to eastward throughout the day, the Sun and-or stars will appear to travel eastward to westward. The angle to the star Polaris will always be equal to the observers latitude. The apparent tilt of the Earth throughout the year does not change this, however it will change the observed angle to the Sun since it is relatively close to Earth as compared to the star Polaris. The Sun will appear in the Sky at a higher maximum angle (ie., more directly overhead) with respect to the horizon in the summertime of the northern hemisphere, and when the apparent tilt of the Earth is towards the Sun.

The angles in the above figure can be found using the concept of the two complementary angles of a right triangle that always sum to 90°, and the concept of vertical angles across from each other which always have the same angle.

Extra: The axis of the Earth does wobble in a circular type of motion, but it is very slow to consider into most calculations for a few hundred years. The effect is that the true pole or axis direction as of now being at the star Polaris will slightly change its direction and apparent location among the visible stars sky by a few degrees maximum. This concept is known as the **precession** of Earth's axis. Precession can easily be seen using a commonly available rotating gyroscope. Note that the tilt of the Earths and-or its axis is still about 23.5° during this precession or wobble cycle, but the axis line will rather move in a circular direction as it wobbles. The period of Earth's total (ie. full cycle, and-or circle) axial precession has been estimated at about 26000 years on average. Most scientists agree that this precession is the main cause of "ice ages" where the polar caps of the north and south pole grow to be much larger in size due to snow and ice, and thereby increasing Earth's solar reflectively (ie. "albedo") and causing the planet to cool even further. Earth's slow wobble is caused by some angular momentum developed due to the occasional Moon's gravity between that of the Earth and Sun.

How To Calculate Your Local, True Or Solar Noon Time If you Know Your Longitude

At solar noon, the Sun is directly in line with your latitude, and it will be at the highest or greatest angle in the sky for that particular day. Every location that has the same longitude on Earth will have the same, true or actual local time. First, find out what is your (east, west)longitude. You may also wish to know your (north, south) latitude.

We usually set out clocks not to our local solar noon, but by the time zone. All the different longitude locations in a time zone will have the same clock time, and this helps people stay on schedule and or in reference with each other and events. Only where the hourly time zone starts will the Sun be directly overhead at 12:00pm. If you live to the west in the time zone your true local (at your latitude) solar noon could be several more minutes later. The Earth rotates at 15° per hour, and from this we have that the Earth rotates 0.25° per minute, or $0.00466\underline{7}$° per second.
.
Here is an example.

If your longitude is 75.842°W, what is your true, local solar noon time on your ("time zone" or standard) clock?

Since each timezone is 15° apart, your time zone is: 75.842° / 15° = 5.0561333... , and the whole value of 5 indicates that you are in timezone 5 west of the Greenwich time zone1, and your clock time is set to be 5 hours earlier than the Greenwich clock ("timezone") time. To be more specific, you are 5.0561333... hours earlier than Greenwich. Since this amount of hours has a fractional value, you do not live on the longitude line at the start of that time zone, but are actually 0.0561333...hours offset from this, and your local, true solar noon will be 0.0561333 hours later than the standardized clock ("timezone") noon. Let us now convert this amount of hours to its equivalent amount of minutes. We can use a proportion or equivalent fraction type of equation to do this:

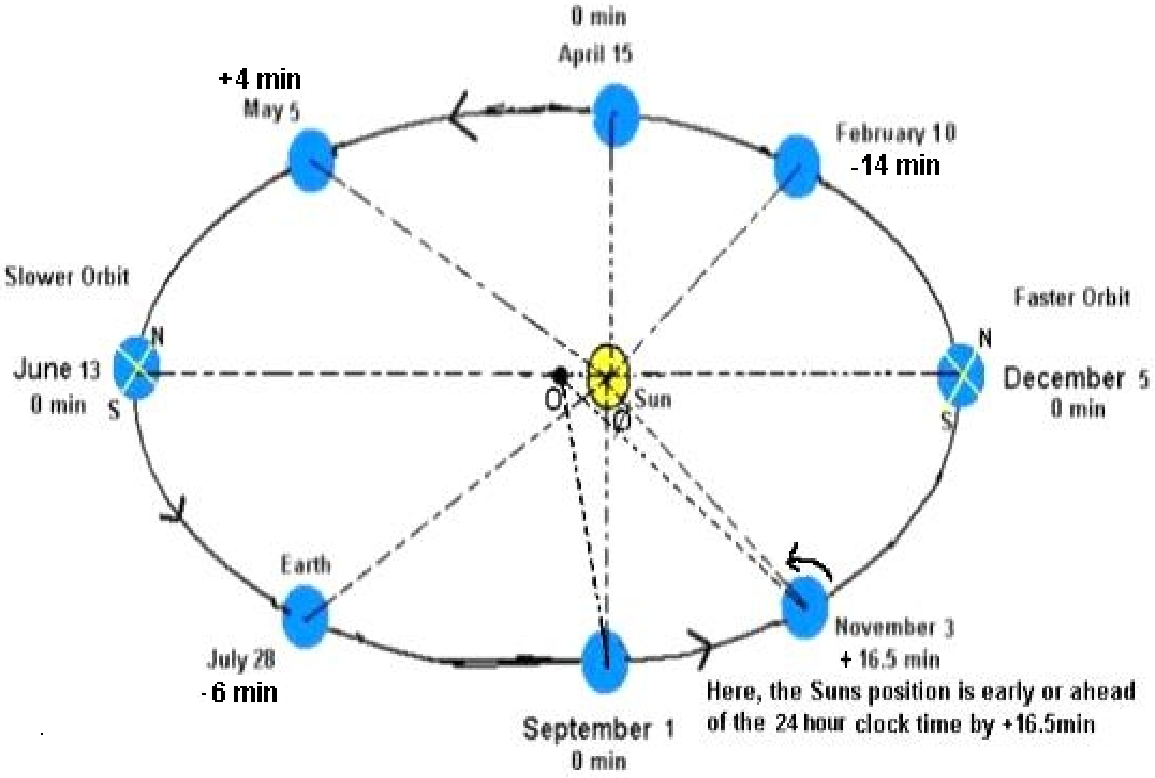
$$\frac{1\text{ hr}}{60\text{min}} = \frac{0.0561333\text{ hr}}{x\text{ min}}$$, after solving for x min, we have:

$x\text{ min} \overset{\sim}{=} 3.368\text{ min}$: your local, true solar noon will be 3.368min past or later than clock or "timezone" noon.

The above is a theorized value, but since the orbit of Earth about the Sun is elliptical, true solar noon may not be this calculated value, but needs to be adjusted. The topic of the **Equation of Time** considers this adjustment, and it and its value it may be thought of as: The Adjustment, Difference or Offset Of True or Actual Solar Noon Time From The 24 Hour, Standard Clock Or Axis Rotation Time. Note that for any day of the year, and regardless of Earths (slightly) elliptical orbit, the Earth always rotates at the same angular velocity on its axis, and that is 1 rotation per day = 360°/24hrs. When Earth is closer to the Sun in the winter time, the Sun will rise later than when the Earth is more distant in its orbit during the summer. Clock time that we commonly use throughout the year is based on the constant 24 hours in day, and does not consider the "equation of time" or changes in our orbit and the current (angle) position of the Sun with respect to Earth during its elliptical (non-circular) orbit during a year. Since the "equation of time (adjustment)" is not considered on our ("time zone") clocks, it is therefore the equivalent time as if the Earth had a pure circular, non-elliptical, orbit about the Sun. There are some special mechanical clocks made which do consider the equation of time, and those clocks are called "Equation Clocks". For these clocks, the adjustment or time offset is displayed on a separate dial, and it can be combined to the displayed time. If the clock was set to true local or solar noon, the adjustment is simply added, otherwise if the clock was set to "time zone noon", then you need to first calculate the true solar local noon from your known longitude as shown in this article above, and then to also combine it with the equation of time adjustment.

The zero time offset days are separated by 90 days and they occur at roughly the time of the start of each season: March 20, June 20, Sept 20, and Dec 20. The equation of time is sinusoidal-like, but having two waves, each with its own amplitude (peak value), and one wave then following the other. Each of the two time offset waves have a 180 days period or time length. There is a spring and summer wave, and a fall and winter wave. Between the zero dates, at about every 45 days, are the maximum offset or equation of time adjustment values, and these peaks are therefore 90 days apart.

Due to Earth's elliptical orbit about the Sun, as the Earth gets closer to the Sun due to its increased gravitational force and resulting acceleration caused by the Sun, the speed of the orbit of the Earth about the Sun increases in the winter months, and the winter season and its corresponding (apparent) tilt of the Earth will actually last less than 90 clock or (yearly averaged) days, and the summer season and its corresponding tilt will be a few more days longer than 90 clock days since the (average per year) speed and orbit of the Earth about the Sun is less. [FIG 289]



APPROXIMATE ORBIT OF EARTH AND EQUATION OF TIME ADJUSTMENT

As can be seen above, the "zeros" or where the clock time offset is 0, and-or differs by the true solar time by 0, occur relatively close to the start of each season on the calendar. Note that an offset of 15 minutes is a quarter of 1 hour, and this will be easily noticeable on a sundial. Using the equation of time concept, you can combine it with the sundial time so as to have the equivalent standard clock time.

This is a simplification of understanding why there is a time offset:

The above figure is an above or overhead view of Earth's orbit about the Sun. Earth's orbit about the Sun is not exactly circular, but elliptic. Due to this, the center (O, for origin or center) of orbit and-or the ellipse is not at the (gravitational) focus of the ellipse. The focus of Earth's orbit is the Sun, but it is not located at the geographical center of the ellipse, and the only exception is for a circle. If the Earth's orbit was not elliptical, but of a pure circular orbit, this offset angle would not happen, and there would be 0 time offset. Observe the two different angles in the above image, and the angle difference indicates why there is a time offset and-or adjustment needed in relationship to the Sun, but for standard ("time zone", 24 hour) clocks there is no offset needed because the Earth was standardized (ie., constant) at revolving on its own (ie., not solar, Sun orbit) axis for one day = 24 hours, and that this value does not change regardless of the season or orbit distance from the Sun.

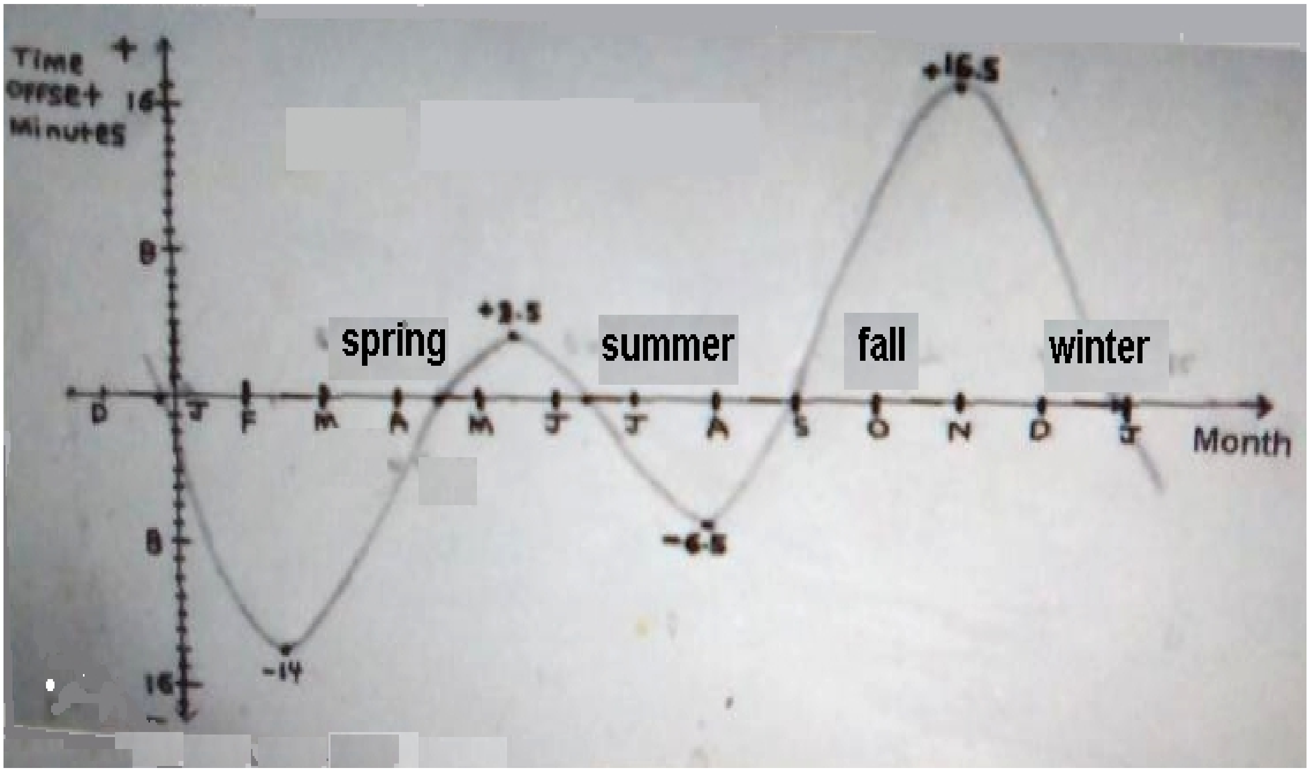
The topic of the equation of time has been studied for years by astronomers and much data about it has been measured and recorded. The equation of time can get somewhat complicated and has not much practical use for the average person, but it is sometimes important to some astronomers, precision sundials (ie., sun clocks) makers, and navigators. If your region uses the concept of Daylight Savings Time, you may also need to adjust your calculated and expected, true solar noon time value by an entire one hour more or less.

The offset times or difference times between the ("time zone", 24h) clock and the solar or Sun time can be measured using a sundial or a vertical pole in the ground. Observe a clock when it indicates noon or 12pm, and also observe the shadow on the sundial when it is indicated as your local (longitudinal) solar noon. For the fundamental equation of time and-or the difference than the expected value on the standard (24 hour) clock), calculate the time difference between solar noon and clock noon. Clock noon is also called "(24 hour) standard time" and sometimes as the local "(24 hour clock) averaged solar time". As for a vertical pole in the ground, its shadow will be the shortest length at solar noon, and where the Sun is at its highest angle in the sky for that day.

Key Data Points For Earth's Equation Of Time :(Offset value or time between solar or true noon and clock time noon)

Day	**Time Offset In Minutes**
February 11	-14 = - (14 min.)
April 15	0
May 14	+3.5 = (3 min. + 30 seconds)
June 13	0
July 26	-6.5 = (6 min. + 30s)
September 1	0
November 3	+16.5 = (16 min and 30s)
December 25	0

[FIG 290] Equation of time, approximation graph.



Because the length of the year is 365.25 and not the (ideal, calendar) 365 days, the equation of time can vary by up to a day over the time of every four years. This complicates the calculation for the equation of time, and pre-made lists for the time offset for each day for a given year are available. Earth's elliptical orbit and the resulting equation of time will also (slightly) affect the expected Earth based coordinate or location of the stars in the sky in relationship to time. It is of note that very distant stars (even outside our local Milky-Way galaxy) and their position are now used to determine exactly when the Earth has made one complete orbit about the Sun, still, the resulting (net, total, average) gravitational effects of other matter (planets, etc) and its location(s) in our local (Sun centered or based) solar system will have a slight effect on the duration of a complete orbit of Earth and-or each planet about the Sun.

The equation of time effect will also affect the sunrise and sunset times by the same values. In general, for everyday applications and use in society, the equation of time adjustment is not considered by the average person and-or business, and is rather only used when exactness or precision is needed beyond that of the constant theoretical 365 orbit time and-or 24 hour clock time.

The equation of time will also effect the actual starting and-or ending day of each season which are normally separated by 90 calendar days, and not the Earth's actual orbit location from Sun, each when it is not considered.

Earth's **perihelion**, is when Earth is closest to the Sun during its orbit around the Sun, and this is about 14 days after the winter solstice on about December 21, and which is also the day with the least amount of daylight and-or "shortest day" in the northern hemisphere of the Earth. Earths perihelion is about January 4 on average and which can vary by a day less or more due to the orbital positions and the corresponding and (net) resultant amount of gravitational forces of attraction of other planets affecting the Earth.

For the southern hemisphere with Earth being tilted toward the Sun during the northern hemisphere's winter, will actually have their summer season start on December 21, and which is the "longest day (light)" in the southern hemisphere.

Earth's **aphelion**, is when Earth is farthest the Sun during its orbit around the Sun, and this is about 14 days after the summer solstice on about June 21, and which is also the day with the most amount of daylight and-or "longest day" in the northern hemisphere of the Earth. Earths perihelion is about July 4 on average and which can vary by a day less or more due to the positions and the amount of gravitational forces of other planets affecting the Earth.

For the southern hemisphere with Earth being tilted away from the Sun during the northern hemisphere's summer, will actually have their winter season start on June 21, and which is the "shortest day (light)" in the southern hemisphere.

"Civil" or meteorological seasons in the northern hemisphere start on:

Spring	March 1
Summer	June 1
Fall	September 1
Winter	December 1

The above dates is how the weather feels on average in the northern hemisphere and they precede the true astronomical and-or Earth's physical seasons and-or days by about 20 days, and which are associated with the solstice and equinox days of Earth's apparent tilt with respect to the Sun and-or solar plane of its orbit about the Sun:

Astronomical (star alignment, other than the Sun), and the climate seasons in the northern hemisphere start on:

Spring March 21 , spring or vernal equinox , Sun rises in the true Eastward and sets in the true Westward ,
day and night are equal in length at 12 hours each. Sunrise at 6AM, sunset at 6PM, and
with true local or solar noon at 12PM "clock time".

Summer June 21 , summer solstice , longest day (light) of the year

Fall September 21 , fall or autumn equinox , Sun rises in the true Eastward and sets in the true Westward ,
day and night are equal in length at 12 hours each. Sunrise at 6AM, sunset at 6PM, and
will true local or solar noon at 12PM "clock time".
Winter December 21 , winter solstice , shortest day (light) of the year : according to a 90 day per season

calendar time.

About sunrise and sunset times throughout the year.

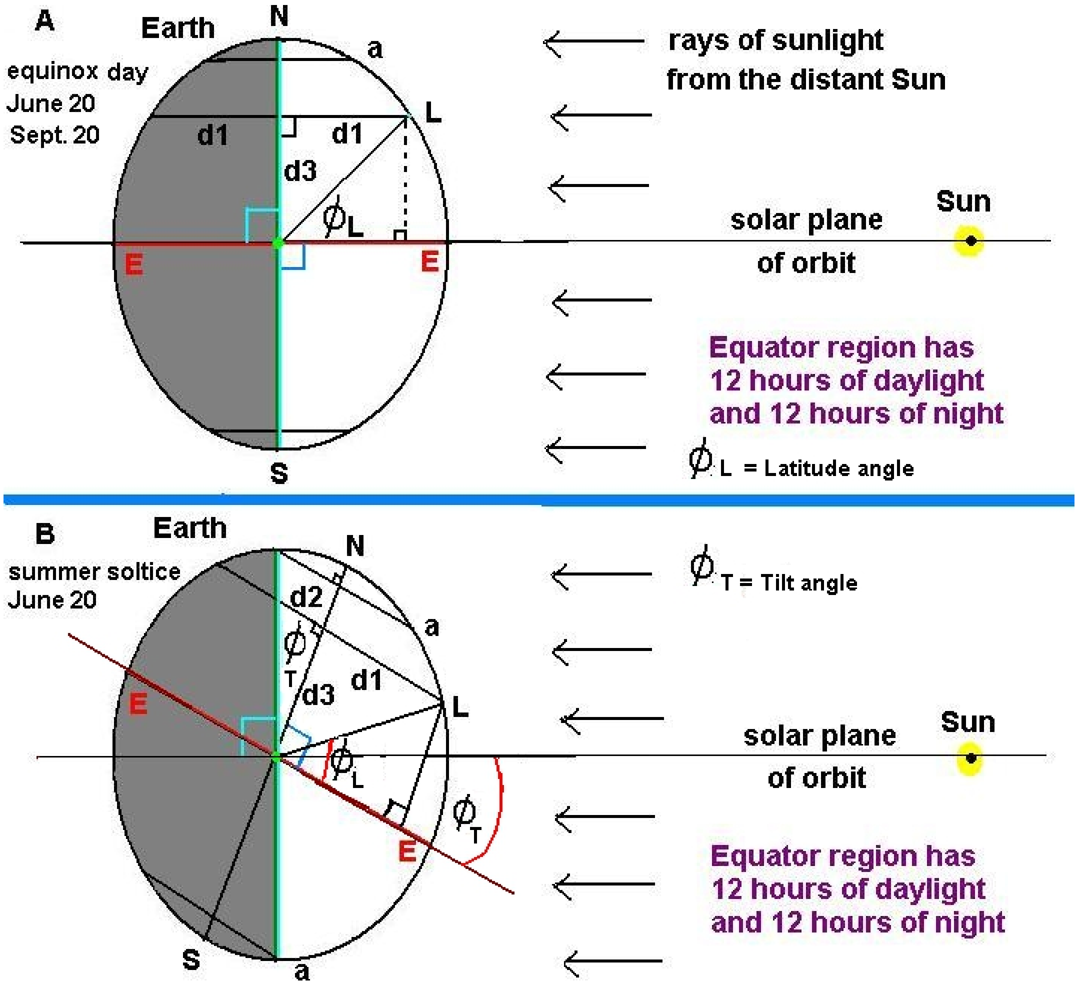
The greater the latitude of a location on Earth, the greater the surface of the Earth at that location is tilted back from the solar plane and the cooler the temperatures will be on average. The sunrise time will be later in the day or as seen on clock-time, and sunset times will be earlier in the day or on clock-time. The tilt of the Earth effectively shifts the path of the Sun across the sky to having a more southern path. The net result of this effect is that there is less daylight time and a longer night time. The Sun will rise in a more south-east direction, and will set in a more south-west direction, and instead of the ideal, directly or nearly east, and directly or nearly west directions as for a location at the solar plane and-or effective "solar equator" latitude region of the Earth that is currently closest to the true solar plane. For a simple example, at about 40° latitude, the sunset time will be about 9pm in the summer, and about 4:20pm in the winter. This time change is periodic and sinusoidal in value since the apparent tilt of the Earth is also periodic and sinusoidal invalue throughout the year.

As the apparent tilt of the Earth changes throughout the year and-or orbit around the Sun, this will change the effective latitude of a location on Earth with respect to the solar plane, and it will then also affect the sunrise and sunset times of the Sun at the horizon. When the northern hemisphere is tilted towards the Sun in the summer season, the sunrise time will be earlier in the day, and the sunset time will be longer in the day. Here, the Sun will appear to travel across the sky in more of an eastward to westward direction, and more above ("higher in the sky", higher angle, higher altitude) locations at those latitudes.

The equation of time offset value throughout the year will also affect the sunrise and sunset times.

CALCULATING THE LENGTH OF DAYLIGHT AT A GIVEN LATITUDE

[FIG 290A]



As shown in part A of the above figure, let us consider the equinox days (typically about March 20, and June 20, but a leap year with an extra day will affect these date values) when the poles of the Earth are equidistant from the solar plane and-or the geographical equator of Earth is at the solar plane. On this date, the Sun will be directly overhead at noon at locations at the Equator circle or arc about the Earth. The imaginary rotation axis or line of the Earth is at 90° to the solar plane.

Throughout the year, the Earth will have a maximum apparent and-or effective tilt of about 23.5° towards the Sun, such as in the summer months, and 23.5° away from the Sun, such as in the winter months. In the winter months, the weather in the northern hemisphere gets lower in temperature due to the lower (with respect to the horizon) east to west arc angle and-or path of the Sun. Locations in the higher latitudes will then have less direct sunlight and will therefore be cooler in temperature. part A of the above figure shows the Earth tilted 23.5° towards the S, and the Sun will appear to travel at a higher angle up in the sky, and the air temperature will be warmer (perhaps 50 °F or more) than during winter.

In the above figure of the globe or sphere of the Earth, and as viewed from being perpendicular to the rays of the sunlight, half of its surface will be illuminated by the Sun as shown by the unshaded region experiencing some amount of sunlight as the Earth turns or rotates on its axis. The shaded region will experience no direct illumination from the Sun, and will be in darkness and-or nighttime. The division between the sunlit and dark (ie., unlit) side of a globe or sphere such as Earth, Moon or some other planet is called the **terminator line**. Half (50%) of a sphere's surface will always be illuminated, and half (50%) will always be in darkness (ie., not illuminated). Depending on what direction the sphere is viewed, only some portion (ie., <=50%) of it will be seen as illuminated, and for example, this is commonly seen as the phases of the Moon as it orbits about the Earth throughout the month. The terminator line is always perpendicular to the rays of light upon the sphere, hence the terminator line is also perpendicular to the solar plane.

Considering the northern hemisphere and latitudes, the total length of daylight time is always shorter (ie., less than 12 hours such as at the equator during equinox) for a greater (ie., higher, from or vertically above the equator) latitude, and the maximum amount of daylight time will also then be even shorter in the winter. In the northern hemisphere, the apparent path of the Sun across the sky throughout the day will appear to be more southern in the winter months when the northern hemisphere "tilts back" or "away from" the Sun. This effect also places the sunrise and sunset locations along the horizon in a more southern direction. Instead of the Sun rising in the true east direction such as during the equinox days, it will rise slightly to the south, hence southward of east, and by 23.5 ° along the horizon. Just the same, it will also set slightly to the south, hence southward of true west, and by 23.5° along the horizon.

Consider that when the Earth effectively tilts back in the winter, the Earth's surface along the horizon will increasingly block more and more of the visible sunrise and sunset, and therefore making sunrise time to be delayed longer in time, and the sunset time to be shortened or lesser by the same amount of time. The total effect of this is a day with less full daylight time where the Sun is visible in the sky. Do not look at the intensely bright Sun, but rather look at sunlit or illuminated objects that are not as bright. The higher the latitude during winter, the greater all these effects mentioned.

In summary, the amount of daylight during the day depends on the location's latitude, and apparent tilt of the Earth with respect to the Sun and-or solar plane, and of which depends on the day of the year being considered. If the daylight at a latitude is shortened by x minutes, the nighttime will be lengthened by the same amount. For all seasons, locations and latitudes, it will always take 24 hours for the Earth to revolve once about axis, hence: daytime length + nighttime length = 24 hours. nighttime length = 24 hours - daytime length , daytime length = 24 hours - nighttime length

If the length of daylight can be calculated, we can subtract half the daylight time value from local noon (12pm) so as to find the sunrise time, and add half the daylight time value so as to find the sunset time. Due to the elliptical, "elongated" or "lopsided" orbit of Earth about the Sun and the associated "equation of time" concept creating a time offset from an ideal circular orbit, this will affect the actual or true sunrise , local or solar noon, and sunset times by a few minutes.

There are two ways to find the length of daylight at a certain latitude and during a certain day of the year, and of which is associated with the apparent tilt of the Earth for that day. This book shows how to calculate the tilt angle value for a certain day of the year.

1. Practical estimation using length measurements on a drawn figure of Earth at a certain day and its "tilt angle"such as shown in the above figures. Once these values are measured, a proportion or equivalent fraction type of equation will be used to find the length of daylight.

$$\frac{\text{24 hours}}{\text{chord length at latitude}} = \frac{\text{(daylight hours)}}{(d1 + d2)}$$

: Extra, tote that: 2 d1 / 24 h = d1 / 12 h ,
chord length at latitude = 2 d1 , and
d2 represents any additional hours of sunlight > 12 hours

2. Trigonometry. We can let DT= total daylight time = d1 + extra daylight time due to the tilt towards the Sun. DT = d1 + d2. We can use a proportion or equivalent fraction type of equation to find the total time of the daylight:

Considering part A in the figure:

$\sin L = \text{opp.} / \text{hyp.} = y / \text{hyp.} = d3 / r$: r = radius of the sphere, but we can set r=1 and use relative values for the calculations. Here L = latitude and-or its corresponding angle:

Letting r=1 for relative values and analysis, which is similar to using percentages. If we let (r) now increase by a factor of (n) we have: r= n(1) = N, then all relative values are to be multiplied by N, or in other words, they are already a multiple of

$n = r$.

$d3 = \sin L$: considering $r = 1$

$d1 = \cos L = \text{adj} / \text{hyp} = x / r = d1 / r = d1$: considering $r = 1$

$2\, d1 =$ latitude chord length : If needed. If d1 is a relative value, then 2 d1 is also a relative value

$\tan T = \text{opp.} / \text{adj.} = d2 / d3$: T = current, apparent tilt angle of the Earth with respect to the solar plane or Sun

$d2 = d3 \tan T = \sin L \tan T$: when $r = 1$ or using relative values

Ex. Considering the figure in part B above, the Earth is tilted at 23.5 ° = Tilt angle , and the Latitude angle is 41° North.

$d1 = \cos L = \cos 41^\circ = 0.7547\underline{1}$ and $d3 = \sin L = \sin 41^\circ = 0.6560\underline{6}$ and

$d2 = d3 \tan T = 0.6560\underline{6} \tan 23.5^\circ = 0.28526\underline{3}$

Using a relative value of 1 for d1, and of which corresponds to 12 hours of daylight:

$$\frac{12\text{ hours}}{d1} = \frac{12\text{ hours}}{1\text{ distance unit}} = \frac{\text{total daylight hours}}{(1 + d2)} = \frac{\text{total daylight hours}}{1.28526\underline{3}}$$, solving for total daylight hours:

total daylight hours = 15.42 hours =~ 15 hours and 25 minutes : the equation of time (offset) could make this result even more accurate by a few minutes

Here are some general considerations, and of which some were previously mentioned:

1. On equinox days (March 20, and September 20) , everyone will have 12 hours of daylight,and 12 hours of darkness (ie., essentially in the shade of the Earth).

2. Axial tilt of a general sphere that rotates, and the daylight time in a certain latitude due to that tilt. We know the time of daylight is less when the northern hemisphere during winter because we know for example that the Sun is no longer rising directly east, but southward of east. That is, the Sun is then below the horizon if it were the normal sphere with a perpendicular axis (ie., not tilt with respect to the solar plane) as mentioned in part A. The Sun will eventually rise, but it will be later in the day, and will set earlier in the day. For days past spring (March 20) and into the summer days, the northern hemisphere tilts toward the sun, and the sunrise and sunsets will get more in the northward direction.

3. Current tilt of the Earth's sphere with respect to the Sun and-or solar plane as it orbits the Sun. This is due to the elliptical orbit about the Sun, and this tilt will also effect the length of daylight. .

4. Notice the south polar region in total darkness when the Earth is at full tilt of 23.5°, and at the same time, the north polar region is in total daylight. These latitudes and regions near the Earth's north pole and south pole are called the Arctic circle and Arctic zone, and Antarctic circle and Antarctic zone. The latitude is: (90° +,- 23.5°) = +,- 66.5°

5. Due to the symmetry of a sphere and with a tilted axis of rotation, if a certain latitude has (s) hours of sunlight at a certain latitude, it will have (24 - s) hours of darkness at that latitude, and the corresponding negative latitude will have (24 - s) hours of sunlight.

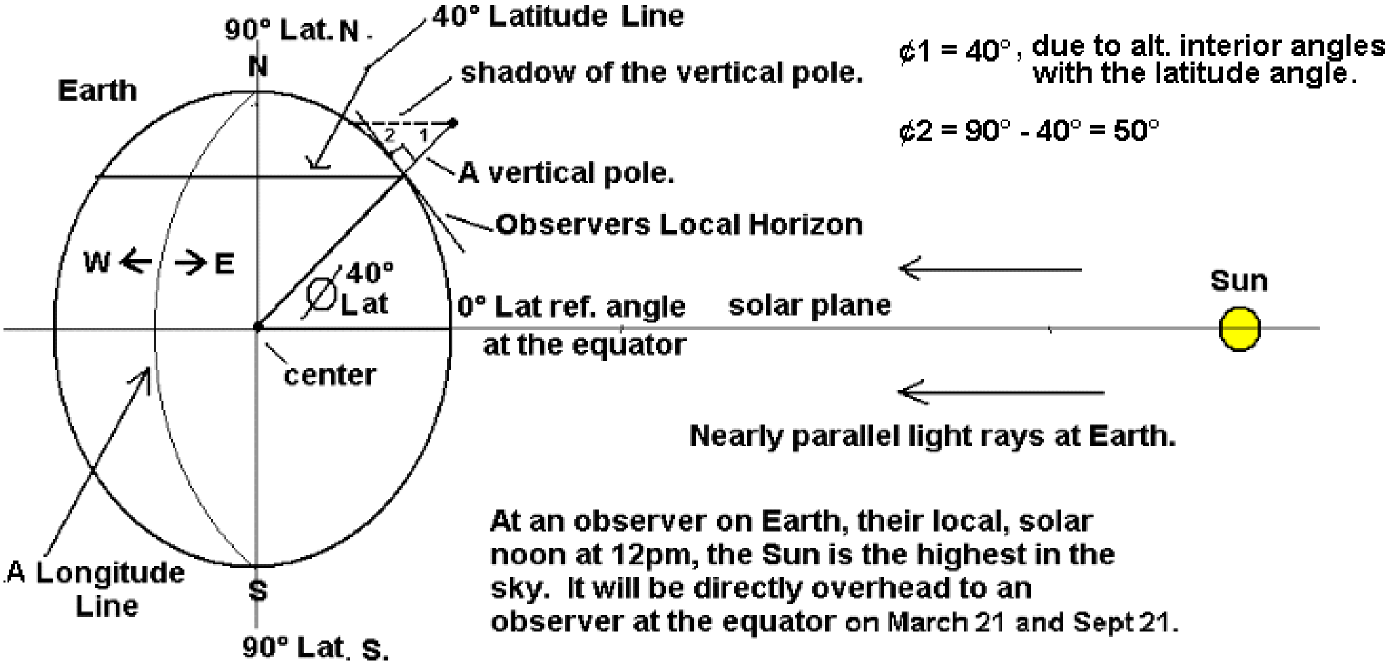
EARTH, SUN, MOON, AND STARS ASTRONOMY

The diameter of the Earth is about 7926 miles at the equator, hence about 8000 miles wide, and is about 27 miles less in distance from the north geographic pole to the south geographic pole and this is due to that Earth is spinning and the amount of (outward) centrifugal force is causing it to bulge slightly wider by about 27 miles at the equator region. The equator is perpendicular (ie., 90° to,a right-angle) to the north-pole to the south-pole axis or line of Earth's daily rotation, and is located midway between its length. The circumference of the Earth at the equator is: C = (pi)(diameter) = (2)(pi)(radius) = (2)(pi)3963mi = 24900mi =~ 25000mi. This circumference value is then also slightly less along Earth's polar axis. The radius of the Earth is often roughly noted as: r = 4000 miles, its diameter as: d = 8000 miles, and its circumference as: c = 25000 miles =~ (25000 mi) (1.609363 km/mi) = 40234 km = roughly 40000 km.

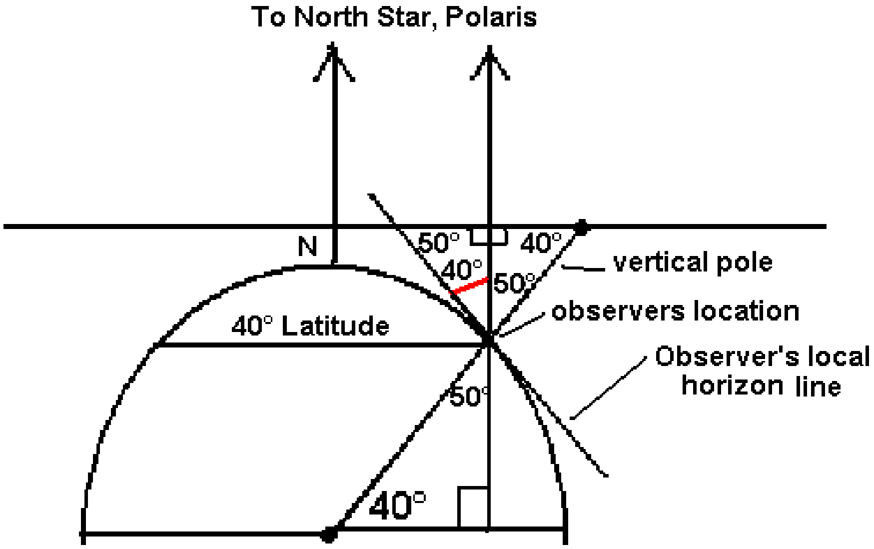
An ancient Greek, and multi-scientist named **Eratosthenes** (of Cyrene, a city in Libya, North Africa, near the Mediterranean Sea) worked at the Library of Alexandria, and in about the year 240BC, he had two people measure the angles cast by the shadow of two vertical sticks on the same day and time (local noon) at two distant locations (Alexandria and Syene, Egypt) that are located directly north and south with respect to each on Earth's surface. Today we would say that these locations directly north and south of each other are located on the same longitude line and-or have the same value of longitude on Earth, and therefore have the same time of day such as solar noon time (ie. true local noon time, rather than a (wide distance, unified) "timezone time" and-or 24 hour, fixed, constant "clock time") where the Sun is highest in the sky, and also have the same sunrise and sunset times. You can place a vertical stick on the ground, and when the shadow from it is the least length, it is solar noon and the Sun is the highest it will be in the sky for that day. Eratosthenes then (closely) calculated Earth's circumference using basic geometry and trigonometry. Today, his scientific method and result are considered highly accurate, and his was done at a time before he knew of the decimal number system. From this circumference value, Earth's diameter and radius could then be calculated also. These values eventually helped the calculation of other important astronomical sizes and distances such as to the Moon and Sun. The Earth was thought (ie., a theory) to be a probable sphere before this time, such as by **Aristotle** in about 300 BC. and due to various astronomical reasoning such as the Moon being round or spherical in shape and therefore, it orbits a (theoretical, not proven yet) round Earth. Aristotle (384BC - 322BC), was a Greek mathematician, and mostly a philosopher about thought and reason, and was a student of the philosopher **Plato (427BC-347BC)**, from Athens in Greece, and who was a student of **Socrates (469BC-399BC),** from Athens in Greece. Eratosthenes also conceived the concept of what we call today as latitude and longitude lines, and hence their intersections (ie., coordinates, address, location) so as to map and-or find locations and-or their distances between them on the Earth's surface. Before Eratosthenes, it was well known, such as by the people of ancient Egypt who studied the Sun and its motion throughout the year(s), and that there were 365 days in a year. Eratosthenes made a more accurate calculation of 365 days plus a quarter (ie., 1/4 of a day, and 1/4 of 25 hours is 6 hours) of a day, hence 365.25 days. After Earth orbits the Sun in 1 year of time, the nighttime stars (which always do not appear to move with respect to each other, and appear fixed in position due to their great distances away) and-or constellations (a visible arrangement of stars) will be in the exact same position as the year before. Modernly, the number of days in 1 year has been adjusted to be: 365.2421875 days. In common "24 hour clock-time" or "365 day calendar time" and-or non-scientific use, a year is still considered as simply being 365 days of time duration or "time length" and an adjustment or correction will be made as a "leap year day" every four years.

Constellations or known groups of stars that are within +,- 8° of the ecliptic are called the zodiac of constellations and stars. Long ago, ancient astronomers divided the ecliptic into 12 constellations called the zodiac, and each is a month long in apparent duration and-or alignment. During the day at noon = 12PM, the Sun is in line with one constellation of the zodiac, while at the same time on the other side of the Earth at midnight = 12AM, we can see the constellation that is 180° or 6 constellations away from the Sun's and Earth's apparent circle or orbit of travel though the night sky and zodiac throughout the year. As the Earth travels counter-clockwise about the Sun, during the year, the Earth and-or Sun will appear to enter a new constellation among the zodiac about every 30 days or 1 month. Ancient astronomers called and used the zodiac as "signs" of yearly events, and would then predict things that will happen during that time of year, such as what season it is - perhaps planting or harvest season. The location of the sunrise and sunsets along the horizon can also be used to determine what season. month, week and possibly the day of the year it is. For modern astronomers, the stars of a constellation are generally now known to be not at the same distance away or "depth" from the observer and-or Earth, but only appear to be that way, and each star may actually be many light years closer or distant to the observer.

[FIG 290B]



In the above figure, the shadow and the corresponding angles created will change throughout the 24 day as the Earth rotates on its axis and the apparent position of the Sun then changes in the sky. This angle also changes day by day throughout the year as the angle between the equator and solar plane effectively changes. What does not change is that since the North Star, Polaris, is a point of light and very distant and is not apparently moving, and therefore its angle with respect to the observers horizon line at their latitude will not change. This angle between an observers local horizon line and the line to the North Star is also equal to the observers latitude on Earth. [FIG 290C]



What could of inspired Eratosthenes to determine if the Earth was round? It was probably several known facts. One fact is that in the Northern directions from certain locations (ie., near the Equator) on Earth, and in the Southern directions from certain locations (ie., near the Equator) on Earth, the average temperature was lower. This hinted of the land at the pole regions which do not get much direct sunlight energy, and due to being more curved away from the direct sunlight. One other fact is that the Sun was sometimes directly above in certain locations (ie., near the Equator), but never directly above in many other locations, and rather at a maximum angle that is less than 90° with respect to the local horizon. The locations were it is directly above are also the hottest locations. Another fact is that people on small boats could not see the low laying shoreline areas, and this is due to the curvature of the Earth. It is also possible that the round Moon shape and the somewhat curved (terminator line) shadow most likely gave Eratosthenes an idea that Earth may also be round (2 dimensional) also, and particularly, a (3 dimensional) sphere shape. The Moon (light and shadow) phases throughout a month of time have a curved shape, and which indicates that the Moon may be a sphere. Eratosthenes new that locations directly south or north or each other had the same (solar) time of day in those locations. For example, in those locations the Sun would be at its highest angle throughout the day. Though in these locations, the shadow lengths of similar poles would be at different lengths, and today we know that this is due to the different latitudes, the indicated time on a solar clock, even if just a stick in the ground, would point in the same direction, and so as indicating the same time of day. The stars appear to move eastward to westward like the Sun does as the Earth turns about its polar (N to S) axis and a point or location on it moves westward to eastward. The stars also appeared to travel about the star Polaris throughout the night and day of each year, and that the star Polaris is always at the same angle in the night sky, and this angle depends on the observers (latitude - north and south) location on Earth. Out at sea, sailors can see a mountain or tall building appear to slowly rise upward from the horizon of the sea as they travel towards it, and people on the shore can see a tall ship appear to go below the horizon of the sea at it travels away from them. Clouds appear to meet with the distant horizon. To Eratosthenes, all these things mentioned seemed to indicate that the Earth might be a sphere, and which rotated from westward to eastward throughout the day and night on an imaginary axis from the north pole to the south pole.

Extra: Notice that at each latitude, that the circumference or circle around the Earth at that latitude is less the further north from the equator, and less further south of the equator. Using the above figure, the radius (Rlat) of this circle at a certain latitude is equal to the bottom leg of the large right triangle shown in FIG 212B. Clat = 2 (pi) Rlat .

Ex. The distance around the Earth at 40° Latitude is: Clat = 2 (pi) **[** Rlat **]** = (6.28) **[** (Cos Lat ¢)(Radius Of Earth) **]** =
= (6.28)(Cos 40°)(4000 mi) = 19243 mi

Another important note is that the longitude lines get closer together and converge at the poles. At the Equator, each degree of longitude corresponds to a distance of:

Total Arc Length / 360° = (Circumference at the Equator) / 360° = 25000 mi / 360° = 69**.**444... mi / 1°
Dividing both the numerator and denominator by 69.444... and arbitrarily inverting the fraction, we find: 0.0144° / 1 mi

For other latitudes, use the circumference around the Earth at that latitude.

The length of each longitude line from the north pole to the south pole is half of the circumference of the Earth:
Total length of a longitude line is: (Earth's circumference) / 2 = 25000 mi / 2 = 12500 mi
Each degree along a north pole to south pole longitude line also corresponds to 12500 / 180° = 69**.**44 mi... / 1° = =~ 70mi / 1°

Earth will rotate on its axis, once ever 24 hours, hence it rotates: 360° / 24h = 15° / h : Earth's angular velocity
Since 360° corresponds to 25000mi at the equator, it rotates : 25000 / 24h = 1041**.**66..mi / h : Earths linear velocity at the equator.

Due to this, each hour increment of time was given a latitude line that is 15° apart. After one hour of time of Earth's rotation, the Sun will be overhead or at its highest point in the sky at the next hourly latitude line to the west.
At the equator, the next hourly latitude line is 1041**.**66 mi away.

$$1041.66 \text{ mi / h} = 1041.66 / 60 \text{ min} = 17.3611... \text{ mi / 1 min.} = 17.3611... \text{ mi / 60s} = 0.28935\underline{2} \text{ mi / 1s} =$$
$$= (0.28935\underline{2} \text{ mi / 1s}) (5200 \text{ ft / mi}) = 1528 \text{ ft/s}$$

Where is the opposite side of the Earth from your current location? It is halfway around the Earth, hence at Ce/2 = 25000/2 = 12500mi, and 180° in (east, west) longitude away from your current longitude, and the latitude of that location will be the same as your latitude, except that it will be on the other side (north (+) or south (-)) of the Equator.

If two locations on Earth are said as being 100 miles apart, what is their angle of separation? This angle is a central angle from the center point of the Earth. On the surface of Earth, a distance from one point to another is actually an arc (like a semi-circle, or segment) of the Earth's circumference. Some or part of these equations and-or values were given above. Writing a proportion type of equation:

First: $\frac{360°}{25000 \text{ mi}}$ is to as = $\frac{x°}{100 \text{ mi}}$, after solving for x° we find: $x° = 1.44°$
The locations are separated by 1.44 degrees on Earth's surface

How the Earth was finally proven as being a sphere shape

With the Earth known as being a possible sphere, and much how like the Moon appears to be round and a possible sphere, mankind has desired to find out if this is true, and then by attempting to travel around the Earth in just one main direction (East or West) and then to arrive in the same starting location from the other direction. In about the year 980AD to 1000AD, **Erik Thorvaldsson** (aka. "Erik the Red"), (950 - 1003), from Norway, the father of Leif Erikson, discovered Greenland to the west of the island of Iceland, and eventually made some settlements (ie., colonies) in Greenland's southernmost coastal regions. It is possible that if there were any native Greenlanders in his area, that they may have told him of lands further westward. **Leif Erikson** (970-1025), from Norway, in about the year 1000AD, sailed west to find new land and resources further west past Greenland and to its south, and rather than specifically trying to go around the Earth, He made a small settlement on the east coast of Vinland (Vine-Land, (grapes) Wine Land, and what is called today as the province (ie., like a large region, or state in a country) of Newfoundland, Canada on the North America continent. Erikson is generally believed to have come in contacts with the natives (North Americans, "Indians") of Vinland.

The knowledge of Erikson's discoveries, was either vague, secret, hearsay and-or an unsurity by the time of Christopher Columbus. **Christopher Columbus** (1451-1506), from Italy, and with funding from Spain, he sailed westward in 1492 and found many islands which he thought were the East Indies islands which were known to Europe ever since Marco Polo's travels and explorations, and which are eastward of India and southward of far-east Asia. What Columbus actually found were the (now called: "West Indies" [westward Indies, when traveling westward from Europe]) islands (particularly Jamaica) off the south eastern coast of what is now called the state of Florida and Central America. Columbus, thinking that he did go around the Earth and landed someplace near the country of India, then called the native people as Indians. The first American natives migrated to north Americas at about 20 thousand years previously from northern Russia called Siberia, north Mongolia (ie., just south of northern Russia, and perhaps a mixed race including what is now the northern China area) of which are all generally a northern Asian race of people. Supposedly during the last "Ice Age", theses people, now called the **Paleo** (Paleolithic era = ancient era, "caveman", "stoneage") people came to the Americas, near Alaska, on a (53 mile wide) ice bridge at the Bering Sea in the northern Pacific Ocean, and between the North Asia and North America continents. Columbus took his discoveries and news back to Europe. and where many ships and people would soon want to make the journey to the "new world". By 1493 Columbus was beginning to create some small colonies in the Dominican Republic (a Hispanic [Spain territory] island) such as the first one called **Isabella**. On the American mainland, **Jamestown** (now in Virginia state) was the first colony of Europeans and was began about 100 years after Isabella in 1607. **Plymouth** (now in Massachusetts state of the United States of America - USA) was the next significant colony started in 1620. The natives were both afraid and in wonder of some of the abilities of the people from across the Atlantic ocean to the east, such as having products made of iron metal, rather than copper, and which was both harder and durable and much less brittle, and therefore, it was considered as an extremely useful and valuable item to them. Some natives, particularly in the South America regions, already knew of and-or had copper, and gold metal products created from melted gold nuggets, but gold is relatively soft and rare and is not practical for tools. Even a discarded iron nail or a small piece of scrap iron metal was considered very useful and valuable to the natives.

Columbus, during his 4 voyages to the "new world", also made some wonderful discoveries such as some new varieties of plants and foods to take back to Europe, and to then grow them if possible. The people of Ireland are well known for growing potatoes, but relatively few know that the plants and seeds for them were brought from the "new world" that Columbus discovered. It did not take too long for the Europeans to realize that the native (ie., original) people that Columbus encountered and called them as "Indians" were not actually from the country of India, and therefore, Columbus did not sail around the Earth to prove it was a sphere. Some of his ship crew, and later the Europeans, probably theorized that the Natives were of some far-east, North-Asian lineage and were not from India. Perhaps by calling the natives as "Indians" he let the European people know in some way that this so called "new territory" or "new world" was already inhabited and controlled by someone else, and it was therefore not necessarily free to obtain the resources and-or to colonize, etc.

The colonies of the United States declared independence from European rule on July 4, 1776 when the Declaration Of Independence was signed, and the United States of America, Constitution was created on September 17, 1787 in the city of Philadelphia in the state of Pennsylvania. This was nearly 300 years after Columbus found the "New World Of The West". Most politicians and-or representatives signed the Constitution, but some did not because of a lack of a written, specific Bill Of Rights. The Bill Of Rights began to be placed into the Constitution as Amendments to the Constitution in 1789. Because of business claims and ties to Europe and the need for African-American slaves to continue working for the economy and needs of the south-eastern states, it took until a costly (life, property, etc.) Civil War (1860-1865) with a large number of soldiers lives so as to obtain the ideals expressed in the Constitution, and to keep the southern states as part of the country. Back then slavery was common for many races and locations since ancient days (even St. Patrick was said to be a type of slave), and with few jobs and education available, and was considered much like that of a helpful servant who was reasonably taken care of in return, and so as to perform the best they could and help many others. Canada became mostly independent of Britain in 1867, and finally in 1982. Mexico became independent of Spain in1821.

The land of the Americas is very long southward and naturally impassable by a ship, westward or eastward, until **Ferdinand Magellan** (1480-1521), from Portugal, and who was later associated with business of the Spanish empire, sailed very far south along the east coast of the Americas and made it to the Pacific ocean to the west. Magellan actually called this vast water as the Peaceful Sea after sailing through the rough seas he encountered in the southern Atlantic Ocean. Today, the Pacific Sea is commonly known as the Pacific Ocean. The Pacific Ocean is the largest ocean on Earth. Magellan made it to the Philippine Island areas in the south-western Pacific ocean, and of which he had once previously sailed near to and knew the geography fairly well, and then he finally knew that the Earth was a sphere shape. These areas area also modernly known as the South-East Asia Islands, and of which are northward and north-eastward of Australia. These South-East Asia Islands are also called the Polynesian Islands and of which are inhabitant by the Polynesian people which are an ancient mixed race of people, most likely from India and Southern Asia. The people of the Philippine Islands are generally considered as the original or main source of the Polynesian or "Pacific-Islander" people(s) that inhabit the islands which are mostly to the south and south-eastward of the Philippine Islands in the Pacific ocean. They are sometimes called the "Oceanic people(s)". One of Magellan's fleet of ships with its captain and crew made it back to Spain in **1522**, and thereby verifying and proving to others that the Earth was a sphere shape, and that the Sun and Moon were probably spheres also. **Marco Polo** (1254-1324), from Italy, had previously explored this central east, far-east, and south-east asia areas in about the year 1270 and brought back several discoveries to Europe, such as pasta (ie., noodles, a food made from wheat, and which did not spoil easily) and printing by using wood blocks as the print pattern. Polo went to find new and better routes, people, and items for trade. Polo traveled on land in 1271, and eastward along the "silk road" trade route toward China, Mongolia and South-East Asia in 1271. His father and uncle had previously explored some of these trading routes. Some of the other countries he explored were Israel, Iraq, Iran, Afghanistan and Pakistan, After reaching China, he met **Khubilai Khann** (1215-1294), from Mongolia, who was the grandson of **Genghis Khan**. Khubilai became a famous ruler in the Mongolia area and later in China. Khann made Polo a diplomat and so as to help travel, learn and explore the far-East areas in the hopes of eventually trading and understanding cultures. In 1292, he began to his sail back around south-east China, south-east Asia, and the continent of India. He landed in southern Iran and traveled back to Venice, Italy on land routes and the Mediterranean sea.. He had traveled 24 years on this journey. He did not sail around Africa, and the Suez Canal in Egypt was not yet built. Polo wrote a book called "The Travels Of Marco Polo" about his journey, and which was then useful for many other map-makers, explorers, politicians, and merchants (business people, traders). Polo is generally credited to also discovering for Europe, that the continent of Asia ended at a great ocean (now called the Pacific Ocean) to the east of China. The first person from the "west" (ie., Europe, before the discovery of the New World - Americas in the Western hemisphere of the Earth) to discover going around the southern tip (Cape of Good Hope) of Africa as a trade route to Asia was **Bartolomeu Dias** (1450-1500), from Portugal, in about 1448.

Australia and its route was eventually reached and "(re)discovered" by Europeans - possibly, and informally by **Christovao de Mendoca** of Portugal in 1522 by sailing eastward from Europe. Australia was formally discovered by **Willem Janszoon**,from Denmark, sailing eastward in 1606, and then later by **James Cook**, sailing westward from England, in 1770, and particularly the East coast of Australia. The European's first name for Australia was New Holland (Dutch), then New South Wales (English), and then Australia which means "the southern land", and particularly since it is south of the equator. Off the east coast of Australia in the Pacific Ocean is the island of **New Zealand** which was first noticed in 1642 by the Dutch explorer **Abel Tasman,** sailing westward**,** and then it was later landed upon and mapped by James Cook in 1769. Tasman is credited to formally discovering the island of Tasmania in 1642, and it is just south of Australia. Tasmania became an Australian state in 1905. Cook is also credited as being the first European to discover and-or make contact with the **Hawaiian islands** and its people in 1778. Today, Hawaii is a state (as of 1959) of the country of the United States of America (U.S.A). The natives of Australia, often simply called the **Aborigines**, meaning "the original, first people and inhabitants of", are most likely an ancient mixed race descended from the migrating tribes of people from both Africa and India. About 4500mi to the south-east of Hawaii, and south of the equator, the Polynesians have reached and inhabited **Easter Island (Rapa Nui)** since about 300AD. Some Polynesians seem to have reached Central America after 100BC and then migrated mostly to the south and mixing with the natives, and with some possibly migrating westward to some of the more eastern Polynesian islands by around 1200AD. Polynesians also seem to have reached the western shore of South America by about 1000AD in the areas of Peru and Chile to the south at nearly 2300 miles to the east of Easter Island. European explorers first seen and reached Easter Island on Easter Day by the Dutch explorer **Jacob Roggeveen** in 1722. Today, Easter Island is a protected territory (ie., like an independent state, and given assistance, etc.) of the country of Chile in South America.

Between the North America continent and the South American continent is an area commonly called Central America, and of which includes the countries just to the south of Mexico on the North American continent, and to the north of Colombia on the South American continent. In Central America, there is a short distance, natural land-bridge from the Atlantic Ocean to the Pacific Ocean in the country of Panama that is just north of Colombia. If ships could travel through here, it would eliminate the need to travel thousands of miles around the South American continent so as to reach the Pacific Ocean to the west. Columbus reached the American continent on his last voyage (1502-1504), and in the area of Panama, and then searching for a ocean passageway to the (Pacific) ocean as described by the natives. The first European to actually explore and describe this (narrow) land-bridge was **Vasco Nunez de Balboa**, from Spain, in 1513. After 10 years of hard effort in the jungle and climate of Panama, a 50 mile long, lake and canal system for ships to travel across Panama was completed in 1914, and thereby saving ships thousands of miles of travel and days of time. This canal is called the **Panama Cana**l, and its concept is much like that of the **Suez Canal** that was previously built in Egypt so as to greatly reduce the travel distance and time around the continent of Africa. The Suez Canal was completed in 1869 and extends about 120 miles from the eastern Mediterranean Sea and southward to the Red Sea, and travels between east Egypt and west of the Sinai peninsula of Arabia. Two other long canal systems of mention are the **Eire Canal** system in the northern part of the state of New York, USA, and is about 350 miles long, and the **Grand Canal** system in eastern China, being about 1100 miles long. Today with planes, automobiles, and trains, transportation can be much faster than via a ship. An advantage of using ships is that free wind power can be used to move (sailing) ships and-or boats, and that very large volumes of goods can be transported to nearly any port that can dock such ships, and-or areas that have good coastal locations to anchor a ship nearby. As of about the year 2000, some have speculated that modern railways can be an alternative option near the Suez and Panama Canals, and this will then also require further ships to complete the remainder of the journey. Europe has built a modern tunnel and railways system beneath the bottom of the English Channel from France To England, and this is often called the "**Chunnel**".

As of the year 2025, trains and boats are still used to transport large masses of materials and many (say from 100 to 1000) people. The front of a boat or ship is called the "**bow**", and is usually moves in the "bow direction" or direction that the bow is pointing to and-or is facing. The right side of ship is often called the **starboard** side, and the left side is often called the **port** side. The origin of the word starboard is due to the (usual) right hand, rudder steering (based on the word "steo") of a small boat, and the port side is then where the boat would then port or dock itself to load and-or unload cargo and-or crew members.

Earth's (pole to pole, "polar", north to south, and rotational) axis is not perpendicular (90°) to it's orbital plane (or "ecliptic", or solar-plane) of it going around the Sun, but is rather tilted with respect to this plane of (0°) reference. This tilt angle value is nearly a constant value for over hundreds of years of time, and as of the year 2022AD, it is about **23.436°**. This tilt angle is also said by astronomers to vary periodically over about 10,000 years as the Sun and entire solar system of planets orbit the center of the Milky-Way galaxy of stars. The tilt angle can vary during this time from 22.1° to 24.5°. The **Milky-Way galaxy** of which we are located in gets its ancient name from the visible long band or grouping of stars seen across a part of the sky at night, and which was called the Milky-Way. This region is actually an arm or "arm-band" of the spiral of the galaxy. All the visible stars we see are in the Milky-Way galaxy, while only a very few other galaxies, such as the Andromeda galaxy or nebula (gas structures, often from an exploded star and-or forming star group) often as faint, "fuzzy" patches to the unaided eye, however most require a telescope to see. The Andromeda galaxy (M31 = Messier object catalog number 31) is considered the closest organized and spiral galaxy to the Milky-Way galaxy, and is about 2.5 million light years away. The Milky-Way galaxy has a few less organized, closer and smaller orbiting satellite galaxies such as the Canis Major dwarf galaxy at 25000 light years away. With just a small telescope or binoculars, many more stars in the Milky-Way galaxy can be seen. Light sensitive, long duration photography with telescopes or some cameras can also image many more stars and-or structures that are even too dim or faint for a large telescopes to image. Individual stars in other galaxies can be seen using such photographic methods.

The diameter of the Moon is about 2159 miles ~= 2160 miles, and its circumference is then about 6782 miles. The Moon's diameter is about (1/4) of that of the Earth, hence about 4 times smaller, and the view of (level) horizon of the Moon's surface is about 4 times less (ie., closer) as distant as compared to the Earths horizontal view to a person on Earth. The circumference of the Moon is also about (1/4) that of the Earth's circumference. The distance to the Moon averages about 239900 miles =~ 240000 miles = $38624\underline{3}$ km away, and this was first roughly calculated by a Greek citizen named **Aristarchus of Samos** in about the year 270BC, and later improved by another Greek named **Hipparchus** in about 129BC. Clearly, the Moon is closer to the Earth than the Sun due to that the Moon always eclipses or blocks the Sun and its light during a solar (ie., Sun) eclipse. The (complete or "umbra") shadow (about 85 miles in radius and-or 170 wide in diameter) of the Moon at the location on Earth where it experiences a full solar eclipse will then be on the Earth for a few minutes or longer over that location in its "shadow path" on Earth. People who experience a partial eclipse are in the shadow zone or region called the "penumbra". A lunar eclipses is when the Earth blocks the sunlight from reaching the Moon, and the shadow of the Earth is then seen on the Moon. Another astronomical fact is that the apparent visible angle (or "width") of the Moon and Sun is the same part of the overhead sky (180°, horizon to horizon if no hills or mountains are in the way), however, this does not mean their distances are even close due to that the Sun could possibly be, and it is rather much farther away and still appears as the same visible angle, width or size as the Moon. During the Apollo Program manned Moon landings (July 1969AD to December 1972AD), a laser reflector was placed on the surface of the moon so as to measure, calculate and verify its known distance from Earth using a high power, quick pulse of laser light from Earth that was aimed at the Moon so as to have a small but usable amount of it reflected back to a receiving station on Earth after an amount of time of travel has passed. Clearly, the distance to the Moon takes half this measured amount of time at the speed of light: Distance to Moon = (speed)(time) = (speed of light) (time in seconds / 2). This distance of separation will also cause a constant, noticeable time delay or "gap" in radio communication such as with people speaking to each other, however it is a low, tolerable value of only about 1.3 seconds to the Moon, or to the Earth from the Moon.

Aristarchus, of Samos, Greece, in about 200BC, believed (proposal, theory) the Earth and other planets and stars orbited the Sun in a heliocentric ("Sun-centered") universe. **Nicolaus Copernicus** (1473-1543), from Poland, calculated and published a verification of this theory is in 1543AD. This was also verified by **Galileo Galilei** (1564-1642), from Italy. in about 1610. In 1610, after being inspired by the recent invention of the telescope, he made the first practical high power (about 20 times magnification or "power", ie., 20x) telescope at that time and made many important astronomical discoveries using it. The (refracting = light bending, usually with glass lenses) telescope was a newly recent patent applied for and-or construction (in 1609) by **Hans Lipperhey (aka Johann Lippershey)** (1570-1619), of Denmark, and it had a low magnification or "power, and it was also known previously that two magnifier lenses held at a distance apart could magnify a distant object. In 1610, **Galileo** discovered with his telescope that planet Jupiter had 4 visible moons of its own, and which revolved around it periodically (at a specific duration or amount of time), and that Earth's Moon had craters and mountains, In 1610, Venus was seen by Galileo to have (sunlight illumination) phases (like the Moon about Earth) as it orbited the Sun, sunspots, and planet Saturn's ring structure. Galileo helped prove the theorem by Aristarchus and later, Copernicus that the planets orbited the Sun. **Johannes Kepler**, in about 1609AD, found that the planets orbit the Sun in a elliptical orbit with the Sun at one of the foci (ie., end-region) of their elliptical orbit, and this is one of his celebrated planetary motion (orbit) laws. Later, in about 1667, **Isaac Newton** created the celebrated mathematical laws for force, gravity and motion (other than the well known: distance = speed x time). Newton is also credited with making the first practical Newtonian or reflecting telescope in 1668, and of which a curved parabolic shaped mirror is used as the main "objective lens" or primary mirror to gather a large amount of light coming from an object, and then direct (by a flat, reflector mirror) it all to be concentrated (and brighter, more intensity) and focused together at the eyepiece lens at the upper side of the telescope tube. Not long after the Newtonian telescope was invented, the famous (calculus) mathematician **James Gregory**, from Scotland, previously conceived the Gregorian telescope in 1663, and which was later built by the famous **Robert Hooke** in 1673. Gregory and Newton knew each other very well and influenced and assisted each other. The Gregorian telescope effectively replaced the eyepiece mirror with a small circular, concave focusing mirror to direct the light (or "light path") back through the center of the main (objective) parabolic mirror to an eyepiece lens at the other or bottom end of the telescope, and this makes another good use of the central incoming light path that is otherwise blocked by the central or secondary mirror that directs the light to the eyepiece lens at the side of the telescope. This construction increases the focal length and magnification to about twice that of a Newtonian telescope. A (Laurent) Cassegrain telescope is similar to a Gregorian telescope except that the secondary mirror is slightly convex instead of concave. Note that using a true spherical mirror does not have an exact common focus point for the incoming parallel rays, particularly at the edge of the mirror, and is then in error a small amount - hence some image aberration or distortion. Catadioptric reflector telescopes (ex: Schmidt-Cassegrain, and Maksutov) use a spherical mirror, but they also have a (nearly flat) correct lens at the front end of the telescope. For a basic telescope, the formula for its image magnification or "power" is the focal length (Fo) of the objective lens divided by the focal length (Fe) of the eyepiece lens. **The basic optical lens power = focal length of objective lens / focal length of eyepiece lens = Fo / Fe**. To increase the power of a telescope, an objective lens with a longer focal length should be used, and-or an eyepiece lens with a shorter focal length should be used. With modern images sensor with a pixel count of many millions, this lens power can be effectively increased so as to have a greater resolution where smaller parts of the object can be discerned. The Yerkes Observatory in the USA has a large refactor (ie., lens) telescope having about a 20" diameter glass objective lens, and about a 60 ft. focal length, and its magnification power is about 500 to 1000 depending on the eyepiece used. The corresponding linear magnifications are their square roots of about: 22 to 32 times wider and-or higher in appearance with the aid of the telescope.

The diameter of the Sun is now considered about 865,000 miles, and this was first roughly calculated by **Aristarchus of Samos** in about 220 B.C. The circumference of the Sun is then about 2.72 million miles. The **distance to the Sun** is now considered about 93 million miles away, and this and the distance to the Moon was also first roughly calculated by Aristarchus using right angle trigonometry during the half-moon illuminated phase, ratios, eclipses and shadows, and the previously (about 20 years earlier) made historical and significant calculation for **the radius of the Earth by Eratosthenes.** At the Sun's equator, **sunspots** (dark regions on the Suns surface, and of which began being scientifically observed and recorded (ie., drawn on paper) in about 1611 by Galileo and others with the aid of dark-glass light filters) will appear to travel from west to east across and around the Sun in about 25.4 Earth days, and about 35 Earth days at its poles. Therefore, the Sun also spins in a counter-clockwise direction as seen from above its north pole, and once on its polar axis at an average of about 30 Earth days. At the equator region of the Sun, a point, sunspot or ejecta (matter released, thrown off outward) on the Sun has a horizontal velocity across or on the Sun of about 2.72 million miles / 30 days = 90582 miles / day = 3774 miles / hour. Some solar ejecta such as low mass, lite-weight particles from a solar storms or burst will also have a vertical velocity outward or away from the Sun, perhaps up to a million miles an hour. These particles may cause electronic signal and circuit interference and-or damage when Earth is in the path of those particles.

For our Sun, there is an 11 year cycle of the appearance of sunspots on the Suns surface, and the number and-or size of the sunspots will be at maximum every 11 years on average. This cycle length could be due to the volume size of the Sun and-or the elements composing it. These things will also determine its temperature such at its core and surface.

The Sun is one star among many with an estimated 100 billion stars in the Milky-Way galaxy alone. Our Milky-Way galaxy is one among an estimated 2 trillion galaxies in the universe. There is some evidence of a **black-hole** [a dense, dark object or mass with a very high amount of gravity] at the center of many galaxies, and this usually provides the gravitational force to hold the stars in their orbits about it, much like how the Sun's gravity keeps the planets in orbit about it.

Due to their sizes and distances from Earth, both the Sun and the Moon both appear to be 0.5° = half a degree wide in the sky, and which is effectively a total angle of180°. All the stars that we see in the night sky with our eyes are in the Milky Way galaxy star system of which our Sun is also a star within it. Other galaxies with other stars composing them are so distant and faint that we cannot see their individual stars without the aid of a high power telescope.

The Earth revolves or spins about its imaginary (pole to pole) line or axis once ever 24 hours from the westward to eastward direction, or counter clockwise as viewed above the Earth at the north pole. That is, nearly: 360°/24hr = 15° per hour = 1° per 4 minutes = 0.5° / 2min = 0.25°/ 1min = 0.0041777..°/sec. The distant, and apparently stationary, Sun and stars will then appear as moving across the sky at 15° per hour, all while the Earth is still traveling (ie., orbiting) around the Sun at about 1°/day = 1°/24 hours = 0.041667°/hour to also consider. Throughout the day or night, the Sun, Moon and stars will appear to rise in the eastward direction and set in the westward direction. As an extra note:
1°/4 min = (360°/360) / 4 min = (((360 x 60) arc-minutes) / 360) / 4 min = 60 arc-minutes / 4 min =
((60 x 60)) arc-seconds / 4 min = 3600 arc-seconds / 4 min = 900 arc-seconds / min = 900 arc-seconds / 60s =
15 arc-seconds / s . For reference, 1° = 60 arc-minutes = 60' , and 1 arc-minute = 60 arc-seconds = 60"

The Earth, like most solar system objects, would also be seen to orbit the Sun in a counter-clockwise orbit when viewed from above the north pole of the Sun. The explanation to this direction is due to how the planets, solar system or galaxy formed out of gases and matter that condensed and thickened due to their gravity (gravitational attraction force), and resulting in their current shapes, sizes and orbits. Planets farther from the Sun generally have more eccentric ("more elliptical") orbits about the Sun and this is most likely due to that the force of gravity at those distances from the Sun is actually greater than the minute amounts of gravity between those distant particles of matter, and this results to a more direct attraction of the particles to move towards the Sun's direction rather than having a pure circular orbit about the Sun.

For planets, the gravitational pull or force from the Sun causes them to orbit in the common counter-clockwise direction about the Sun. The collective or resulting amount of gravity from the stars orbiting the center of the Milky-way galaxy in a counter-clockwise direction may have influenced this counter-clockwise direction of planets around the Sun. Because planets have a velocity or speed of travel, they do not keep traveling in a straight direction past the Sun, or fall into the Sun with its high value of gravity force, but the resultant sum of those two forces results is a circular-like (or elliptical) orbit of a planet about the Sun. Because the force of gravity from the Sun increases as an object or planet gets closer to the Sun, its speed or velocity will likewise increase as it gets closer to the Sun if it orbits the Sun in an elliptical orbit.

Since the Earth orbits the Sun every 365 days, the Earth orbits the Sun in about 360°/365days = 0.9863°/day, about 1°/day. At the Equator line or region of the Earth, and looking directly upward at the same time every night, all the stars will then appear to have moved from their previous position in the sky by about 1°, and is actually just slightly less than 1°

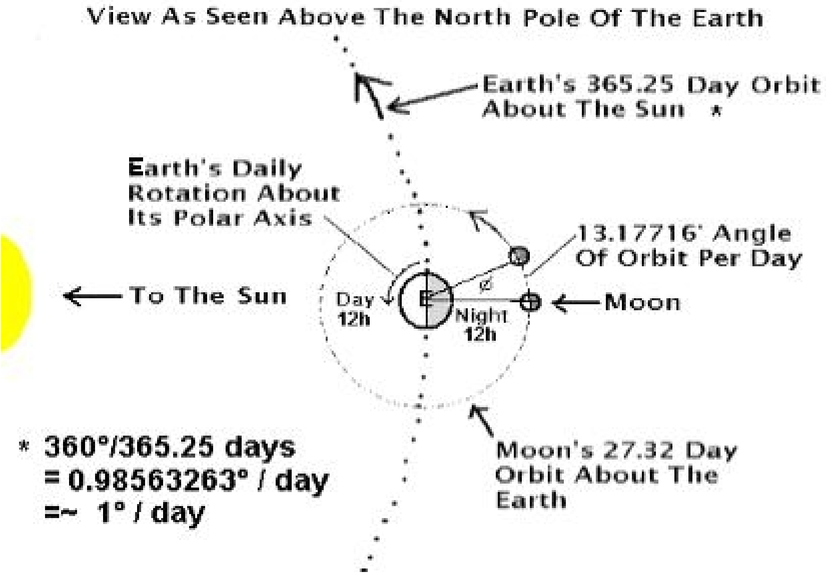
The Moon orbits (rotates about, goes around) the Earth once about every 27.32 days. A complete day of axis rotation of the Moon is also 27.32 Earth days long. During 1 year of time, the Moon will orbit the Earth (365.25 days / (27.32 days/orbit)) =~ 13.36933 times. **Because both the Moon's orbit duration time about the Earth and the Moon's own "day" length of its rotation on its axis have the same time duration, we always see the same side or hemisphere of it, and it then appears as if it does not rotate on its axis.** If you were on the Moon, the Earth would always be located at about the same location in the sky, and also seen as having shadow and light phases just as we see of the Moon from Earth. The side or hemisphere of the Moon that we do not normally see is called "the far side", and the side we always see is called the "near side". As indicated, the Moon also rotates on its axis once every 27.32 days, hence a "Moon-day" is 27.32 days long. Since the Moon rotates on its axis, the Moon has periodic day and night phases and with each phase being (27.32 Earth-days / 2) = 13.66 Earth-days units of time apart. As the Moon rotates, it will have 13.66 Earth-days of (some to complete) sunlight, and 13.66 days of (some to complete) darkness. I mentioned the word "some" because the full (lit) Moon or new (dark, unlit) Moon only lasts for a few seconds in reality as the Moon is still constantly rotating on its axis, and appears to the average person to last about 2 or three days of time length. But for example, as soon as a full Moon happens it will then soon begin to develop a thin dark crescent which will start to "wax" or cover over the Moon as the light "wanes" or is removed away. Because the Moon does not have much of any appreciable amount atmosphere gases, there isn't much, if any, of a "twilight" (brightening and-or darkening) to be seen in a theoretical (Moon) sky, but rather a more abrupt changes in the light levels. Because the Moon lacks an atmosphere, it is a great location for astronomical viewing and radio-astronomy, and the far-side is effectively shielded from most electronic noise from Earth.

For the same seen "Moon phase(s)" (ex., new moon to full lighted moon and back to new moon, etc.) as seen from on Earth, and the Sun in the same sky location as seen on the Moon (ie., a "moon-day or rotation on its polar axis) as it also orbits the Sun as part of the Earth-Moon system, takes about 29.53 Earth days of time. 29.53 days is nearly 30 days of time which is commonly spoken "month of time".

The Moon (slightly elliptical) orbits about the Earth at: 360°/ 27.32 days = (average of) 13.17716° / day = 13.17716 deg / 24hrs = 0.549048 deg / hour of movement (orbiting) about or around the Earth. Because of this motion, the Moon rises in the sky and-or is at the same position in the sky every night about 53 minutes later than the day before. In short, this is actually due to the extra time needed for the Earth to then "catch up" to the moving or advancing Moon about the Earth, and have it appear in the same location in the sky.
From above the surface of the Moon at its north pole, the Moon will be seen to revolve counter-clockwise on its axis, and also have a counter-clockwise orbit around the Earth, and this motion is exactly timed so as to eventually make the Moon appear as to not rotate on its axis, and always having the same side of it facing Earth. Setting up some proportions type of equations:

60 min / 15° = X min / 13.17716° , Xmin = about 52.71 min : the Moon appears "late" by this much every day
13.17716° / 24 hours = X° / 1 hour , X° = 0.549048° / 1 hour : how much the Moon appears to move in the sky per hour eastward or "backwards" with respect to the apparent motion of the stars.
Ex. In the 12 hours of the night, the Moon will appear to travel about:
(0.549048°/hr)(12hr) = 6.589° eastward with respect to the position of the stars.

[FIG 290D]



In the above image, the night, shaded or dark regions on the Earth and Moon is due to those areas being not illuminated by the Sun and-or effectively shaded by the other side of that body. The Moon orbits the Earth at about 0.549° / hour, hence compared to the (distant, seemingly fixed in position) stars apparently moving at 15° / hour across the sky, and the

Moon will appear to only move at (15° - 0.549°) / hour = 14.451° / hour, and it will then take about 12.45$\underline{6}$ hours for it to appear to travel from the eastern horizon to the western horizon for a total of 180° For simplicity, the Moons orbit in these basic calculations was considered as circular rather than slightly elliptical.

365.25 days = 365 days + 6 hours and 27.32 days = 27 days + 7.68 hours = 27 days + 7 hr + 40 min + 48s

The distances to the planets and stars can be estimated from the concept of what is called (visual) parallax. **Parallax** is where you observe an (hopefully , nearly fixed in position, apparently stationary) object from two locations where each location is separated by a distance, such as the stars when viewed from Earth when it is at two locations, such as say 180° about the Sun every 6 months. This maximum natural and practical astronomical distance of separation is equal to the diameter of Earth's orbit = 2 (radius) = 2 (93 million miles) = 186 million miles apart. The larger this observation distance or separation, here at 186 million miles, and the more that an object that is closer to Earth, the more that it will appear to shift (ie., parallax, perceived error from being straight or true) in reference to the further distant background objects such as other stars. Our human eyes and understanding also essentially utilizes the concepts of visual parallax so as to effectively see in "3d" and have a depth or amount of the field of view, and so as to help indicate the distances to objects we see, and especially with objects closer to us. Parallax and or motion can also be determined using two photographs taken at different times and-or when separated by a distance. You can also see the effect of parallax using a still object in front of you and closing one eye and opening the other, and then repeating this with the other eye, and that object will appear to shift in position or location. Photographic images of the stars from distance spacecraft can help determine the amount of parallax and the distance to a star(s).

As a technical note to the above image, the Moon actually goes around the Earth in the counter-clockwise direction when seen from above the solar plane, and the Earth goes about the Sun in the counter-clockwise direction. For many analysis of astronomical rotations or orbits, it is often done in a clockwise direction so as to be standardized, familiar, and-or for simplicity. For some more about astronomy, see the topic ahead in this book called Major Objects In Our Solar System.

Due to both the orbit of the Moon and Earth's length of day, the Earth is always visible from the near-side of the Moon's surface, and in fact, it is nearly always in the same location above the local horizon in the Moon's sky, and remember that the Moon is orbiting Earth which is then its "focus" of orbit. This facts helps with radio communications between people on Earth and the Moon. From the Moon's surface, Earth will appear to be larger than that of the (smaller diameter) Moon as seen from Earth's surface. The Moon appears to be about 0.5°or half a degree wide in the sky from the surface of Earth, and Earth will appear to be 4 times wider at almost 2 degrees wide in the sky as viewed from the surface of the Moon, and it would even be possible to view and-or give Earth's cloud and storm weather and forecasts from the Moon by just visual observation and-or having binoculars (essentially two small telescopes side by side, and one used for each eye). Here is a simplified calculation using right-angle trigonometry:

Tan ¢ = opposite side of angle / adjacent side of angle = 8000 mi / 240000 mi = 0.3333$\underline{3}$

¢ = ArcTan (Tan ¢) = Arctan (0.3333$\underline{3}$) = 1.909$\underline{2}$° =~ 2° visually.

COMMON WHOLE NUMBER DIVISIONS AND-OR FRACTIONS

When the numerator is 1, the value of the faction is also called as, and equal to, the reciprocal of the denominator. Note these helpful example where reciprocals are fundamentally involved:

$$\frac{2}{3} = \frac{1}{3} + \frac{1}{3} = 2\left(\frac{1}{3}\right)$$: hence twice or 2 times the reciprocal of 3 and which is (1/3).

$$\frac{1}{20} = \frac{1}{2\,(10)} = \frac{1}{2}\left(\frac{1}{10}\right) = 0.5\,(0.1) = 0.5\,(10^{-1}) = 0.05$$

$$\frac{1}{0.5} = \frac{1\,(10^{0})}{5\,(10^{-1})} = \frac{1\,(10^{(0-(-1))})}{5} = \frac{1}{5}\,(10^{+1}) = (0.2)\,(10) = 2$$

To convert a numeric (decimal) fractional part of an inch to sixteenths of an inch, divide by (1"/16) = 0.0625".   1inch = 16, sixteenths of an inch
Ex. 0.5 in = 0.5 / 0.0625 = 8 sixteenths of an inch = (8/16)in = 8(1in/0.0625)
Ex. (3/16) in = 0.1875 in , 0.1875in / 0.0625 = 3 sixteenths of 1 inch

Given an amount of kilograms (kg), 3 digits of the (decimal) fractional part is equal the number of grams (g) extra to add to the total number of kilograms.   1kg = 1000g ,   kgs = whole amount of kg + fraction of 1kg
5.345 kg = 5kg + 0.345kg = 5kg + 345g
The 3 digits past the grams part is the number of milligrams (mg).
1g = 1000mg.   1mg = 0.001g = 1mg = 0.000001kg = 1 millionth of a kg
Ex. 5.345678kg = 5kg + 345.678g = 5kg + 345g + 678mg
Ex. 345.6g = 345g + 0.6g   = 345g + 600mg

TABLE OF COMMON SQUARE ROOTS AND CUBE ROOTS

To help people consider and-or make "look up" or quick reference tables, the computer program used to created the following table of square and cube roots is given after these tables.

```
-------------------------------------------------------------------------------------------------------
COMMON SQUARE ROOTS

  1  1                    2  1.4142135623731      3  1.73205080756888

A COMPUTER PROGRAM TO CREATE A TABLE OF SQUARE AND CUBE ROOTS

```
/*------------------------------------------------------------------------------
  CommonSquareAndCubeRoots.c

     This program creates a list of common Square and Cube Roots.

     This will display the square and cube roots of the integer numbers from 1 to 100.
     Also shown is some optional formatting control for the displayed values, such as
     using the field width before the data type, and also using the - format specifier
     operator to left justify the values in the desired character width space.

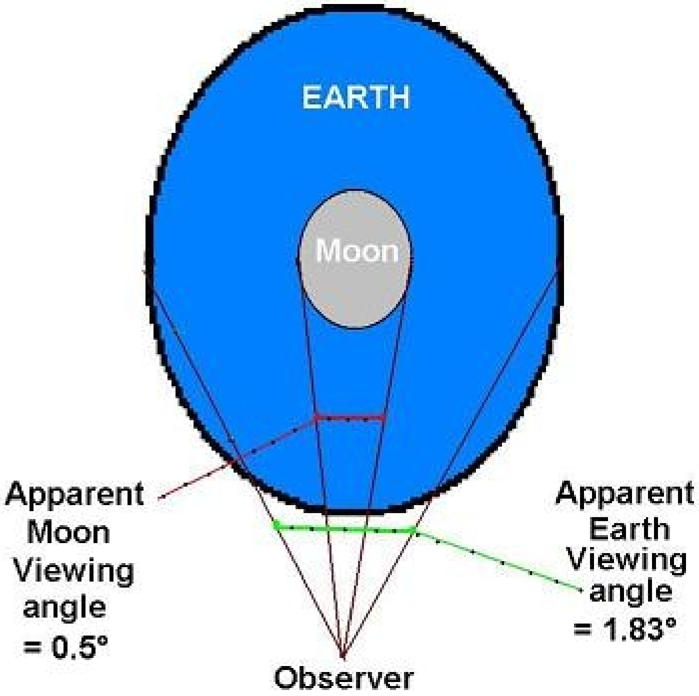
RELATIVE AND APPARENT SIZES OF THE EARTH AND MOON

The figure below shows the relative, apparent sizes of the Earth and Moon as viewed from the surface of each other.

[FIG 291]



Surely, the size of the Earth appears much larger from the surface of the Moon than the Moon appears from the surface of Earth simply due to their natural diameters, and at the same distance. It is very possible to give Earth's weather forecasts from the surface of the Moon, and possibly see a large city using binoculars or a telescope.

The diameter of the Moon is about 2160 mile, hence roughly 2000 miles wide. The diameter of the Earth is about 7918 miles, hence roughly 8000 miles wide, and this is about 4 times wider than the Moon. The distance to the Moon is about 240000 miles. Using basic trigonometry, the apparent visible angle of the Moon from the surface of Earth is about 0.5 degrees, and the apparent visible angle of Earth from the surface of the Moon is about 1.83 degrees. This apparent viewing angle is directly proportional to both the size or diameter of each, and the distance between each.

$$\tan \text{¢} = \frac{\text{side opposite to the angle}}{\text{side adjacent to the angle}} = \frac{\text{diameter of object}}{\text{distance to object}}$$

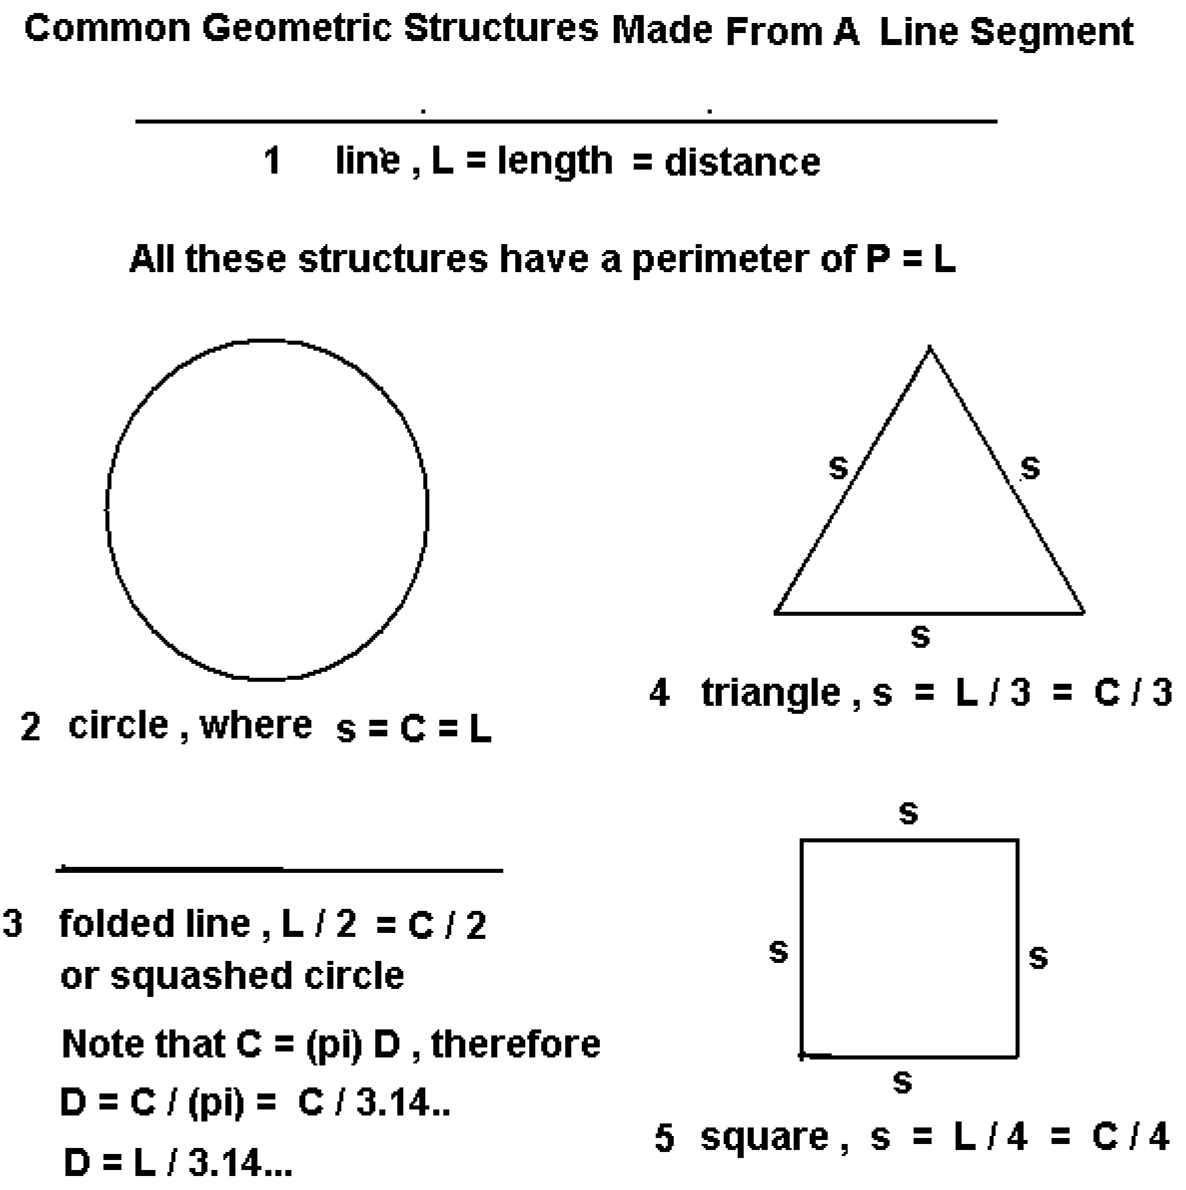
$$\frac{\text{Diameter of the Earth}}{\text{Diameter of the Moon}} = \frac{7918\text{ mi}}{2160\text{ mi}} = \mathbf{3.66}5\underline{7} = \frac{\text{Earth's apparent angle from the Moon}}{\text{Moon's apparent angle from the Earth}} = \frac{1.83^\circ}{0.5^\circ} = \mathbf{3.66}$$

In some photos the astronauts took from the surface of the Moon, the Earth is visible in some of those photos, however, due to that the camera they used had a wide angle lens, distant objects with a relatively narrow image width angle are much smaller in the image than they appear visually, and objects close to the lens are relatively large with a wide image width angle on the image.

COMMON GEOMETRIC STRUCTURES MADE FROM A LINE SEGMENT

Part of all things math or science is learning at least some of the vast knowledge already available, and then applying it to make some knew discoveries and-or ideas that can be shared with others in a cooperative effort.

[FIG 292]



In the above figures, s = a side length   and   L = total perimeter length

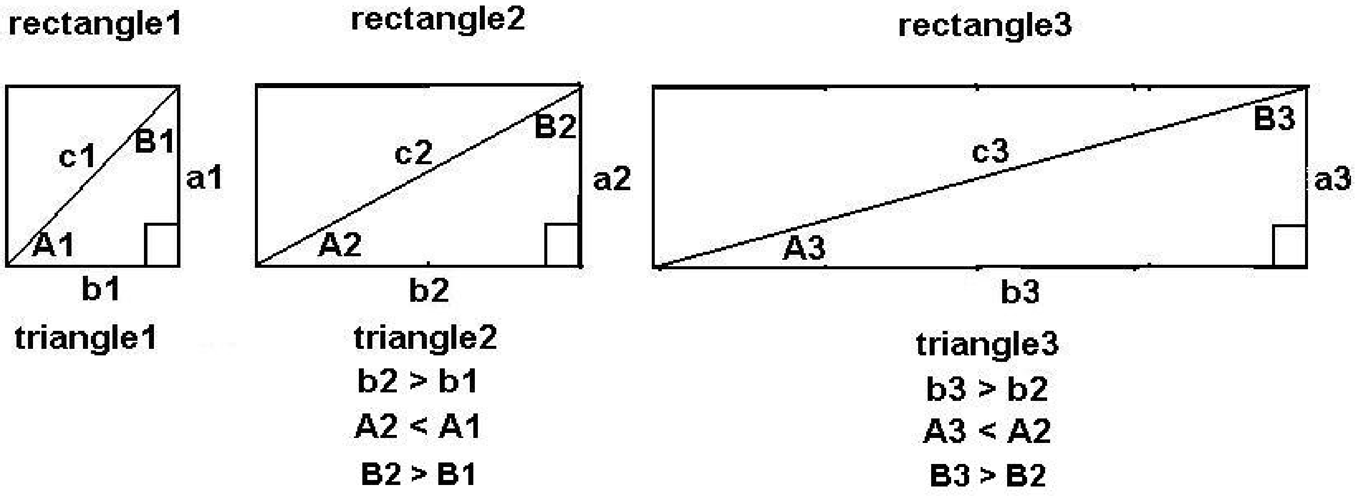
A Right Triangle Study And The Angles Created When One Of Its Leg Sides Is Extended

In the figure below, the right triangle on the left side will have side (b) extended in length, and while the side opposite the angle, here side (a), remains the same length. The result is that angle A will get smaller in value as side (b) is extended.

The rectangles are shown if you want to consider that structure and the angles created by a diagonal line, which here is the hypotenuse of the two symmetrical and identical right triangles.

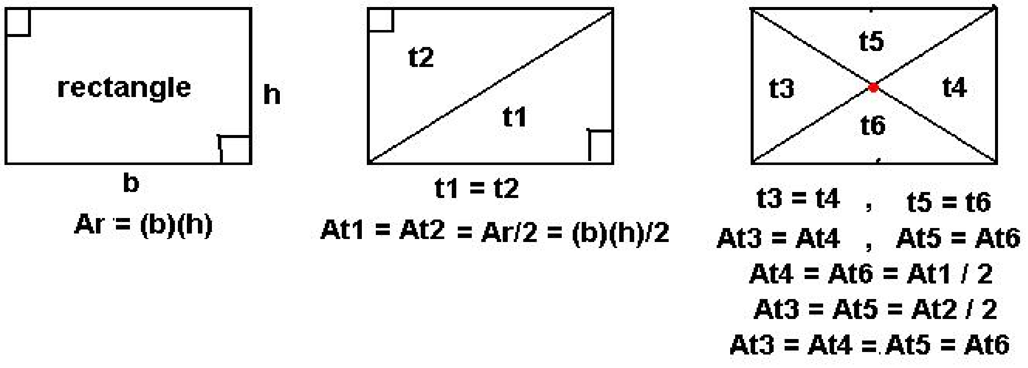
Consider tan A = side opposite A / side adjacent A = a / b , and as (b) increases, tan A ratio value decreases and therefore, A = arctan (tanA) will decrease in value.

[FIG 293]



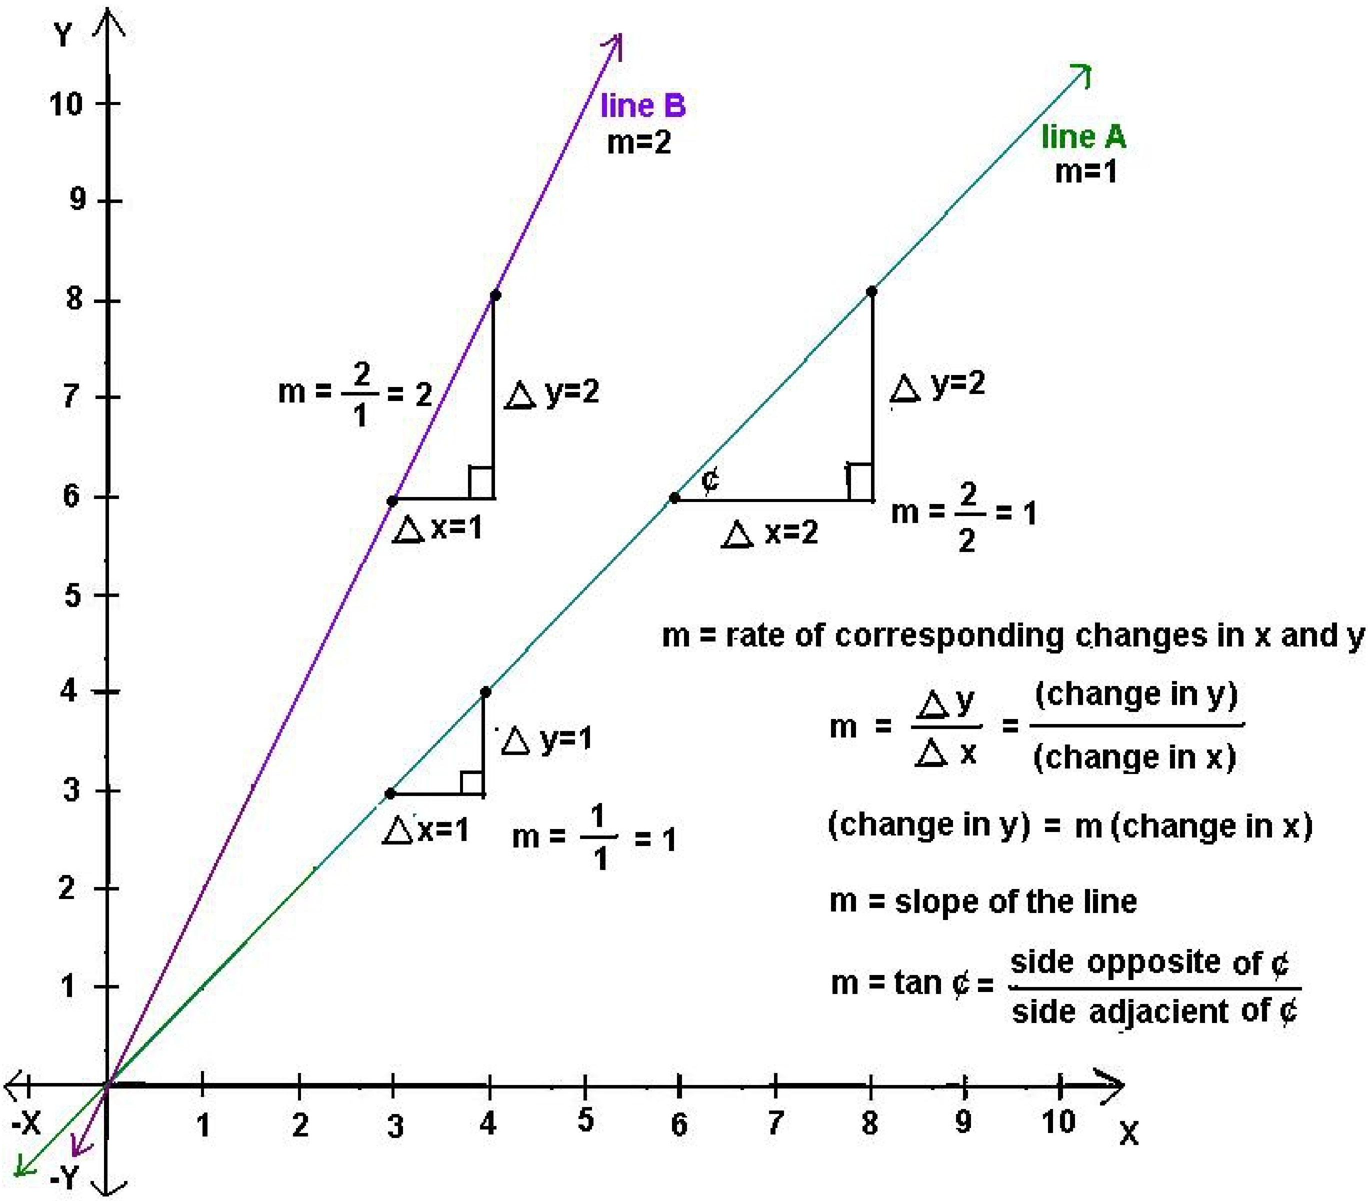
Note for example, that for angle A2 to be equal to angle A1, that side a2 would have to increase by the same ratio or factor (n) that side b1 did, and that value is: ratio = n = b2 / b1. Doing this would also create a similar triangle with all three angles being the same value, and the ratio of corresponding sides between each triangle would be the same value, here (n), and it would be said the triangles and-or its sides are proportional to each other, and are essentially, magnified versions of each other. Also note how the A and B angles change, and so as to maintain the 180° internal angular constant sum of a triangle.

Given a rectangle, drawing one internal diagonal will create two identical (right) triangles of equal area (A), and drawing its two internal diagonals of equal length will crate two pair of identical triangles. These 4 internal triangles will each have the same area. The two diagonal lines intersect at the center point of the rectangle, and which is at half the length of each side and diagonal line of the rectangle. [FIG 293A]



A Graph To Help Understand Linear Equations And Slope

[FIG 294]



Between any two points on a line, the slope of the line between those points is a constant value of (m). Note that when (x) changes by a value, that (y) does not necessarily change by that same value unless when (m) does actually equal 1. As shown in the above graph, when (x) changes by a value, (y) does not always change by that same value, and (y) will actually change by the product of the (m) times the (change in x), hence the change in (y) is like a magnified or amplified value of the (change in x). What can be said is that for any point on a line, when (x) changes by 1, that (y) will change by (m) which is the slope value.

For some simplicity of understanding, these lines intercept the (y) axis at 0, hence (b) the y-axis intercept for the line, and-or starting offset of the (y) variable is 0. The basic format for a linear equation with (b) set to 0 is: y = mx + b = mx + 0 = mx. The equation for Line A is: y = mx = 1x. The equation for Line B is: y = mx = 2x.

For a curve such as for a parabola equation (ex: y = x^2), the slope between any two points is constantly changing slightly in value from point to point. If the points are relatively close in value, the curve between those two points can be approximated by a line segment between those two points, and its slope will be the average of the two close in value slopes of the curve at those points. The greater the number of line segment approximations of a curve, the more they can represent the actual curve and its analysis.

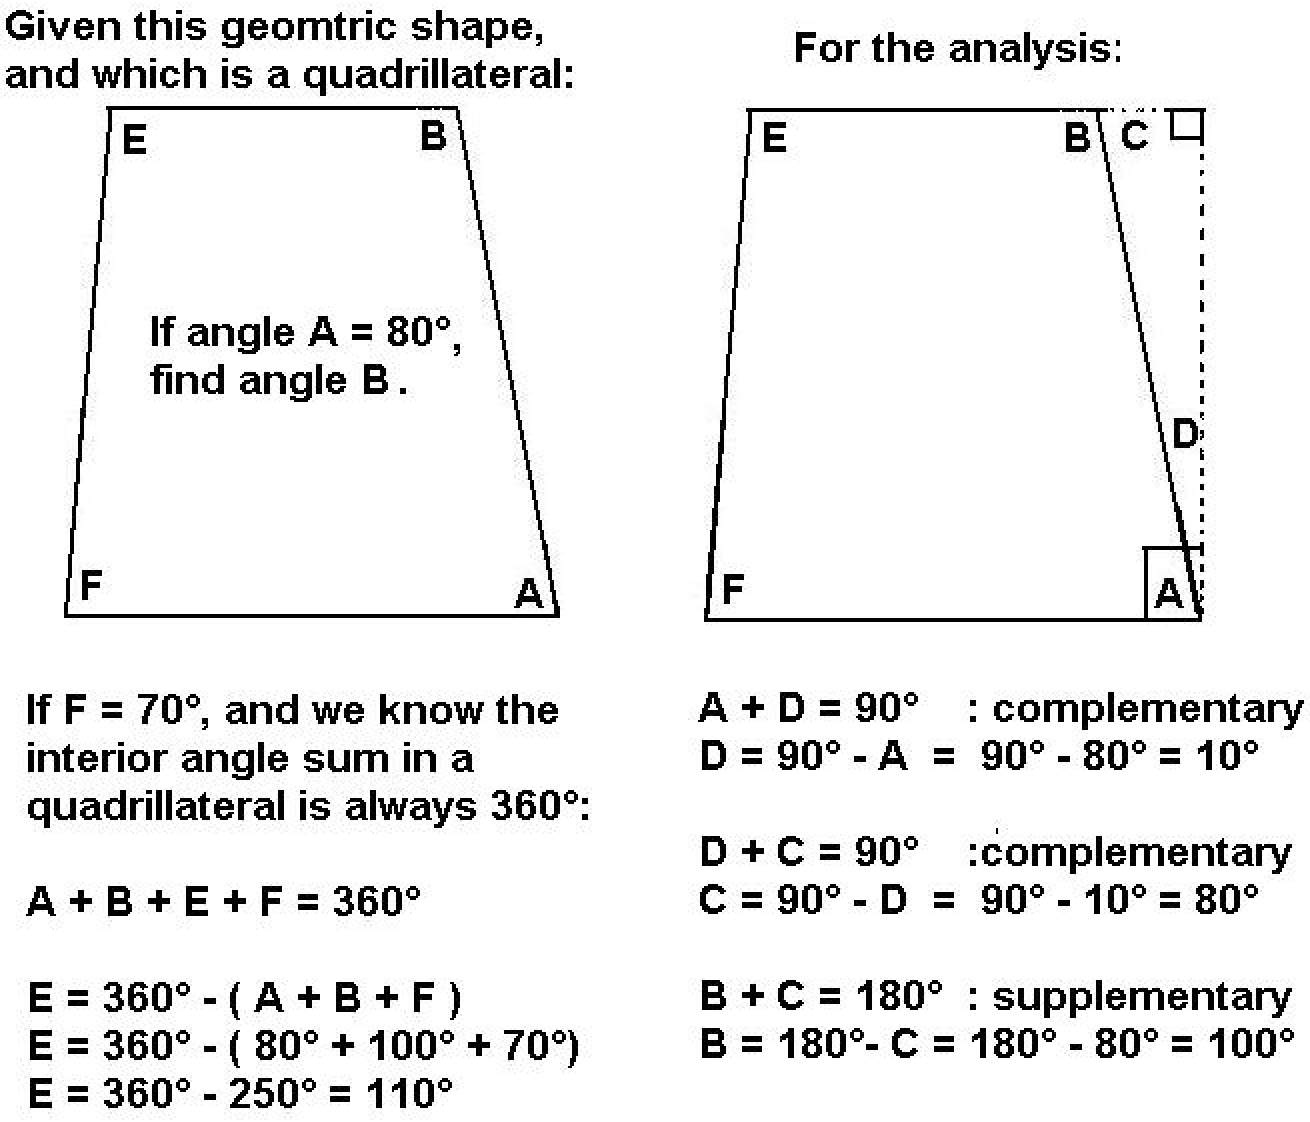
It was mentioned above that:

(change in y) = m (change in x)

For a line where the slope = rate of corresponding change in (y) due to a change in (x) = m is constant, if the (change in x) is a certain value such as 1 unit, the (change in y) will be a constant certain value depending on the value of its slope. Likewise, for a curve, where the slope = m is not constant but changing in value between successive points on it, the corresponding (change in y) value is no longer constant. The slope of a line is equal to the numerical co-efficient of the variable x and of which is only raised to the first power for lines. The slope value of a line or curve is also the (first) derivative of the equation for that curve. For a line, this derivative is a constant numerical value with no (x) variable in it. For a curve such as the parabolic curve: y = x^2 where the slope is not a constant value, the (first) derivative of its equation is not a constant value but an expression with the (x) variable within it. For the equation: y = x^2 , the first derivative of it is: x^1 = x , and this is not a constant value but depends on the value of (x) on or along that curve, and in fact, here, it is equal to the value of (x). The derivative of a parabolic curve is a linear expression and-or equation.

An Example Of Finding An Angle Of A Geometric Structure

[FIG 295]



Given this geomtric shape, and which is a quadrillateral:

If angle A = 80°, find angle B .

If F = 70°, and we know the interior angle sum in a quadrillateral is always 360°:

$A + B + E + F = 360°$

$E = 360° - (A + B + F)$
$E = 360° - (80° + 100° + 70°)$
$E = 360° - 250° = 110°$

For the analysis:

$A + D = 90°$: complementary
$D = 90° - A = 90° - 80° = 10°$

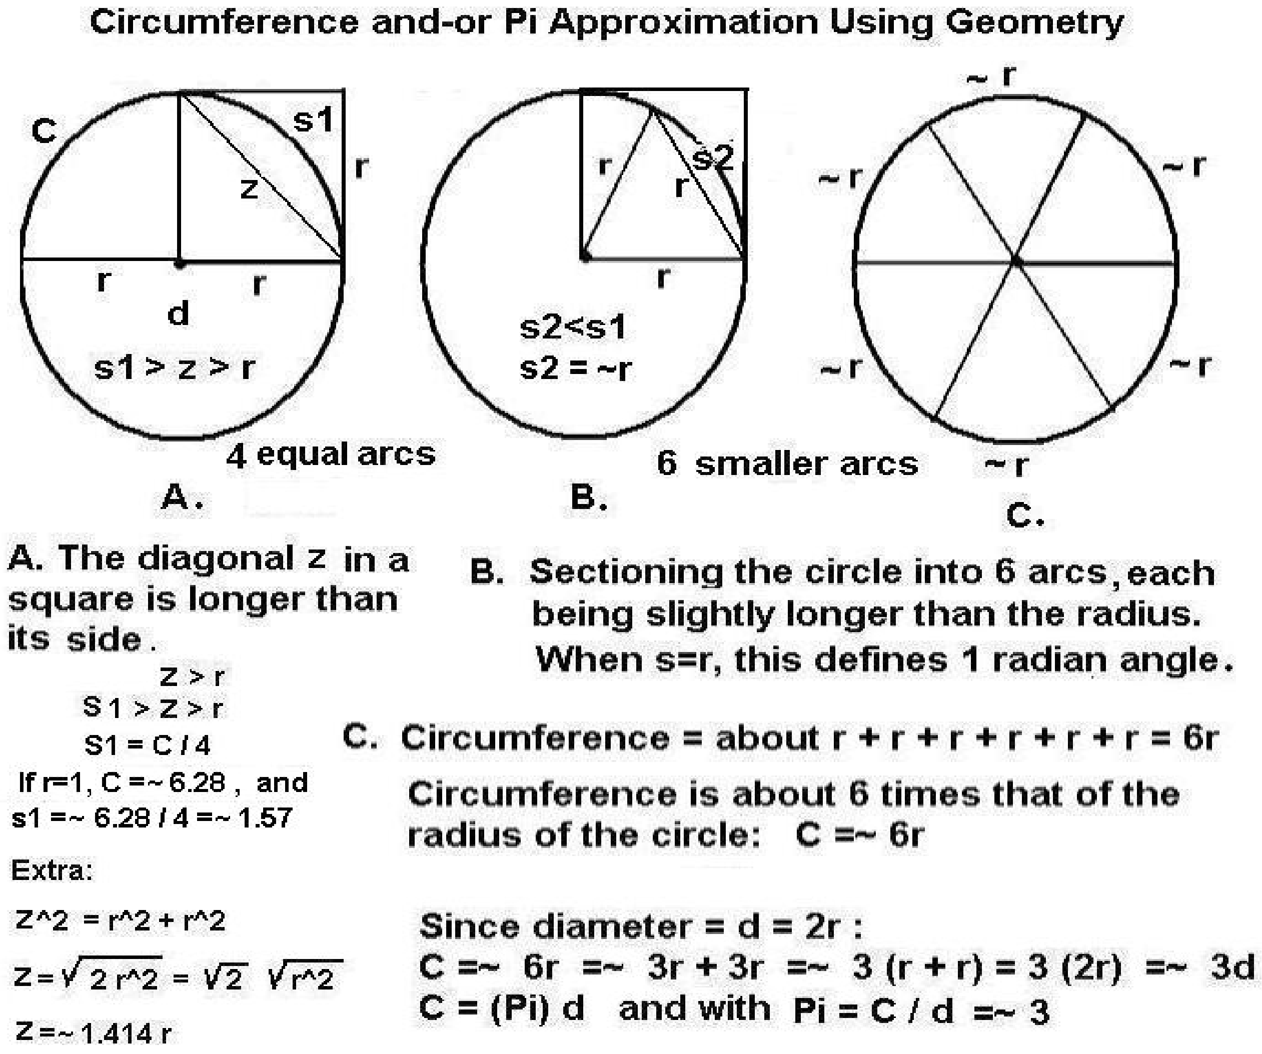
$D + C = 90°$:complementary
$C = 90° - D = 90° - 10° = 80°$

$B + C = 180°$: supplementary
$B = 180° - C = 180° - 80° = 100°$

Note the top and bottom lines of the quadrilateral, and that these lines happen to be parallel, and therefore the side or line on the right side of the construction is a diagonal line that transverses those parallel lines. Due to this, the alternate interior angles at the intersection of the transversal line are equal in value: C = A = 80° Angle D shown is not the full alternate interior angle to angle B, but is only part of it. For D to have been an alternate interior angle, either its initial or terminal side has to be at the parallel line, and not the right triangle shown that is used during the analysis of this example.

Circumference and-or Pi Approximation Using Geometry

[FIG 295A]



Circumference and-or Pi Approximation Using Geometry

A. The diagonal z in a square is longer than its side.

$z > r$

$S1 > z > r$

$S1 = C / 4$

If $r=1$, $C =\sim 6.28$, and $s1 =\sim 6.28 / 4 =\sim 1.57$

Extra:

$z^2 = r^2 + r^2$

$z = \sqrt{2 r^2} = \sqrt{2}\ \sqrt{r^2}$

$z =\sim 1.414\, r$

B. Sectioning the circle into 6 arcs, each being slightly longer than the radius. When s=r, this defines 1 radian angle.

C. Circumference = about r + r + r + r + r + r = 6r

Circumference is about 6 times that of the radius of the circle: C =~ 6r

Since diameter = d = 2r :
C =~ 6r =~ 3r + 3r =~ 3 (r + r) = 3 (2r) =~ 3d
C = (Pi) d and with Pi = C / d =~ 3

A. Shows that the diagonal, and here a chord beneath the arc segment, in a square is longer than its sides, and here. the arc segment of the circle in the square is actually longer than the straight line diagonal distance, and a straight line is always the shortest distance between two points, and any other way is therefore always longer B. shows the sectioning of the circle into 6 arcs of equal length with each equal to the radius of the circle. C. By observation, the circumference of the circle is about: r + r + r + r + r + r = 6r. We see that the circumference is at least 6 times the length of the radius length, but is also slightly greater since each similar arc segment or length (s) is slightly greater than (r). Since diameter = d = 2r, C=~ 6r =~ 3r + 3r =2(r + r) = 3(2r) =~ 3d. The circumference is about 3 times the length of the diameter length. C=(pi) d, and with (pi) =~3 and C / d = (pi). (pi) = C / 2r = 0.5 (C / r) What else can we learn from all this?

Since there are 360° in a circle, its circumference or full arc length (St = C) corresponds to 360°. 1° will correspond to an arc length of C / 360:

An arc of: C is to 360° as is an arc of: (C/360) is to (360°/360) = 1°. ,
In equivalent fraction expression after dividing both numerator and denominator by 360:

$$\frac{C}{360^\circ} = \frac{\frac{C}{360}}{\frac{360^\circ}{360}} = \frac{(C / 360)\text{ length or arc length}}{1^\circ}$$ is to : arc length of a given circle that corresponds to a central angle of 1°

If there are 6 arcs of equal length, then each arc (s) corresponds to:

$\frac{360^\circ}{6\text{ arcs}}$ = 60° / 1 arc = 60° per arc : after dividing the initial numerator and denominator by 6

Today, we know that (Pi) is very close in value to 3.0, but is actually about 3.14159265, hence:

C = (Pi)d = (pi)(2r) = 2(pi)(r) = 2(3.14159265)(r) = 6.283185307 r

C / r = 6.283185307 : the radius length can go about the circle 6.283185307... = 2(Pi) times , and the diameter length can go about the circle 3.14159265... = (Pi) times , C / d = (Pi)

C / 6.283185307 = C / 2(pi) = r , and the angle that correspond to this is:

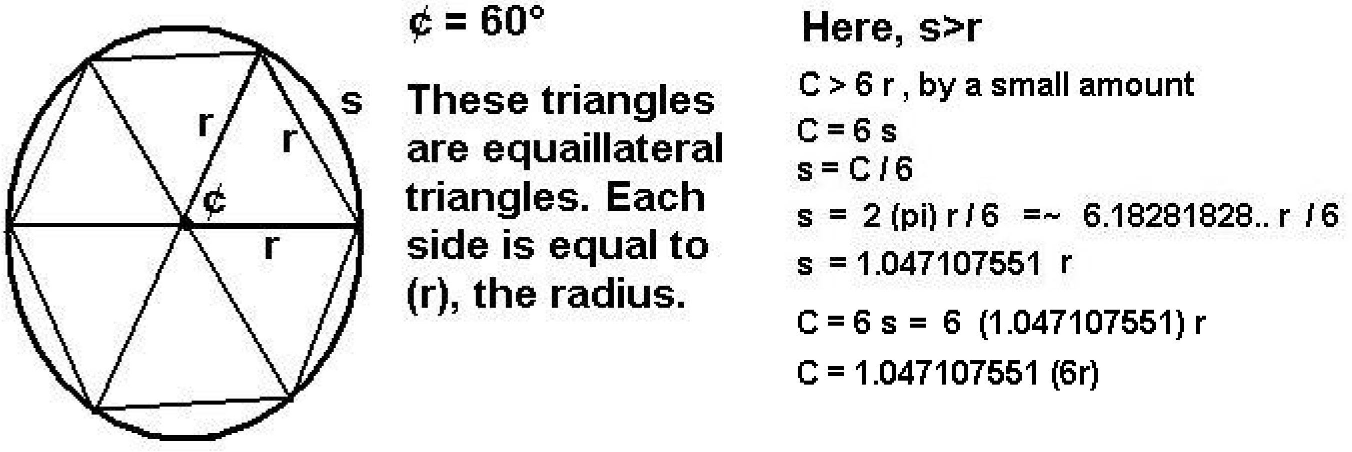
360° / 6.283185307 = ¢r = the angle where s=r , and this is an angle equal to 57.29577951° and is called "one radian (unit or angle)", and 60° is a close approximation of this transcendental value, and since (Pi), a transcendental value, was used during its calculation.

If you want to draw a 57.29577951° angle , you can consider a right triangle with the side adjacent to it as equal to r=1.0, and that the tangent of a 57.29577951° angle is: 1.557407725, hence the opposite side will be 1.557407725 times longer.

$$\tan 57.29577951^\circ = \frac{\text{side opposite the angle}}{\text{side adjacent to the angle}} = \frac{a}{b} = \frac{\text{corresponding height at side b where r=1}}{\text{a corresponding base value of r=1}} = 1.557407725$$

Mathematically: (height or side opposite the ¢) = (tan ¢) (side adjacent ¢) = 1.577407725 r : for this example

This figure shows both how to divide the circumference up into 6 equal arcs using equilateral triangles with each side equal to (r), and that this arc length is actually slightly greater than (r), and therefore it actually creates an angle slightly greater than 1 radian. Dividing 360° into 6 equivalent angles, each angle is: 360° / 6 = 60° [Fig 296]



¢ = 60°

These triangles are equaillateral triangles. Each side is equal to (r), the radius.

Here, s>r

C > 6 r , by a small amount

C = 6 s

s = C / 6

s = 2 (pi) r / 6 =~ 6.18281828.. r / 6

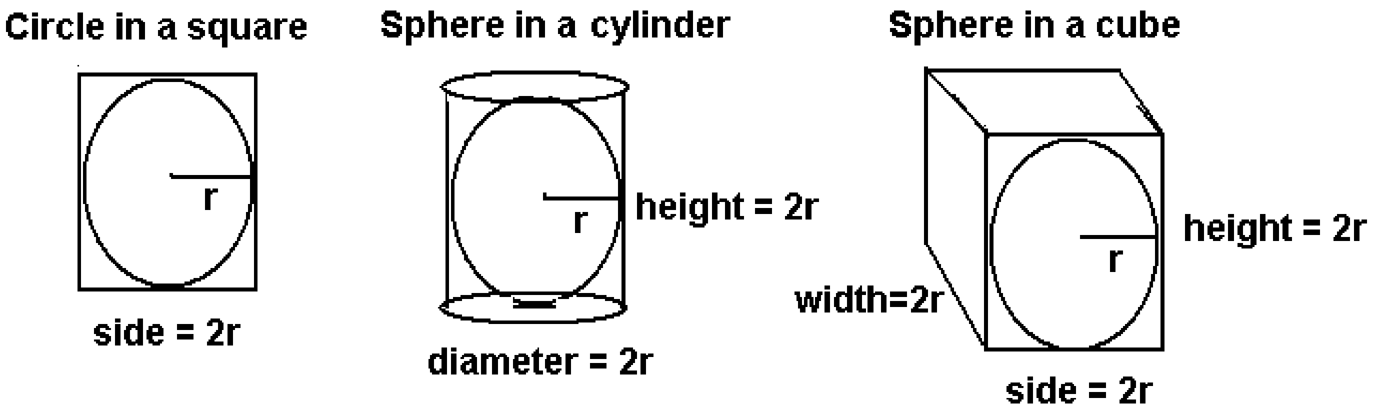
s = 1.047107551 r

C = 6 s = 6 (1.047107551) r

C = 1.047107551 (6r)

A GEOMETRIC STUDY FEATURING THE SQUARE, CUBE, CIRCLE AND SPHERE

This study features the sphere and its radius (r) in reference to some other basic geometric structures. [FIG 297]



Clearly as drawn, the circle within the square has less area than the surrounding square. The sphere within the cylinder has less volume than the surrounding cylinder. The sphere within the cube has less volume than the surrounding cube.

Area of square = As = side^2 = (s)(s) = s^2 = (2r)(2r) = (2r)^2 = 4r^2 , If we let (2r)=d, we have: As = d^2 = s^2

Area of the circle = Ac = (pi) r^2 = 3.14... r^2
If we let r = (d/2), we have: Ac = (pi)(d/2)^2 = (pi) d^2 / 4 = ((pi) / 4) d^2 = 0.785398163 d^2 = 0.785398163 As

Area equations have a squared (ie., second power) variable in them, whereas volume equations have a cubed (ie., third power) variable in them.

Ac < As and **Ac / As** = (pi) r^2 / 4 r^2 = 3.14 r^2 / 4 r^2 = **Pi / 4** = **0.785398163** , a constant
Ac = 0.785398163 As

The difference of area between a square and its internal circle is, and letting radius = r = diameter / 2 = (d/2) , d=2r:

As - Ac = d^2 - (pi) r^2 = d^2 - (pi) (d/2)^2 = d^2 - (pi) d^2 / 4 = d^2 (1 - (pi) / 4) = 0.214601836 d^2 =
= 0.214601836 d^2 = 0.214601836 (area of the square) =~ 21.5% (area of the square)

Extra: As - Ac = s^2 - (pi) r^2 = (2r)^2 - (pi) r^2 = 4r^2 - (pi) r^2 = r^2 (4 - (pi)) = 0.8584074 r^2
Also: (0.8584074 / 0.214601836) = 4
Also: 0.214601836 d^2 = 0.214601836 (2r)^2 = 0.214601836 (4 r^2) = 0.8584074 r^2

Note that for the sphere in the cylinder having the same height (here, 2r) as shown in the figure above, that the lateral or side area (Acl) of the cylinder and surface area of the sphere (As) have the same surface area: **The surface area of a sphere (As) is 4 times its largest disk area which has an area of a circle: (pi) (r^2). As = 4 (pi) r^2.** As a verification to these facts, this cylinder's lateral area can be divided into 4 identical triangular areas, At, and with each having a base of [(2)(pi)(r) = C], and a height of (r). At = (base) (height) / 2 = 2 (pi) r^2 / 2 = (pi) r^2 , and 4 of these areas sum to 4 (pi) r^2

Alc = As , Alc = (base) (height) = ((2)(pi)(r)) (2r) **= 4 (pi) r^2** = As : surface area of a square

Another consideration or verification is that if you cut a sphere along its height (2R=D) and unfold it and flatten it, the resulting shape would be a rectangle with a base of (C=2 Pi R) and a height of (2R), and this rectangle will have an area of: (base)(height) = (2 Pi R) (2R) = (C)(2R) = **(C)(D) = 4 (Pi) R^2**. **If you were to create an infinite number of very thin rectangles around the side of the sphere, where each rectangle width approaches 0, this the would also be the result as**

just shown. If the surface of a cylinder having a height of D=2R, is cut along one side, and laid flat, it would have the same surface area of a rectangle of: (width)(height) = (2 Pi R)(2R) = 4 Pi R^2, hence having the same surface area of a sphere with the same radius.

Surface area of a cube = (6 sides) (side or "face" area / side) = 6 (s)(s) = 6 s^2 : using d for distance or length
Surface area of a cube = 6 (A of a square side) = 6 s^2 side (s) of a square or cube

Volume of cylinder = Vcylinder = (Area of base)(height) = (Ac)(2r) = ((pi) r^2) (2r) = 2 (pi) r^3 =~ 6.2818 r^3
Even though the base and sides of a cylinder are circular, its base area value can be conceived as being that of a square and its height can be conceived as the height along a cube, and this is essentially shown in the equation.
Let's set the base area of a cylinder equal to that of a square: Ac = (pi)(r^2) = As = s^2 , then, s = sqrt(Ac)
Cylinder height can also be replaced as the distance of the cylinder, such as if it was a pipe length.

Volume of sphere = Vs = $\frac{4\,(\mathrm{pi})\,r^3}{3}$ =~ 1.33333... (pi) r^3 =~ $4.1887\underline{9}$ r^3 = roughly 4.2 r^3

Note the previous article and that: $4.1887\underline{9}$ = (pi) + (2pi) / 6 = (pi) + pi/3 = 4 (pi) / 3 = 3.141592654 + 1.047197551 = 4.188790205

Vs < Vcyl and Vs / Vcyl = 4.188790205 r^3 / 6.283185307 r^3 = 0.6666666 ... = 2/3 and Vcyl / Vs = 3/2 = 1.5

Volume of cube = V**c** = (Area of square base)(Height of cube) = (s^2)(s) = **s^3** , If s=2r, Vc = (2r)^2 (2r) = (2r)^3 = 8r^3

Volume of sphere = Vs = $4.1887\underline{9}$ r^3

Vs < Vc and Vc / Vs = $4.1887\underline{9}$ r^3 / 8 r^3 =~ $0.523\underline{6}$: where r = s/2 and=or s = 2r

Calculating the volume and-or equation of a sphere is not easy as other geometrical objects, and this is due to that the sides of the sphere are not linear or straight, but are curved. The most common derivation for the volume of a sphere is found by a large sum of volumes of a (infinitely) thin cross sectional disks of the sphere, and where each disk has an area of (pi)r^2 and a very small thickness which is the same value for each disk. Volume of each disk = (the area of each disk)(thickness of each disk). These disk volumes are all effectively summed using integration, and the reader can explore this elsewhere and further if need be. The most common derivation of the formula for the surface area of a sphere is somewhat similar.

With an experiment, a sphere can be placed within a cylinder or cube of the same height (here, = 2r), and then a fluid such as water can be placed in the region surrounding the sphere. The volume of the sphere will be equal to the total empty volume of the cylinder or cube, less (ie., subtract) the amount of water in the surrounding region when the sphere is in it.

Vcontainer = Vobject + Vsurrounding_region , mathematically:
Vcontainer = Vsphere + Vsurrounding_region , mathematically:
Vsphere = Vcontainer - Vsurrounding_region

If the sphere radius r=1, a "unit sphere", and if the container is a cylinder as shown in the above figure:

V**s**urrounding_**r**egion = V**sr** = Vcylinder - Vsphere , Let us now find and express these values and mathematical relationships expressed as ratios:

V**sr** = 2(pi)r^3 - $\frac{4(\mathrm{pi})(r^3)}{3}$ If r=1:

V**sr** = 2(pi) - $\frac{4(\mathrm{pi})}{3}$ = $\frac{6(\mathrm{pi})\ -\ 4(\mathrm{pi})}{3}$ = $\frac{2(\mathrm{pi})}{3}$ = 0.6667 (pi) =~ 2.0943951

$$\frac{V\mathbf{sr}}{V\text{cylinder}} = \frac{(2(\text{pi})r^3)/3}{2(\text{pi})r^3} = \frac{1}{3} = 0.333333\ldots$$, mathematically: V**sr** = (1/3) Vcylinder

$$\frac{V\mathbf{sr}}{V\text{sphere}} = \frac{(2(\text{pi})r^3)/3}{(4(\text{pi})r^3)/3} = 0.5$$, and the reciprocal of this is:

$$\frac{V\text{sphere}}{V\text{sr}} = \frac{(2/3)\,V\text{cylinder}}{(1/3)\,V\text{cylinder}} = (2/3)(3/1) = 6/3 = 2$$

$$\frac{V\text{sphere}}{V\text{cylinder}} = \frac{(4(\text{pi})r^3)/3}{2(\text{pi})r^3} = \frac{2}{3} = 0.6666\underline{7} =^{\sim} 66.7\%$$, mathematically: Vs = (2/3) Vcylinder , the reciprocal is:

$$\frac{V\text{cylinder}}{V\text{sphere}} = \frac{3}{2} = 1.5$$

Values for the particular example where r=1:

V**sr** = Vcylinder - Vsphere

V**sr** = 6.2818 units^3 - $4.1887\underline{9}$ units^3 =~ 2.09301 : as shown above

Below is a similar analysis using the volume of a cube:

Note that the volume of a cube does not have (pi) variable in its equation.

$$\frac{V\text{sphere}}{V\text{cube}} = \frac{(4(\text{pi})r^3)/3}{8r^3} = \frac{(\text{pi})}{6} = 0.523598775$$: slightly more than half, ~ 52.4% and the reciprocal of this is:

$$\frac{V\text{cube}}{V\text{sphere}} = \frac{8r^3}{(4(\text{pi})r^3/3)} = \frac{6}{(\text{pi})} = 1.909859317$$: slightly less than 2

$$\frac{V\text{cube}}{V\text{cylinder}} = \frac{8r^3}{2(\text{pi})r^3} = \frac{4}{(\text{pi})} = 1.273239545$$, and the reciprocal of this is:

$$\frac{V\text{cylinder}}{V\text{cube}} = \frac{(\text{pi})}{4} = 0.785398163$$: about 78.5%

The volume of a cone or pyramid has been shown in this book to be equal to:

$$V\text{cone or }V\text{pyramid} = \frac{(\text{base area})(\text{height})}{3}$$ and that:

$$V\text{cone or }V\text{pyramid} = \frac{V\text{cube}}{6}$$: **when the height is equal to half the height of the cube, hence (2r)/2 = r**

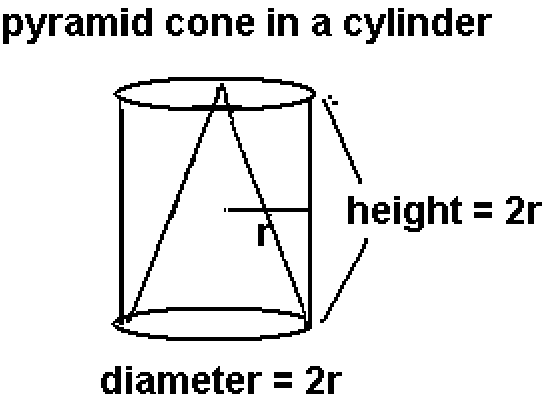
$$V\text{cone or }V\text{pyramid} = \frac{V\text{cube}}{6} = (1/6)\,V\text{cube} =^{\sim} 0.166\underline{7}\,V\text{cube} =^{\sim} 16.7\%$$

Checking: If we multiply the volume of a pyramid or cone by 6, we should then have the whole or entire cube volume with a side equal to (2r), and Vcube = (side)^3 = (2r)^3 = 8 r^3:

(6) $\text{Vpyramid} = \frac{(2r)^2\,(r)}{3}(6) = \frac{4r^3\,(6)}{3} = \frac{24\,r^3}{3} = 8\,r^3 = \text{Vcube}$ **: when height = (r)**

The sum of volumes of a cone and sphere with the same radius (r) and therefore total height of (2r), will equal a cylinder with the same radius and height.

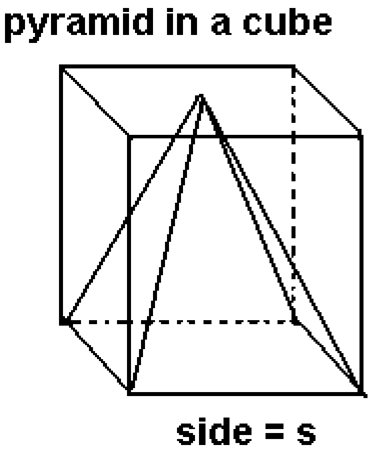
Now a pyramid cone in a cylinder will be discussed. A cone can be thought of as a pyramid with an infinite number of flat sides. [FIG 298]



$\frac{\text{Vcylinder}}{\text{Vpyramid}} = \frac{(\text{pi})(r^2)\,(2r)}{(\text{pi})(r^2)(2r)/3} = \frac{2(\text{pi})r^3}{2(\text{pi})r^3/3} = 3$: when height = (**2r**) typically, or if simply: h = r. Also note that the reciprocal of this is:

$\frac{\text{Vpyramid}}{\text{Vcylinder}} = \frac{1}{3} = 0.3333... =^{\sim} 33.33\%$: extra, the **volume of a paraboloid** is 50% that of the volume of its circumscribing cylinder, hence the difference is 50% - 33.33% = 16.6$\underline{6}$% = 0.166$\underline{7}$ / 1.00 = after division: 1.0 / 6 of the cone volume. See further below also.

If (1/3) of a cylinder is occupied by a cone, then: 1 - (1/3) = (3/3) - (1/3) = (2/3) of the cylinder is not occupied by the cone. [FIG 299]



$$\frac{\text{Vpyramid}}{\text{Vcube}} = \frac{(s^2)(s) / 3}{s^3} = \frac{s^3 / 3}{s^3} = \frac{1}{3} = 0.333333.... =^{\sim} 33.33\%$$

, and the reciprocal of this is:
A cylinder can be viewed as being an infinitely sided pyramid.

$$\frac{\text{Vcube}}{\text{Vpyramid}} = 3$$

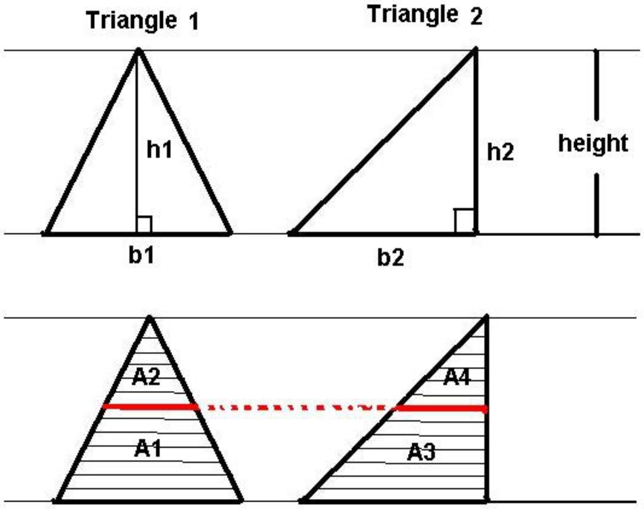
Given many various triangles, if the base and height are the same value, their areas will all be the same. Likewise, given a cone or pyramid in a cylinder, prism or cube (a special instance of a prism, rectangular solid shape), as long as the height is the same, the volume of the pyramid or cone is the same. For example, the tip of the cone or pyramid may be at one of the upper corners of the cylinder or prism.

Extra: Since **Vs** = 4/3 (pi) r^3 = 1.33333 (pi) r^3 = **4.1887$\underline{9}$ r^3** **: volume of a sphere given its radius**
: 4.188790205 r^3

r = cube-root (Vs / 4.18879) =
r = cube-root Vs / cube root 4.18879 = (cube-root Vs) / 1.611991954 =
r = 0.62035050491 (cube-root Vs) : radius of a sphere given its volume

Ex. A volume of 1 liter = 1000 mL = 1000 cc = 1000 cm^3 = (10 cm)^3 = (10 cm)(10 cm)(10 cm) = 1000 cm^3
Now considering a sphere having this same volume as this cube shape:
r = 0.620350501 (cube-root 1000 cm^3) = 0.620350501 (cube root 1000)(cube root 1cm^3)
r = 6.203$\underline{5}$ cm , d = 2r = 12.407 cm , note that this is greater than 10cm which was the base of the equivalent cube shaped volume and is 12.407 cm / 10 cm =
Ds = diameter of a sphere = 1.2407 times wider than a cube of the same volume
To imagine how this can be, imagine a cube shape of clay, and if you push the 8 corners and edges inward so as to make a sphere shape, that material will be added to the existing central volume of material, hence making it slightly wider than the cube was initially.

Extra: **Cavalieri's principle** states that given two volumes of any shape, if at the same height or distance from the base side and the cross sectional planes of each have the same area, then their volumes are the same. For example: Consider a vertical cylinder shape and then dividing it into many slices like a stack of disks or coins. Now consider a second instance of this construction and-or volume where the disks are then randomly offset from the center line or axis of the cylinder, and that second construction will still have the same volume as the first cylinder. From this we can also reason that at any particular height or corresponding segment of these two volumes, that those volumes are also the same. The basic formula for such volumes is the base area (Ab) times the height (h) = V = (Ab)(h). This principle could be thought of as being based on another principle for triangles, and if the area of the base side of any two triangles is the same, and the heights are the same, then their areas of both triangles are the same: At = (base side)(height) / 2 = bh / 2.
[FIG 300]



In the above figure, triangle 1 and triangle 2 have the same area since they have the same base length (b1=b2) and height (h1 = h2).

In the lower section of the above figure, we see the same triangles divided into an infinite number of plane sections of the same thickness and parallel to the base side. Each corresponding planar or surface area section of each triangle is the same, and therefore at any similar height in the triangles the corresponding areas are the same. Here A1 = A3, and A2 = A4. Note for example that A2 is also equal to the total area of the triangle less the area A:. At = A1 + A2, and A2 = At - A1. If you were to move each section of triangle 1 so as to produce triangle 2, it becomes clear that the areas are the same, Likewise, at any height, this can be done and the corresponding area segments of the triangle are the same.

We know that if the height of a triangle changes by a factor of (n), that its area will also change by that same factor:

A = bh / 2 , when (h) is changed by a factor (n):

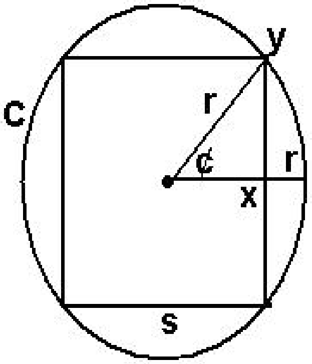
nA = b (nh)) / 2
nA = n (bh / 2)

If the height for triangle 1 and triangle 2 is 1 unit, and if it is sectioned (as sown by the red line in the figure above) into A1 and A4 respectively and having the same height of (nh) where (n) is a value lower then 1, hence (nh) is a fraction of (h), then those areas are the same.

If the height chosen is 90% of the original height of the triangle, hence, n=0.90, and the area of that segment is 90% of the area of the entire triangle.

Much of this concepts of this article with planar areas can also be applied to volumes of some geometric figures such as mentioned at the beginning of this article about a cylinder and stack of coins or disks.

Extra: An analysis of a (largest) square in a circle. [FIG 300B]



r = 1 sin ¢ = opp / hyp , hyp = r = 1
¢ = 45° cos ¢ = adj / hyp

y = sin 45° (r) = 0.7071 units
x = cos 45° (r) = 0.7071 units

s = 2y = 2x = 1.414 units

As = 1.414^2 = 2 sq. units
Ac = (pi) r^2 = pi (1) = 3.14 sq. units

Ac / As =~ 3.14159 / 2 = 1.57 = (pi) / 2
As / Ac =~ 0.636943

C = 2(pi)r = 6.28 , Ps = 4s = 4 (1.414) = 5.656
C / Ps = 6.28 / 5.656 =~ 1.1109 , Ps / C =~ 0.9

An oddity to explore is that the product of some of the values shown in the above articles of:
(0.785398163) (0.636619772) = 0.5 , and also that the product of their reciprocals is therefore equal to 2. Can you find a new geometric constant(s) to consider?

If the area of a circle and square are to be the same value, you can solve for a variable by setting their equations as equal, and then using the known values to solve for an unknown value and-or variable:

Ac = As , (pi) r^2 = s^2 , Mathematically: r = sqrt(s^2 / (pi)) and s = sqrt[(pi) r^2]

Volume Of A Paraboloid

The volume (Vp) of a paraboloid (a parabolic shape rotated once on and about its central axis so as to create a three dimensional shape and-or solid) is amazingly equal to one-half the volume (Vc) of a cylinder of the same radius and height. In other words, the circumscribing cylinder will have twice as much volume as the paraboloid. A simple way to verify this is that the paraboloid and its exterior or inverse volume completely fill the volume of the cylinder. At any height and thin segment of volume, the corresponding section of volume of the paraboloid and its inverse always sum to the same value of that of a thin segment or cross sectional slice of that cylinder, and of any height of that cylinder.

$Vp = \frac{Vc}{2}$ = (area of cylinder base) (height of cylinder) / 2 = (pi) r^2 (h) / 2 : with cubic units of length = units^3
, if h=r , Vp = Vc / 2 = (pi) (r^2) (r) / 2 = (pi) r^3 / 2

The **sagita**, depth or "**sag**" of a parabolic curve is equal to the height (ex.: h = y = x^2) at that location along that curve.
The volume of the sagita when considered equal to the volume of the paraboloid is: Vs = Vp = Vc / 2

The volume (Vb) beneath the sagita of the paraboloid can be found by: Vb = Vc - Vp = Vc - Vc / 2 = Vc (1 - 1/2) =
= Vc (1 - 0.5) = Vc (0.5) = Vc / 2 = (2 Vp) (0.5) = Vp , hence Vb is equal to the volume of the parabola.
Vb = Vp = Vc / 2. Vp + Vb = Vc

It is incorrect to think that at half the volume of a given cylinder, that the volume of the corresponding internal paraboloid will also be half, and this can be seen if you draw cylinders with the same radius and with one cylinder being at half the height.

The area beneath the curve of a basic or common parabola is:

A = S = f(x) dx , and where f(x) is the anti-derivative equation in question, and if the equation is y = x^2 , its anti-derivative is: x^(n+1) / (n+1) = x^(2+1) / (2+1) = x^3 / 3. Initially shown is the general or indefinite integral of the sum equation, and without the specific function, limits or bounds. Here is a definite integral form with the lower limit (a) and upper limit (b) of the sum:

[Extra: note that: (f(x)) (dx) can be considered as a infinitesimally small piece of area: (height) (width)]
[The generalized Sum of these infinite number of bits of area in question is formally found by taking a difference of the two areas.] And:

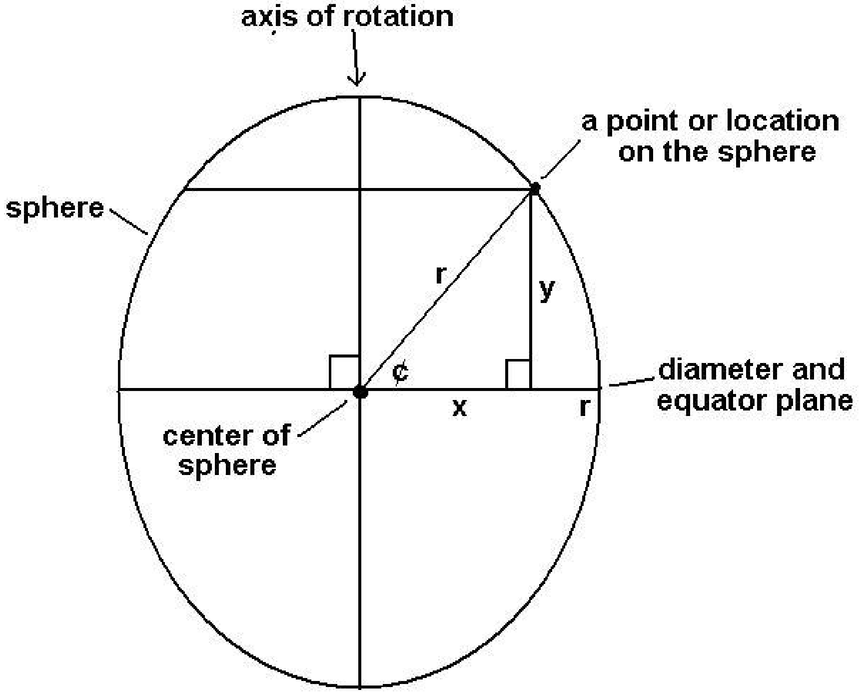
$$A = S_a^b \; x^2 \; dx = S_a^b \; (x^3 / 3) = F(b) - F(a) = A_b - A_a$$

: If (a=0), then simply: $A = \text{Area} = A_b$
: A = (b^3 / 3) - (a^3 / 3)

Finding The Distance A Point On A Sphere Is From The Axis Of That Sphere

All points on the surface of a sphere have the same distance from the center of it. Likewise, all points at the same radius distance from the center of a circle have the same distance from the center. When a radius line is extended from the center of a sphere to a point on the sphere, the radius line and-or point on the surface of the sphere is at a certain angle, ¢, from the center. If the sphere was Earth, this angle would be the longitude angle from the equatorial plane which is considered as the 0° reference position for other angles.

Knowing this angle mentioned, we can then find that points distance to the axis of rotation of that sphere. This distance, here equivalent to the value of (x), is actually the radius distance of a circle at that latitude value about that entire sphere. A similar discussion using many of these concepts as previously given in this book during a topic dealing with latitude and angles, but this discussion here was made to generally consider smaller spheres, perhaps less than 10 feet or 3 meters in diameter. [FIG 301]



sin ¢ = side opposite angle / adjacent angle = y / r , y = r sin ¢ , ¢ = arc sin (sin ¢)
cos ¢ = side adjacent angle / hypotenuse = x / r , x = r cos ¢ , ¢ = arc cos (cos ¢)

Circumference around the sphere at that latitude angle (¢L) and radius value (x) = C = 2(pi) x = 2(pi) r cos ¢L

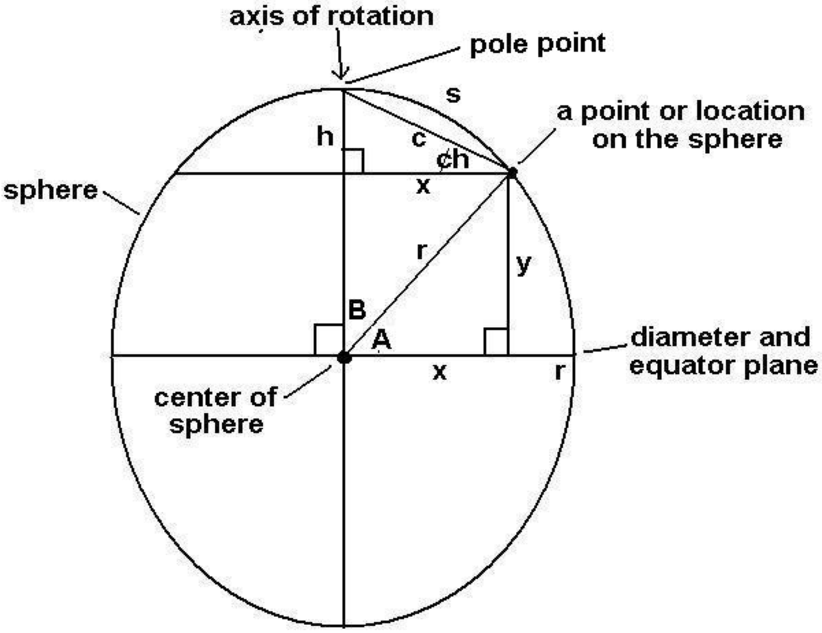
For the near sphere of the Earth, it has a radius of about 6378 km = 3959 mi =~ 3960 mi =~ 4000 mi ,
and with the diameter at twice that value of about: 12756 km = 7919 mi =~ 8000 mi

The circumference of the Earth at 0° latitude, which is at the Equator is:
C = (pi)d = (2)(pi)r = (2)(pi) 3959 mi =~ 24875 mi =~ 80148 km =~ 25000 mi

At the latitude of 45° North of the equator: The effective circular radius about the Earth is: x = r cos 45° latitude ,
x = 3959 mi (0.70711) =~ 2799 mi =~ 2800 mi. and C = 2(pi)r = 2(pi)x = 2(pi) 2800mi = 17589 mi and this circumference value can be easily calculated as: Clat = (C of Sphere) (COS latitude) = (25000 mi)(COS lat.)

Below is a continuation of the previous discussion and shows how to find the distance from the point on the sphere to the pole at the axis of rotation.

Ex. Given angle A, find c and s: [FIG 302]



r = y + h , mathematically:

$h = r - y$

$c = \sqrt{h^2 + x^2}$: via the Pythagorean Theorem of a right triangle

c is also the chord length beneath the arc segment s

Since A + B = 90° , B = ¢s = 90° - A

From: $$\frac{s}{C} = \frac{\text{¢}s}{360^\circ} = \frac{As}{Ac}$$

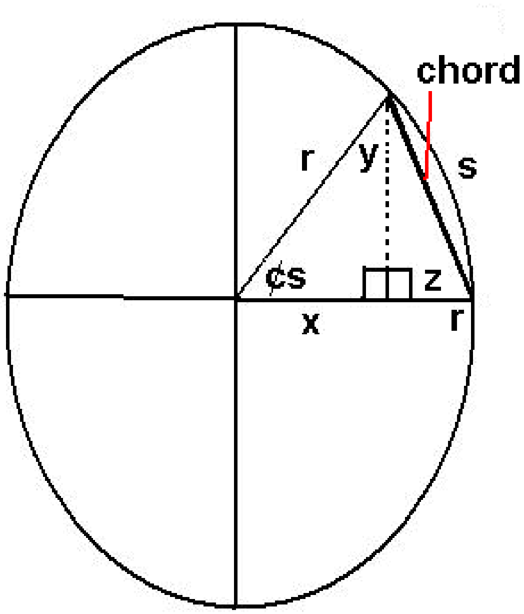
$$s = C\,\frac{\text{¢}s}{360^\circ}$$

Extra:

tan ¢h = opp. / adj. = h / x : x = r cos A

¢h = arctan (tan ¢h) and at the pole, the angle of declination of line (c) below the horizontal or horizon is 90° - ¢h, and since this angle and ¢h are complementary angles of a 90° angle. This angle is also equal to ¢h due to alternate interior angles created by a transversal line - here, line c

Continuing the previous examples, here is another example of solving for a chord length given the angle, here (¢s) corresponding to the arc length, and the radius (r) of the circle. [FIG 303]



From the previous discussions and examples, we know that: for a right triangle (here an inner triangle of the outer and larger triangle) is:

y = r sin ¢s

x = r cos ¢s

r = x + z

z = r - x = r - (r cos ¢s) = r - r cos ¢s = r (1 - cos ¢s)

The chord side is also the hypotenuse side of the smaller internal triangle with sides (y) and (z). Using the Pythagorean Theorem:

$$\text{chord} = \sqrt{z^2 + y^2}$$

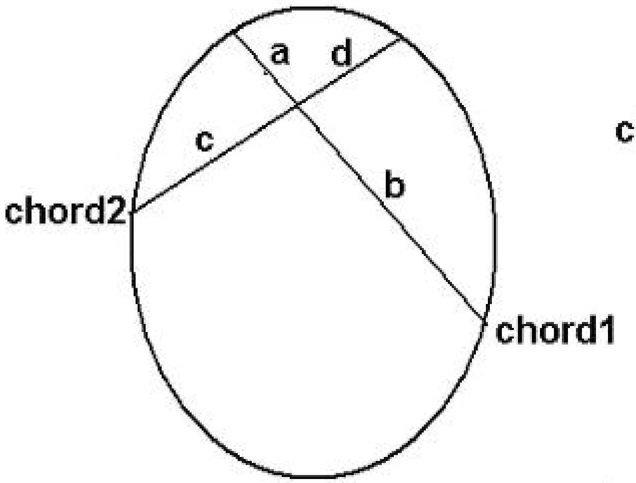
Also of note is that the larger triangle being studied here is also an isosceles triangle having two sides of equal length, here (r). The third side of an isosceles triangle is known as the base side, and the two angles created there by the other two sides are equal in value and are called the isosceles base angles. These base angles have a value of: (180° - ¢s) / 2

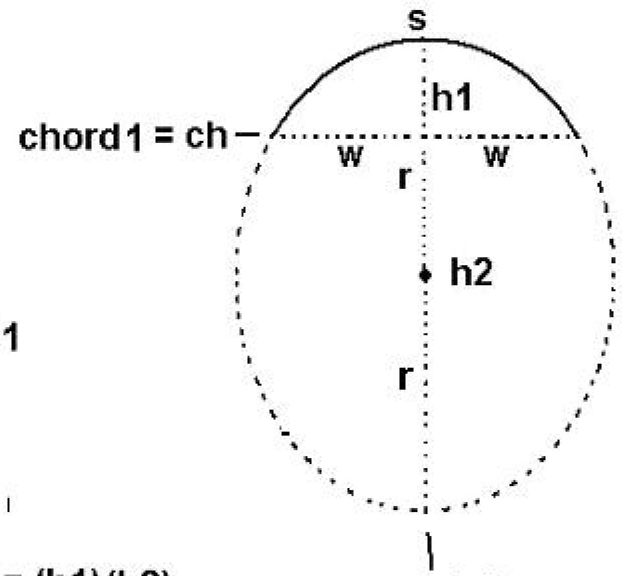
As for finding s or ¢s, it was shown previously in the book that:

$$\frac{s}{C} = \frac{¢s°}{360°} = \frac{As}{Ac}$$, therefore, mathematically: $$s = C \frac{¢s}{360°}$$: C = Circumference = 2 (pi) r

Finding The Radius Of Curvature Of An Arc Segment Of A Circle

Here is how to solve for the corresponding radius of a circle given just a segment or arc of it. The method used here will consider the **Chord Theorem** that Euler discovered. This theorem states that given two chords of a circle that intersect, that the products of the two segments of each chord are equal in value. Euler discovered this by considering the concepts of inscribed angles, and similar triangles created by two chord lines that intersect in a circle. For a simple verification of the chord theorem, consider the chords from the endpoints of (a) and (c), and then from (d) to (b) creating two similar triangles and of which have the same angle at the intersection point of the two lines. The angles created within a circle could be thought of as interior angles. Also draw a quadrilateral with the two lines as diagonals within it, and the chords as sides of it. As mentioned in this book, if the inscribed angles have the same arc length, then those angles are equivalent. Given that two angles of a triangle are equivalent, the third angles will also be equivalent due to the 180° internal sum of angles. We then have for the similar triangles: $a/c = d/b$, and mathematically this equals: **(ab) = (cd)**. [FIG 304]





Chord Theorem

(a)(b) = (c)(d)

(w)(w) = (h1)(h2)

h2 = w^2 / h1

chord 2 and diameter (d)

w = chord1 / 2

s = arc of a circle

d = h1 + h2 = 2r

radius = r = d / 2

$$r = d / 2 = (h1 + h2) / 2 = (h1 + (w^2 / h1)) / 2 = (w^2 + h1^2) / (2\,h1)$$

From the above formula for (r), if we multiply it by 2 so as to have the diameter (d), we have:

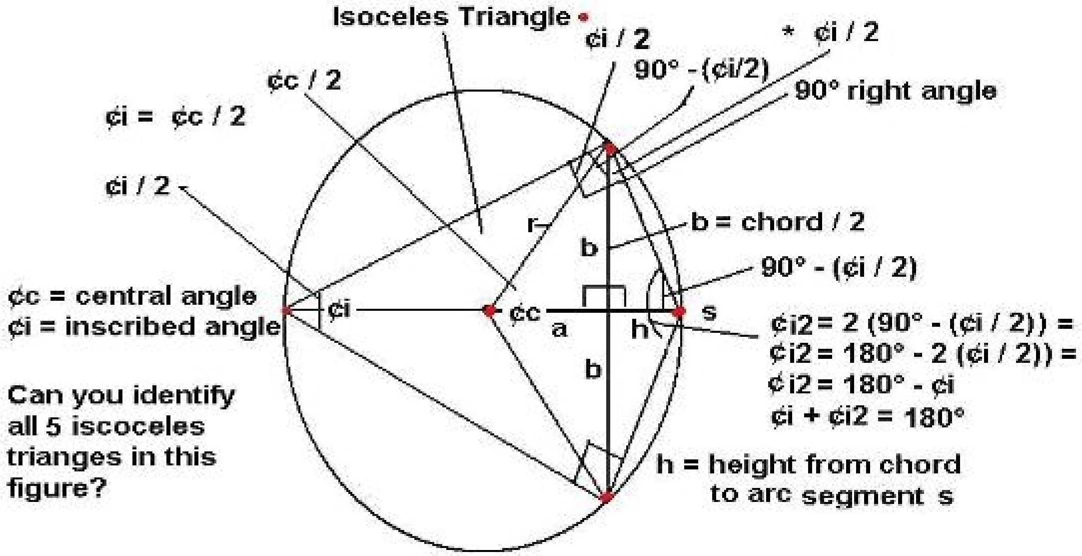
$$d = 2r = 2\left(\frac{w^2 + h1^2}{2\,h1}\right) = \frac{w^2 + h1^2}{h1}$$

, extra: $h1 = w^2 / h2$, when $h1 = h2$:
then: $h1 + h2 = 2h1 = 2h2$ and $h1/h2 = 1$ and $r = h1 = h2$

For some verification of the chord theorem, at the point of in intersection of the two lines, two pair of equivalent vertical angles are created, and by extending these sides of the angle and connecting their endpoints by a straight line, two pair of similar triangles will be created. For example, some equivalent ratios of their corresponding sides are: $a/c = d/b$, which can be simplified to $ab = cd$ as shown above. To help this verification, consider that any and all arc segments of a circle have the same focus point at the center of the circle. The radius line of a circle will be perpendicular to a chord line at its center or half-length point. The length of an arc segment and its chord length is also proportional to the angle from the center of the circle, and here, all points on that arc segment will have the same distance from the center of the circle, however the distance from each point on a chord to the center point is not a constant value. For other points in a circle besides the center point, an arc length and chord will be determined by both the angle created at the point of intersection of two lines within a circle, and by the distance that the line intersection point is from the center and-or arc. Just the same, the larger the radius of a circle, the larger the arc length and-or its chord line. The two corresponding arc segments and their chords lengths created due to having the same similar vertical angle will be proportional in value to their distance from that point of intersection.

A point within a circle other than the center point of a circle will be a point on 1 unique radius and-or diameter line, and will also be the center point of 1 unique chord line. Since a chord line is perpendicular to the radius line to its center point, that chord line will have a negative reciprocal slope value of the radius line. The farther that inner point is from the center of the circle, the smaller that unique chord line, corresponding arc length and central angle that the arc subtends and-or corresponds to.

Another method to find the radius of curvature. [FIG 305]



The internal angles within this 4 sided quadrillateral sum up to:
¢i + ¢i2 + 90° + 90° = 360°

When given h and b:

* Tan (¢i / 2) = opposite side / adjacient side = h / b
(¢i / 2) = arctan [tan (¢i / 2)]
¢c = 2 ¢i
¢c / 2 = 2 (¢i / 2) = ¢i

Sin (¢c/2) = opposite / hypotenuse = b / r
r = b / Sin (¢c/2)

a = r Cos (¢c/2) = r - h
h = r (1 - Cos(¢c/2))
h = r - a

b = r Sin (¢c/2)
b^2 = r^2 - a^2

Much of the previous discussion about central and internal angles has been previously mentioned in this book.
Since any quadrilateral can be divided into two internal triangles with each having an internal angle sum of 180°, the total sum of the internal angles of a quadrilateral is: 180° + 180° = 360°.

Extra: For another formula for **chord length** given the central angle (¢c) corresponding to it, and the radius (r) of the circle:
If (a) is half the chord and-or length, then: sin (¢c / 2) = a / r , a = r sin (¢c / 2) , chord length = 2a = 2r sin (¢c / 2)

AN EXTRA NOTE ABOUT TORQUE AND POWER

You may wish to also view to article in this book about a flywheel and its mechanical and kinetic energy storage, and of which also contains some similar equations.

T = (force)(lever arm) = FnLm , : T = torque, and with units of Newton-Meters
T = (force)(L) = maL

Work = Energy = (force)(distance) = FnDm : with units of Newton-Meters

Power = Energy / Time = Work / Time = Joules / Second = J / s

P = F d / t , and since d = v t , v = d / t , therefore:

P = F v : F in newtons , v in m/s , now expressing this in terms of Torque:

P = T v = T w , and since torque involves rotation, v becomes angular or rotational velocity = w, and with units of radians per second = rads / s

If given, we must first convert revolutions per minute (rpm) or revolutions per second (rps) into rad / s for the power needed or used for/of the applied torque.

d = (v)(t) : a linear or scalar distance

If given a revolutional velocity = rotation / time = ¢ / t, and not a length distance or linear velocity = d / t :

¢ = (w)(t) = an angular, revolutional or rotational distance , if we divide this amount of angle by the amount of angle or angular rotation per rotation, we can find the number of rotations. The amount of angular rotation per revolution or rotation is 360° = (2)(pi) radians =~ 6.28 radians
w = ¢ / t

Ex. A wheel rotated 10 times in 5 seconds:

$\frac{10 \text{ rot}}{5 \text{ sec}}$, and this fraction can be reduced to: $\frac{2 \text{ rot}}{1\text{s}}$ = 2 rps , hence a frequency of 2 rot/s = 2 cycles/s = 2 cps = 2 hz

w = ¢ / t = (N rotations) (2)(pi) radians / s = (2)(2)(pi) rads / s = $12.566\underline{4}$ rads / s

(12.5664 rads / s) / (6.28 rads / rot) or= (12.5664 rads / 1s) (1 rot / 6.28 rads) = 2 rot / s

(1 rev / s) (60s) = 60 revs also: N rps (60s) = (N rev/s) (60s) = N 60 revs = N 60 revs / min

(60 revs) = (1 rev / s) (60s) = (1 rev / s) (1 min) , mathematically, by dividing both sides by (1 min):

(60 revs) / (1 min) = (1 rev / s) , switching sides

1 rev / s = 60 rev / min

$1 \text{ rps} = \frac{1 \text{ rev}}{\text{s}} \frac{(60\text{s})}{\text{min}} = \frac{60 \text{ rev}}{\text{min}} = 60 \text{ rpm}$: **1 rps = 60 rpm or= (N) 1 rps = N rps = N 60 rpm**
rps = rpm / 60

360° = 1 rotation or revolution = an angle of 2 (pi) =~ 6.28 radians

$$\frac{1\text{ rev}}{s} = \frac{360°}{s} = \frac{2(\text{pi})\text{ rads}}{s} =^{\sim} \frac{6.28\text{ rads}}{s}$$

rotational or angular velocity = w =

$$w = \frac{\text{angular distance}}{\text{time}} = \frac{\text{rads}}{s} = \frac{\text{rads}}{s}\,\frac{(\text{revs})}{(\text{revs})} = \frac{\text{rads}}{\text{rev}}\,\frac{\text{revs}}{s}\text{ , and:}$$

Given a number (N) of rotations or revolutions per second = rps:

$$w = \frac{2(\text{pi})\text{ rads}}{(\text{rev})}\,\frac{(N\text{ revs})}{(\ s\ )} =^{\sim} \frac{6.28\ N\ \text{radians}}{s} = 6.28\ (\text{rps})\ \text{radians} = \frac{6.28\ (\text{rot})}{s}\ \text{radians} = 2(\text{pi})(\text{cps}) = 2(\text{pi})\ f$$

: cps = cycles per second
: f = rotational frequency

Given a rotating circle where r=1 and-or 100% for general, relative or proportional analysis:

angular velocity for 1 rotation = w = (angular distance for 1 rotation = 360°) / t =
w = 2(pi) rads / s = 2(pi) / s = 6.28 rads / s = 1 rotation / s = 1rps

linear v for 1 rotation = v = linear d / t = Circumference / s = 2(pi) r / s , If r=1m: c / s = 2(pi)(1) m / s = 6.28 meters / s

If r=1, v = linear distance / s , and if there is 1 rot / s or= 1 rev / s = 360° / s, this can interpreted as: 2(pi)(r) / s = 1Cm / s . w = 6.28 rads / s, also, at r=1, 1 Cm / s = 6.28m / s , and
Work = (Force)(distance) = Fd = F (6.28m) joules , and if this was done in 1s, Pw = W/t = E/t = 6.28F J/s = 6.28F watts

If there are N rotations or N revolutions per second, we simply multiply (d) or (C), and (w) by (N) to find:
v = d / t = NCm / s and w = (6.28N rads) / s

Pw = Ej / s = Work / s = (force)(distance) / s = F (velocity) = Fv , and in terms of torque , rotating or twisting forces:
Pw = Fv = Tw = T (6.28 N) rads / s = T (6.28)(rot / s) rads / s

, if given a rpm value , 1 rps = 60 rpm , multiplying both sides by N:
N rps = N 60 rpm , dividing both sides by 60 and switching sides:
N rpm = (N / 60) rps , Ex.: If given 60 rpm , 60 rpm = (60/60) rps = 1 rps

$$Pw = T\,w = T\ 6.28\ (N\text{ rpm})\text{ rads} = T\ (6.28)(N\text{ rpm} / 60\ )\text{ rads} / s = \frac{T\ (6.28)(N\text{ rpm})}{60}\text{ rads} / s$$

(N rot) / s = (N rps) = w can be thought of as in terms of a linear equivalence of: (nc) / s = d / t = v , and
rpm = (rot / min) can be thought of as: (nc) / min = nc / 60s = (N rot) / 60s

Some extra angular velocity expressions:

This book generally uses the w symbol for angular or rotational velocity.

1 rps = 2(pi) radians / s = 6.28 radians / s : rps expressed using angular velocity = w = angular distance / time
1 rps = 1C / s : rps expressed using linear velocity = v = linear distance / time , C = circumference at the radius
1 rps = 1 C / s = 2(pi) r / s , If r=1m , 6.28m / s = v

This is the same numeric value as the angular velocity, hence angular or twisting velocity can and should be used in terms of torque, and of which is often expressed in terms of rps or rpm. For torque, the angular velocity has units of (radians / s). Given rps or rpm, these rotational velocity values will then need to be converted to their equivalent angle velocity values of radians per second.

1 rps = 1 rev / s = 2(pi) radians / s =~ 6.28 rads / s
1 rps = 1 rev/s and after 1 minute = 60s of time , (1 rev / s) 60s = 60 rev after, for, or per 1 minute = 60 rpm
1 rps = 60 rpm = 60 rev / min , and after multiplying each side by N , we have:
N rps = (N 60) rpm .
N rps = (N 60) revs / min = (N 60) rpm
N rps = N revs / second = N (2)(pi) radians / s
N rpm / 60 = rps and N rpm = 60 rps = 60 (revs / second)

rotational velocity and corresponding linear velocity:

N rps = N (rot) / s and (rps) Cm / s = (rps) (2(pi)(r)) m / s : C = circumference

Since C = (2)(pi) r , r = C / (2)(pi) and C / r = (2)(pi) , If r was an arc length on the corresponding circumference, there will be (2)(pi) =~ 6.28 times or instances of it , hence a circumference has a full rotational angle of (2)(pi) radians = 360°

F = hertz = hz = cycles, pulses or vibrations / second = cps = rps = N

linear velocity = v = $\frac{\text{distance}}{\text{s}}$ = (rotational linear distance) (rotational frequency) = C (cps) = **C F** = **2(pi)(r) F , m/s**
C = circumference , r = radius in meters , F in hz = c/s

linear velocity of a point on a rotating circle or disk structure = v = C F = (circumference of circle) (frequency of rotation)

After an amount of time, there will be N revolutions of this circle, disk or wheel, and the total distance traveled =

total distance = v t = (C F) t = C F t = C (revolutions / second) (seconds)

Ex. The circumference of a car wheel was calculated to be: C = (2)(pi)(r) = 2 meters. If the car is traveling at 15 meters per second, what is the rotational frequency of that wheel?

From **v = C F** , **F = v / C** = $\frac{\frac{15m}{s}}{\frac{2m}{1}} = \frac{15m}{(s)(2m)} = \frac{7.5}{s}$ = 7.5 hertz = 7.5 cycles or revolutions per second

Ex. An **anemometer** (ie., a windspeed meter) has windcups (wind , force collection cups) at a 12cm radius. If it is spinning at 240rpm, what is the windspeed in meters per second?

240 rpm = 240 revs / minute = 240 revs / 60s = 4 revs / s : after dividing num. and den. by 60

12cm = 0.12 m
v = C F = (circumference)(frequency) = (2)(pi)(r) (F) = (2)(3.14)(0.12m) (4 / s) = 3.0144 m/s

AN IMPROVED ALGORITHM TO SOLVE DIFFICULT EQUATIONS

Previously in this book, a method and-or algorithm called EQSOLVE2.C was shown how to evaluate difficult expressions and-or equations. Below is an alternate and-or improved version of it, and it uses only just one main loop, and has been placed in a more usable example program.

```
/* -----------------------------------------------------------------------------------
FESA.c ,    FAST NUMERICAL ALGORITHM (FANA)    or
            FAST EQUATION SOLVING ALGORITHM (FESA)

   An non algebraic, mechanical-like numerical method or algorithm to zero into
   or approach the result and having a high precision.

   Compiler used:  TinyC  ,  ANSI standard, fundamental C only.

   When using just 1 term of the equation shown below, the result essentially finds
   the log of that number, and which is the exponent.
   Ex.   If result=number=1000 ,  and a=10,  then x=logarithm=exponent=3
   Note that the number of a logarithm cannot be a negative value.
   A logarithm can be negative in value, such as when the number is less than 1.
   The logarithm of 1 as the number, using any base, is 0.  If the number is less
   than 1, then the logarithm will be negative in value.

   For testing, I usually used:   2^x + 3^x  =  35
                            and:   1^x + 2^x  =  35

    The program can be modified as needed - perhaps to display it better.

```
This program and algorithm in it is: (c) J.P. Albertson , 2022, author of
the Mathization ebook.  Donations will help me and this effort to help
others, and the verified link is in the ebook and-or in my channel
description.  The .pdf format book can be viewed on a phone or computer,
and is filled with basic math, algebra, trigonometry, advanced topics, and
science.  It is a helpful supplement to any course, home learning and-or work.

This Fast Numerical Algorithm will find the value of (x) in this expression:

a^x + b^x + c^x + d^x + e^x + f^x + g^x + h^x + i^x + j^x = result

Enter the number of initial terms to use: (1 to 10): 3
```

```
Enter the positive valued result of the expression or 0 to quit.

result = 110

Enter a: 5.0

Enter b: 6.0

Enter c: 7.0

c^x  =  7^2 = 49

Press A Key
```

MORSE CODE

Since antiquity, signals other than verbal sound signals have been a way to communicate, especially over long distance by using things such as sound, light (electric, sunlight and mirror(s) = heliostat or "heliograph", and flares = visible rockets and-or a light suspended below a parachute), smoke, hand, and various (woven cloth or fabric) flag signals. Even a mechanical bell operated by a thread can be used for simple communication for say up to several hundred feet. Once an electric signaling system was developed not long after the discovery of the battery (ie. voltaic pile) in about 1800, an electric buzzer (audio sounder, much like a vibrating speaker having one tone), made it practical to communicate nearly immediately (ie., with nearly no time delays) over long distances, day or night, from city to city, from valley to valley past distant mountains. This was the modern form of communication before highways and mail delivery, trains and telephones, still, horses, carrier and boats were available.

A signal will requires a pulse or brief instance of the method used such as light, and the duration of it needs to be experimented with so as it can be received and-or recorded well enough to be deciphered later and to have meaning. With a signaling pattern or code system, more information can be communicated. In order to count a number of pulses, there also needs to be a lack of a pulse in between each pulse transmitted. We could code or express each pulse as a value of 1, and a lack of a pulse as 0. Samuel Mores recorded his two types of pules as a dot or dash, either written or on a paper tape.

Pulses of electricity could be sent and the specific number of pulses sent could represent a certain predefined or coded (another form, non-verbal, non-text) message. Even today as of the year 2022, in most hospitals, an electric buzzer or signaling system can be used by a patient in a certain indicated room to request some attention from the medical staff located down the hall, or on a different floor, or in a different building. Many homes, rooms, gates and buildings still have a door buzzer or tone system for signaling (ie., electronically requesting) attention is needed, and these are commonly called "door bells" or "door buzzers".

Samuel Morse invented the **Morse Code** communication system so that each text letter of the alphabet, and number, could have an associated code or coding sequence to it, and this made the telegraph much more useful and practical . Later, his Morse Code was adapted to the standardized International Morse Code system. Morse's system uses pulses, but two different types of short and long pulses. A short or quick (ie., in time length) pulse called a "dot [**.**]" could be considered as analogous to a 0, and a longer pulse called a "dash" [-] could be considered as analogous to a 1. Due to that there may be several of the same types of the pulse in a row, such as three dashes or three dots, there is still a necessary spacing and-or timing delay between pulse each so as to being able to recognize or distinguish each, and it is standardized as the time of 1 dot or short pulse between each pulse. A dash or long pulse is standardized as being 3 short pulses or dots long in time duration. Between each group of pulses for a letter, the timing space or duration of silence (ie., no signal) is equivalent to three pules, and between each word, the timing space is 7 pulses or dots. An experienced user should slow their speed of communication down so as to work better with novice or slow users.

Though the telephone replaced the telegraph and Morse code, Morse Code is still being used for relatively inexpensive, low power (as low as one watt to several watts) radio communications, and which use a very narrow range of bandwidth (ie., frequency range) which effectively concentrates the transmitted radio energy so it can be received at long distances away. There are special frequency bandwidths allocated for using Morse Code, radio communication, and are typically used by radio hobbyists to test their equipment, range and quality of the radio communication transmitted and-or received.

Below is a Morse Code chart:

A	. _			**X**	_ . . _
B	_ . . .			**Y**	_ . _ _
C	_ . _ .			**Z**	_ _ . .
D	_ . .				
E	.				
F	. . _ .				
G	_ _ .			**1**	. _ _ _ _
H	. . . .			**2**	. . _ _ _
I	. .			**3**	. . . _ _
J	. _ _ _			**4**	. . . . _
K	_ . _			**5**	. . . . .
L	. _ . .			**6**	_ . . . .
M	_ _			**7**	_ _ . . .
N	_ .			**8**	_ _ _ . .
O	_ _ _			**9**	_ _ _ _ .
P	. _ _ .			**0**	_ _ _ _ _
Q	_ _ . _				
R	. _ .	**S**	. . .	**T**	_
U	. . _	**V**	. . . _	**W**	. _ _

Each letter has up to 4 pulses. Each pulse is one of two pulse types:
A dot signal may be said as a "dit" or "di" or "de"
A dash signal may be said as a "dah" or "da"
SOS = . . . _ _ _ . . . : use to quickly request help, keep transmitting.
If your location is unknown, radio source direction can be used to find you.

Each number always has 5 pulses.

: For the numbers:
: Each dot can be considered as a count of 1
: Each preceding dash can be thought of as a count of 2

Note the opposite pulse types of: **(S , O)** , (A , N) , (B , J) , **(E , T)** (F , Q) , (G , U) **,** (K , R) , (L , Y) , **(M , I)** , (D , W) , (P , X) , (D , G) , (G , W)
Note the similarities of: **(E , I , S , H)** , (S , V) , (F , U) , (G , Q) , (A , R) , (P , W) , (I , U) , (M , G , Z , 7) , **(T , M , O)** , (J , O) , (J , P) , **(E , A , R)** , **(T , N , D , B)** , (T , N , K , C) , (O , J) , (G , U, W) , (A , W, J) , (A , U , V) **,** **(E , A , W , J)**

Many people can learn and memorize the Morse code system, but many other people will find it difficult to learn and-or use, and a simple pulse code or (pulse, signal) counting method and standardize system can be used instead. One such method is the **Tap Code** and of which you can look up about further, and the main benefit is its simplicity of just needing to count and record the number pulses received, and then to decode what they mean in terms of letters. If possible, it would be helpful if one person counted the pulses and another person nearby recorded them. Between each pulse transmitted and-or word, there still needs to be a perceived or recognizable silence so as to be able to recognize each unique or individual pulse. Below is a adaptation of the 5 row by 5 column Tap Code, and it rather uses 6 rows and 6 columns so as to include both the 26 letters alphabet and the 10 the numbers in the decimal system. The standardized Tap code has no explicit number characters or letters, and the letter K is omitted from it, but C can be sent in its place, and this keeps the code table at a 5 by 5 arrangement. To send a letter or number, first pulse the corresponding row value it is in, and then pulse the corresponding column value it is in. Perhaps the receiver can be instructed to return a signal that the two values and-or letter was received, and that they are then ready to receive more, resend, wait, etc. To send punctuation, a prearranged code method can be used, such as for example using Q or QQ to mean a question mark.

Tap Code , standard

	1	2	3	4	5
1	A	B	C	D	E
2	F	G	H	I	J
3	L	M	N	O	P
4	Q	R	S	T	U
5	V	W	X	Y	Z

: It is recommended to learn the rows first: A=1, F=2, L=3, Q=4, V=5 , and then the others letters in that row will be just a few letters away, and depending on the column value. One mnemonic for the first column is: "**A** **F**riend **L**oves **Q**uickly". A special character like N = (3,3) can be used to indicate a number follows.

Possibly (N , N) = (3 , 3) , (3 , 3) can be used to signal a number value will follow next, and of which can be the number of pulses having the same value as the number itself, and then (N , N) can signal the end of the number, and that letters will follow next.

[FIG 306] An Example Of A Modified Tap or Pulse Codes

	1	2	3	4	5	6
1	A	B	C	D	E	F
2	G	H	I	J	K	L
3	M	N	O	P	Q	R
4	S	T	U	V	W	X
5	Y	Z	0	1	2	3
6	4	5	6	7	8	9

One mnemonic for the first column letters in relationship to the corresponding row values can be:
"**A** **G**ood **M**an **S**tays **Y**oung **4**-ever".

With this modified tap or pulse counting code system, to send the letter J, send 2 pulses, then send a recognizable delay, and then followed by 4 pulses:

Letter = (Row pulses, Column Pulses) : Rows are horizontal = left to right , Columns are vertical = up and down.
J = (2, 4) = ... : = J is located at: row 2 , column 4

A way to signal or indicate you are ready to send a message is to perhaps shine a lamp continuously until the receiver shines theirs which signals that they have received and acknowledged your communication request signal, and then communication can begin. A set time(s) of communication can be also be used to help communication on a regular or synchronous (ie. synchronized, happening at the same time, "synced", coincidental) basis, instead of being asynchronous (ie., unsynchronous, non-synchronous, without specific timing and coordination, hence random-like or randomly).

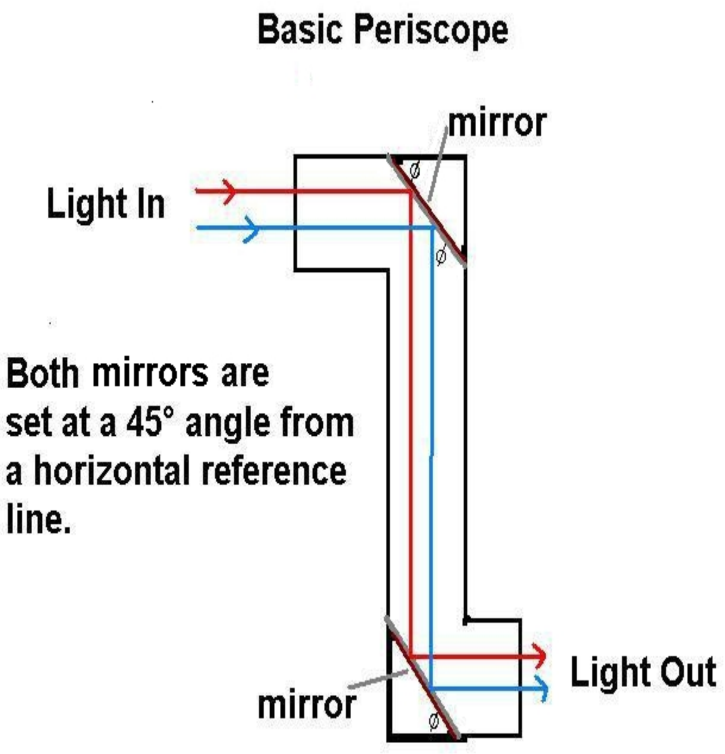
A computer can be used to code, send, receive and decode pulses to letters like this and each pulse is analogous to receiving a binary number 1 or logical true which is usually represented as 1. To distinguish each row and column value, and each letter, a silence or 0 needs to be sensed, and the specific duration of it will determine if the next pulse is the start of another pulse or letter. It is possible to use a certain frequency or tone to signal that a new pulse will be sent, and tone(s) and-or pulsed-tones can be used to signal the specific row or column value is being sent. With this latter method using pulsed-tones, the timing and-or communication synchronization becomes less of an issue. In a modern computerized communication system, it may be rated as being able to transmit up to 10 bits or pulses per second. The timing of each bit is then: 10 bits/second , and after dividing the numerator and denominator by 10, we find that; 10bits/s = 1 bit / 0.1s. After each tenth of a second or 0.1s, the computer will be instructed to send or sense (ie., "read") the next bit value of either 0 or 1. A longer delay could be used to signal the next byte of data will be communicated. After receiving 8 bits or a byte of data, it can be stored in a file. A special byte value may even signal a (communication) control code, such as start of transmission, end of transmission, error, resend, new line of text, etc. The ASCII communication code for text messages has several control codes having a byte value in the range of 0 to 31.

Again, for effective communication, a language or code as a standard must me used.

How To Construct A Periscope

A periscope can allow an observer to see over an object blocking their view, and-or for safety purposes to avoid injury. You can construct one out of cardboard, wood, or plastic, and held together by some type of glue or hot-glue stick, but tape is possible for initial tests. You can experiment with various sizes so as to see what works best for you. An example size to experiment with might be the main (square) tube having a length of 1 foot =~ 30.5 cm. Two mirrors need to be cut and have their sharp edges sanded to be slightly rounded using a piece of sandstone bought or found, and by an **experienced person** using work gloves. The shape of the mirrors can be square shaped with each side being about 2 inches =~ 5 cm long. To protect the mirror, the back of it can be coated with glue or paint and-or even a piece of thin wood or plastic.

[FIG 306B]



An Example Of A Batchfile Program for Intel-DOS Personal Computers

As mentioned in various locations in this book, often when dealing with computer programs, a batchfile is a series and-or batch (ie., a pile, a quantity, several) of operating system commands that can easily do a certain task without much user input or concern. A batchfile can be considered as both a computer command and program. Usually these tasks are related to the files, screen, or printer. For the batchfile program below, it is for computers that have an Intel style, DOS style operating or command line system and of which allows these batchfiles. This batchfile program will copy the dragged-and-dropped (using the mouse) file onto it into several disk drives locations. These locations and-or file directories (sometimes called folders) can be edited as needed by your system and needs, for example, maybe your computer does not have a certain drive, etc. To make a batchfile, enter its text into a text file with a text editor, and then rename the .txt filename extension to .bat. If you are able, you can research the available batchfile commands for your computer system. A good way to do this is to type and enter the HELP command on the command line. For the fine details on using batchifles commands you will need to research batchfile programming since it is beyond the general scope of this math and science book. Another helpful batchfile was placed after this first one, and it allows the user to quickly go to the current directory's command line of which the batchfile is in. You can often place a program such as a batchfile into the Windows (R) operating system's SENDTO folder, and when you mouse-right-click on a filename, you can select SENTO and the program to use that file. To place a program into the SENDTO folder so it can be accessed from any directory or folder, select: Start, then Run, and enter: "sendto" , and the SENDTO folder will be shown and you can then place what you need to be there.

Batchfile also have some of their own unique commands for "batchfile programming" and you will need to research all of these if you want to and obtain the literature or reading material. People, such as secretaries who work with many computer files can benefit from using batchfiles and-or learning how to program and-or edit them. For example, the REM command is used to enter a remark or comment such as what the batchfile is about or doing and this command not displayed on the screen. ECHO is used to display text on the screen. ECHO with a period after it is used to display a blank line. @ECHO off is used to not display the following commands in the batchfile program.

```
@echo off

rem  copytodrives.bat
rem (c) JPA 2023 and previous

@echo off

echo Batchfile To Copy An Input File To Several Locations
echo Can use drag and drop, or copy and paste, or enter
echo the filename on the command line.
echo.

rem  If no input file was on the command line or dragged and dropped onto the batchfile
rem  filename, the following code will be skipped over, and will resume at the HERE1 label
rem This older command may not work right on newer computers:    if "%1"=="" goto HERE1

 if [%1]==[] goto here

echo Copying %1 to these locations:
echo.

echo Copying to drive c:\
copy %1 c:\    /y
REM Can use copy %2   c:\    /y      , and %3 etc. to copy several selected files, drag and drop , or mark and copy
REM                                    then paste this on the batchfile command.  Be sure to do this for all the drives.

echo.
```

```
echo Copying to drive d:\
copy %1 d:\    /y

rem echo.
rem echo Copying to drive e:\
rem copy %1 e:\ /y       /* Currently on my system, E is the CD read only drive   */

echo.
echo Copying to drive f:\
copy %1 f:\     /y

echo.
echo Finished
echo.

rem normal batch file termination here:
rem When the pause command is encountered during processing, the user is prompted to press a key to resume.
pause
exit

:HERE1
echo off
echo To use this batch file, please drag and drop the file you
echo want to copy to your drives onto the batch file icon.
echo.
pause
exit
```

This batchfile below allows the user to quickly go to the current directory's or folder's command line of which the batchfile is placed in.

```
@echo off

rem  ToThisDOS.bat
rem  This batchfile allows the user to quickly go to the current directory's or folder's command line.
rem  (c) JPA 2023  , Author of the Mathization , Math and Science ebook

echo.------------------------------------------------------------------------

echo Type HELP to see many of the available DOS or computer system commands.
echo Type HELP command_name to see about a specific commands usage.
echo.
echo CTRL C  or  CTRL BREAK  can sometimes be used to terminate a command.
echo.
echo Type EXIT to return to system.
echo.------------------------------------------------------------------------
echo.

cmd.exe
```

A COMPUTER PROGRAM TO COPY A FILE TO ANOTHER FILE

```
/*------------------------------------------------------------------------------------------------------------
copyfile.c

                Copy a file to a new file and-or location. This is similar to the
                DOS or WINDOWS operating system command called "copy".
                Ex.  copy myfilie.txt  myfile.bak

                  It will help if this program is in the same directory, other wise you can
                 consider putting this program in one of the computer's "environment
                 variables" called "PATH" which indicates where the computer system
                 will to search for the commands, etc. typed/entered on the command
                 line, or clicked on by the mouse selector/pointer, etc.  The PATH
                 variable is often located in the batchfile called "autoexec.bat" that is ran
                 when the computer is first started, however, this PATH variable can also
                 be modified from within a user made batchfile.  You may also consider
                 placing a program(s) in the Window's SENDTO folder so as it will be
                 seen and available in the mouse right-click menu.

               For Now, I am letting the user input the filenames, rather than use the
               drag-and-drop input file onto the program name when programmed to
               accept command-like arguments

```

```
                printf("\nWavelength = %.15g meters = %.15g feet",(c/f) , (c/f) * 3.28084 );
              };

      if(choice==2){ printf("\n\nEnter the wavelength in meters:  ");
                fflush(stdin); scanf("%lf",&w);
                if( (w<0.0) || (w > c) ){  printf("\a"); continue; };    /* let 300 million meters be max.. */
                printf("\n");
                printf("\nFrequency = %.15g hz",(c/w));
              };

      printf("\n\nPress A Key");  fflush(stdin); getch();

     };  /* end of main loop */

return;
};
/*---------------------------------------------------------------------------------------*/
```

Here is an example of the above programs input and output:

```
Frequency Or Wavelength Calculator Program
(c) JPA 2022 , Author of the Mathization,
Math And Science book

----------------------------------------------

The Speed Of Light Is 299,792,458 m/s = about 300,000,000 m/s  =~  186000 miles/s

1 Input Frequency To Find Its Wavelength.

2 Input Wavelength In Meters To Find Its Frequency.

      1 m = 100 cm = 3.28084 ft = 39.37 in
      1 cm = 0.01 m = 0.3937 in  =  6.3 sixteenths of an inch
      1 ft = 12 in = 0.3048 m = 30.38 cm
      1 in = 0.08333...ft = 0.0254 m = 2.54 cm exact

0 Exit

Enter Choice:  1

Enter the frequency in hz:  1000000

Wavelength = 299.792458 meters = 983.57108790472 feet

Press A Key
```

A COMPUTER PROGRAM FOR A HOMEMADE PROGRAM LOOP

With many of the older BASIC programming languages, a programming loop is made using both a LABEL statement and the GOTO command. A loop is a programming concept to reuse code, and often, to do so many times in an easier way that rewriting commands or instructions to do things, often the same thing, "over and over" or repeatedly. A **label** is an identifier used to mark or and-or save its location (ie., a memory address) in the program's code or statements so that it can be executed (ie., performed) when called using the GOTO command. For the C programming language, the GOTO command is rather the lower case version of GOTO, and is: goto. Note that goto is also one of the C programming keywords, and therefore, it cannot be reused to mean something else, such as the name of a variable used in your program. The GOTO command is also very similar to using the JUMP or JMP command with an assembly and-or machine programming language. C already has formalized built in loop keywords and-or programming constructs such as the for() loop, and the somewhat simpler while() loop. Of more use for a LABEL is that it can be used to create a location within the current function, and it will indicate where to go to and-or return to on occasion and-or need, and not necessarily being used only to create homemade loops. The GOTO command is one of the available program flow commands. More often, the use of the GOTO keyword is to jump or skip over (ie., not to be used or processed) programming statements of code that are currently not to be used for some reason or logic. Computer purists and-or "high level" programming ideals would rather programs use only the "higher level" constructs of more strict or formalized groupings or functions, and rather than using the more primitive-like fundamental computer machine or hardware code or operations like the goto command. The goto statement or command is much like a software to physical switch and-or a machine control settings that can be used to access and control the CPU (Central Processing Unit, IC circuit, "chip") of the computer machine.

```
/*------------------------------------------------------------------------------
homemadeloop2.c

Using the goto command to create a loop programming construction.
It is also possible to create a function construction with goto.

(c) JPA  2022
------------------------------------------------------------------------------*/
#include "stdio.h"
/*----------------------------------------------------------------------------*/
void main(void)
{
int n=0;

/*----------------------------------------------------------------------------*/
/*        A FUNCTION OR LOOP TO PRINT NUMBERS 0 T0 9   */
/*----------------------------------------------------------------------------*/
startloop1:  ;        /* A label is assigned a memory address to go to in the executable, run-time machine code
                         of the program. */

    printf("%d  ",n);
    n=n+1;
    if(n==10){  goto endloop1; };    /*  : essentially a homemade "break command" */

    goto startloop1;        /* : go to the start of the loop,  it can also be used as a loop continue command */

endloop1:  ;
/* ---------------------------------------------------------------------------*/

printf("\n\nPress a key: ");   fflush(stdin);   getch();

return;
};
```

```
/*------------------------------------------------------------------------*/
```

Program output:

```
0  1  2  3  4  5  6  7  8  9

Press a key:
```

A COMPUTER PROGRAM TO CONVERT A NUMBER OF SECONDS TO Y:D:H:M:S FORMAT

Many other conversions can be thought of and put into this program example, and-or other programs.

```
/*----------------------------------------------------------------------------------------
TimeConverter.c

This example program converts an input number of seconds to Y:D:H:M:S format
or:   Years:Days:Hours:Minutes:Seconds  format

For reference:

1 minute = 60 seconds
1 hour = 60 minutes = 3600 seconds
1 day = 24 hours = 24 (3600s) = 86400s
1 year = 365 days  =  365.0 (86400s) = 31,536,000s     When using the basic amount 365.0 days.
                                                        See below.

As a test of this program , the user can input 31626061 for the seconds value,
and the result should be: Y:D:H:M:S = 1:1:1:1:1    As another test, 86460 seconds
should give 0:1:0:1:0    Another test of 90061 should give:  0:1:1:1:1

NOTE and for floating point values in general, scientific notation and-or powers
of 10 can be input using letter e or E which means the exponent of 10. 10^e or 10^E
Ex.  To input 3600 , you could use:  3.6E3 or 3.6e3  which can be interpreted as
3.6 (10e3)  or=  3.6 (10^3)

       /* For equivalent DAYS leftover or remaining.  */

       D=input / 86400.0;
       temp = input - (double)( ((long int) D) * 86400.0);  /* subtract the number of seconds in those days */
       input = temp;    /* as like a new number of seconds input to work with*/

       printf("\nRemaining Days = D = %.15g",D);
       /*  printf("     The whole number of Days  = %ld",(long int) D); */

  /*-------------------------------------------------------------------------------------------------------------------*/

     /* For the equivalent HOURS left. */

       H=input/3600.0;
       temp = input - (double)( ((long int) H) * 3600.0);  /* subtract the number of seconds in those hours */
       input = temp;    /* as like a new number of seconds input */

       printf("\nRemaining Hours = H = %.15g",H);
       /*  printf("     The whole number of  Hours  = %ld",(long int) H);  */

  /*-------------------------------------------------------------------------------------------------------------------*/

     /* For the equivalent MINUTES  left. */

       M=input/60.0;

       temp = input - (double)( ((long int) M) * 60.0);  /* subtract the number of seconds in those minutes */
       input = temp;    /* as like a new number of seconds input */

       printf("\nRemaining Minutes = M = %.15g",M);
       /*  printf("     The whole number of  Minutes  = %ld",(long int) M);  */

  /*-------------------------------------------------------------------------------------------------------------------*/

     /* For the equivalent number of  SECONDS  left or remaining.  */

       S=input;

       temp = input - (double)( ((long int) M) );  /* subtract the number of seconds in those minutes */
       input = temp;    /* as like a new number of seconds input */

       printf("\nRemaining Seconds = S = %.15g",S);
       /*  printf("     The whole number of  Seconds  = %ld",(long int) S);  */

     printf("\n\n%ld seconds = Y:D:H:M:S = %ld:%ld:%ld:%ld:%ld",(long int) inputseconds, (long int)Y,(long int)D,
              (long int)H, (long int)M,(long int)S);

};
```

```
        /*------------------------------------------------------------------------------------------------------------------------------------------------*/

        printf("\n\nPress A Key To Continue: ");  fflush(stdin); getch();

   };  /* end of  loop 1 */

return 0;
};
/*---------------------------------------------------------------------------------------------------------------------------------------------------------*/
```

Program use example:

```
------------------------------------------------------------
TIME CONVERTER PROGRAM
From the Mathization Ebook.
(c) JPA 2023

This program converts an input amount seconds to
Y:D:H:M:S = Years:Days:Hours:Minutes:Seconds format.
A sidereal or same star position year is 365.256363004 days
long in time value.  A Sun alignment or "complete orbit" solar year =
365.242190402 days long in time value.

A common calendar or clock year = 365 days long and a leap-year clock year is 366
days long which usually happens every 4 years so as the Earth will be aligned to the
same star, and  at the same time of day.   If the year is evenly divisible by 100, the leap
year (366 days) is skipped and the 365 day year is used.  If the century year (evenly
is divisible by 100) is a 4 year leap year, it will be skipped unless it is evenly divisible
by 400. This program will assume and use the common 365 day calendar year.
For each non-leap-year which considers only 365 days, it is 0.242 days short, which is
slightly less than a quarter of a day, and this quarter of a day each year adds up to about
4 days every 4 years of clock (non-astronomical) time..
------------------------------------------------------------

Program Choices:

1 Input the number of seconds to convert to the Y:D:H:M:S format
0 Exit Program

Enter Selection:  1
Enter the number of  Seconds: 31626061

31626061 seconds = 1.00285581557585 Years = Y
Remaining Days = D = 1.04237268518519
Remaining Hours = H = 1.01694444444444
Remaining Minutes = M = 1.01666666666667
Remaining Seconds = S = 1

31626061 seconds = Y:D:H:M:S = 1:1:1:1:1

A Computer Program To Convert Between Fahrenheit, Celsius, and Kelvin Temperatures

```
/*-----------------------------------------------------------------------------------------
temperatures.c

A Computer Program To Convert Between Fahrenheit, Celsius, and Kelvin Temperatures

Note, the Celsius and Kelvin temperature scales are linear.  Each 1 degree rise in
Celsius is 1 degree rise in Kelvin and vice-versa.  This is not the case with the
Fahrenheit scale in relation to the Celsius and Kelvin scales.  When converting from
Fahrenheit to Kelvin or vice-versa, it is best to first convert its value to Celsius.

    };     /* end of outer loop */

};
/*-----------------------------------------------------------------------------------------------------------------------------*/
```

Memory Allocation

Placing file data into electronic RAM ((dynamic) random access memory) can improve the speed of programs and reduce the wear on a disk drive, but it can also be dangerous if power to the computer is interrupted and all that data in memory has then been erased or lost, and so it is good to back up that data or just any new immediate data or records that have been created or changed, and onto a disk drive and-or external storage. **Saving data on several locations or drives is generally a good idea if that data is safe from drive failure and-or hackers (infiltrators, etc).**

The above program read each byte from the file and then displayed it, and then continued this till there were no more bytes of data in the file. You can also place or "load" all of file data into a portion of memory by first requesting use of some memory with the memory allocation function such as **malloc().** Allocating memory during a running program is called **dynamic memory allocation**. Here is some example and necessary code statements to consider into a program such as for a new version of the previous program about displaying a text file:

```
.
.
.
#inclulde <malloc.h>        /* formally include the header file that the malloc() is in */
..
unsigned char *p;      /* this will be the pointer to access the block of assigned computer memory */
long int n=0L;          /* basically a counter variable used for incrementing the pointer, but here technically, the pointer
                          stays the same value and-or location, but a temporary pointer value and-or location is the resultt */
.
.
p=malloc(filesize);  if(p==NULL){  printf("\n\n\a * * * MEMORY ERROR * * * , Press a key "); fflush(stdin); getch(); exit(0); };
.                        /* here, the filesize variable used represents the size or number of continuous bytes of memory to be
                          allocated for  the programs use */
.
/* Get or read a f byte from the file and put  or write it into memory.  Do this in a loop  until all the file bytes are stored in
 memory.  */

fread(&c,1,1,fp);    /* here the byte read from the file identified, associated or assigned as (fp) to will be assigned to
                       variable (c) which should have an unsigned char data type  */
.
.
 *(p+n) = c;      /* In the file reading loop, place the byte read from the file into fast memory, after reading this byte the next
                    file access position will be automatically incremented to the next byte address, hence by 1 byte. */

n=n+1;           /* increment by one so as the temporary pointer is updated to the next byte in computer RAM memory */
.
.
\* Get or read a byte in memory and put or write it into the file:   */
.
n=0L;
.
.
c=*(p+n);      /*Get a byte from memory so as to then write it to the file.  Do this in a loop until all file bytes are written.  */
.
.
free(p);    /* "Free up", "give up" or de-allocate the allocated memory so that the computer and-or program can use it if
              needed, and which may include needing a larger or smaller memory allocation  */
```

SOME COMPUTER PROGRAM IDEAS TO CONSIDER

First, it is perhaps better for a programmer to write their own functions to do something, even if a function already exists, and they can create a new, modified and-or enhanced version. After all, every program consists of individual functions to help it perform what the program needs to do, and to keep it readable and orderly. Programmers should keep a collection of all the functions they created, and so as to have them available for later use, editing and-or study.

1. A program to **split a file** into smaller file size segments, and is also capable of rebuilding a file from those file segments being joined together into one file. This is helpful for very large files, such as video files, that are larger than the 700Mb space on a compact disk (CD) storage. It can also be a way to send a file that is greater in size than a standard file size attachment for email, such as say 20Mb. Each file segment must be sent as a separate attachment. Years ago, it was very common to receive and install a large program such as the Windows operating system from about 10 floppy disks. After installing the first disk, the computer program would display a message prompt such as "Please insert disk #2, and press a key", and so on.

2. Create a **byte editor**. Make a function(s) that reads and-or writes a byte(s) at a certain address(es), location or byte number. For example, the function arguments might be:

   ```
   unsigned char  readbyte(fFILE * fp , unsigned long address);
   void writebyte(FILE * fp , unsigned long address);
   ```

   The basic concepts from the computer programs can be considered. Ask the user to input the address (either the offset or logical address of the byte, or physical address value), and-or the byte value of it is to be edited to.

3. **Create a database**. The data for each record can be placed in a single data file, or a single, readable/editable (such as by non-computer programmers, etc) text file. For example, each record or group of related data might include a persons name on one line and some other numerical data on the following lines. This data can be searched for given a persons name, record or account number or some other number or keyword(s). The data can be read and processed to display things such as a certain record or some average of a specific piece of data in all the record. It is even possible to load all the data into computer memory for faster access, and then save the data to a file when completed. You may wish to allow random comments or notes to be included in this data, such as for future reference, and you will need to delimit or set it apart from the other data by using with some special character(s) or words. For a basic and helpful start to this, you may first consider the computer program in this book called: A Computer Program To Calculate Some Statistics Of Data. A C language programmer may wish to look up the **struct** keyword in C, and it is essentially for creating a user defined data type and-or programming construct that is composed of one or more of C's data types, and is analogous to creating a record of related information. struct essentially means a (data) **struct**ure. An array of the standard data types can also be used as a record of data, but it is usually for data elements having the same data type such as char (1 byte sized data) or int (2 byte sized data).

   A **union** is a special C programming construct that is somewhat like a struct data type, however, all the data in it essentially coincides (hence the name union) or overlaps each other, and you can access a certain byte(s) and-or other data type size that is in it. Generally, a union is for numeric data types, and where you then want to access each byte, or even a single bit of a larger data size type. You can also access bits of a byte using homemade functions and-or bits of a byte via bit per bit manipulation such as for example ANDing a byte value with 128d = 10000000b so to find the value (1 or 0) of the most significant bit of a byte. Ex. bit =(databyte & 128). For a basic union example, a union might consists of a two byte integer, and two char data types which are essentially 1 byte data types each. After assigning a value to the integer in the (data) union, each byte of it can be accessed by the char data types.

4. This book has programs, such as the calculator to solve one expression at a time which contains only one or two numeric operands such as 5 * 3 and the result is 15. This book also shows some ways so as to solve equations within a program, but it would also be very helpful to allow the user to input a text string consisting of longer and more complex expressions such as 5 * (3 + 1). What is needed to solve general user input expressions is to **create an equation parser** code within a program and-or entire program which separates the (text, string form) equation into its more manageable composing terms, and then calculate the value of each term, and then combines these term values

so as to produce the result of the entire equation. This would make a better calculator, and possibly one which includes optional variables and loops. Considerations for a parser should include expression evaluation from left to right as for the standard order of operations, and grouping symbols such a parenthesis surrounding an inner expression which have a higher precedence and must be calculated first. When you write a computer program, the language compiler already has an equation parser and solver built into it, but its for use by the programmer and generally not the user of the created programs.

5. **Create your own simple computer language**. The easiest way to do this would be to create a Basic-like language where each line of the input text-source file program is processed from top down or one after the other. The language interpreter program created should at least include the allowing of user input such as text strings, variables, loops of which can be made using the goto command and program location labels, screen display output, basic math calculations, and advanced programmers might wish to include a general equation parser for solving for the result of user input expressions. This interpreter program can use the compilers built in string, math and other functions, etc., and-or write your own as shown in this book. An example of a user-made string function would be one that converts a text string to a numerical value so that it can be used elsewhere in the program, such as in a numerical expression.

6. **Write simple program for a company**. This company can be either imaginary or real. First find or choose a topic to make a program about and what the result and-or output of the program should be. Consider what equations to use, and the values(s) to be input by the user. Allow the program to have a "help screen" or "about" menu option so as to display what the program is about, how to use it, possible helpful data, recommendations and-or options. The date, author, copyright, and-or owner of the program and contact information can also be displayed . Then consider some other programs to create for the same company and-or other companies. If a company pays you for a program, you will need to negotiate with them if they are also buying the copyright also, and so as to have all rights to the use of that program including the possibility of reselling it elsewhere, and surely, your price of the program will then need to be negotiated and fair. In a way, you will then have to become like a business person. If possible, advertise your programming work(s) so that you and others may also have a chance to gain from them.

A MENTION OF THE BASIC PROGRAMMING LANGUAGE AND A SIMPLE MATH PROGRAM

This book focused on just using the C programming language, and which was developed in about 1972 so as to make programming easier and faster for many people by using a higher level language other than the commonly taught and used machine code (ie., strict, pure computer instructions, and with each is assigned a number so as to call and-or use it) and-or assembly languages (helps create programs written using machine code and-or higher level instructions that are actually composed (ie., constructs) of several machine codes). There are many other standardized programming languages such as Cobol, Fortran and BASIC. **BASIC** means **B**eginners **A**ll-purpose **S**ymbolic **I**nstruction **C**ode. Here Code essentially means "computer language", and for a specific computer program created or written, the program code for it is often called the "source code", "source code program" or "source program". BASIC's initial development was in about 1963, and was several years before the C programming language.

Shown further below is a minimal description and example of what can be called a simple or minimal program written using the BASIC language. Only a few commands and-or keywords will be used out of the many (perhaps 50 or more) keywords assigned strictly for use with the BASIC interpreter program and-or for BASIC language program. In short, a variable name cannot be one of the keywords already set aside for the BASIC interpreter program, and it can not contain spaces.

If you are interested further in BASIC programming, please purchase a book(s) about it from a book store that has it. The example program here does not have all of the BASIC keywords and functions such as the DIM keyword to define an array or dimension of similar data values. Simple forms of BASIC programming are sometimes available on some hand-held calculators, and is this good enough for people who need to make an immediate and simple program so as to produce a useful numeric value(s) rather than using the more advanced and intricate programs for a larger computer system. BASIC is also capable of complex programs. To run or execute BASIC language programs, please first obtain a BASIC language interpreter program(s) that is compatible with your computer system and-or phone.

The BASIC interpreter is actually a computer program in itself. It will usually have the .exe or .com filename extension. The interpreter can run or execute computer programs written or expressed using the BASIC programming language. This BASIC interpreter is similar to a C compiler that can run or execute computer programs written or expressed with the C programming language. Most BASIC interpreters do not produce a stand-alone program like a C compiler does. Some BASIC interpreters may include support for the WINDOWS ((c) by the Microsoft co.) operating system for many personal computers, and even this is actually a computer program running on the computer. The BASIC interpreter will read each statement in the program that was written using plain text, and it will then convert it to its corresponding machine code and-or language that the computer requires to function. The interpreter will do this for each statement, one after the other when encountered in the specific program flow (path or branch) and execution taken, and in essence, it does not compile all the machine codes into a complete machine code program which can be run without an interpreter program. Some modern BASIC interpreters can compile a .bas program into an .exe file that can be ran without the interpreter program used to make it.

For math programming considerations, we will need to know the specific commands and syntax (ie., analogous to spelling) of the mathematical operations available in BASIC. We will also need to ask the user to input values, and then let the computer perform the calculation(s) as expressed in the program upon those input values (ie., mathematical operands) and-or constants, and then to then display a result(s).

If you are already familiar with the C or other programming language, you will be more prepared and understand the nature of a programming language like the BASIC programming language.

In BASIC, the string (technically an array of text characters) identifier is similar to using a numeric variable name and-or identifier, however, the $ symbol will follow it. Ex. N is a number, and N$ is a text string N will be considered a numeric floating point variable and-or value, and N$ will be considered a string variable. In common BASIC , a variable does not have to be declared and-or initialized (but it can help with editing and understanding the program). A variable can be a single text letter, or it can have two text letters and a number, or a single text letter followed by a number, and usually (depending on the interpreter) must be upper-case (capital) letters. Many BASIC interpreters will also allow more than 2 characters for an identifier, but only the first two or three are usually accepted and they must be unique in the entire program. Numbers can be floating point values which may have a "decimal" or fractional portion. To express the integer value of a floating point value and without the fractional portion use the % symbol following it. Ex. If N is a floating point value: PRINT N% , and this will print only the whole portion of the value. Strings can be displayed without them being assigned to a string variable,and this is called a string literal or string constant. For example: PRINT "Welcome"

Variable names and-or identifiers do not have to be declared in BASIC , unlike in C. If these values are not initialized, they will be initialized or assigned a value of 0 or a NULL (ie.,=0, empty, non) string, essentially a value of 0 which is the null character or string terminator character or identifier.

Line numbers are generally treated as like reference locations in a program. You can consider them as like labels that are used for reference in the C programming language. They can begin at 1, but in practice, they may begin at say 10 and skip ten for the next line number: 10 , 20 , 30 , and so on, for this allows possible new statements to be inserted between these lines and-or statements if needed later.

To write a program for a BASIC language interpreter, use a common, plain ASCII text editor which does not include formatting characters in the saved file such as would happen with a word processor. Rename the file to have the .bas filename extension, rather than having .txt as for a text file.

To include more than one statement on a line, separate them by a colon (:) character. For the typical BASIC language interpreter program, if there are more than one statements on a line, they will not be executed if the previous statement evaluates to false. The C programming language would include other statements to be executed in the braces syntax.

```
10 REM  HYPOTENUSE.bas
15 REM

280 IF (N=0) THEN END
283 IF (N=1) THEN GOTO 95 ELSE GOTO 255
286 REM  AN OPTION TO  USING THE ELSE STATEMENT ABOVE, YOU CAN USE:    285  IF (N<>1) THEN GOTO 257
300 END
```

Some common math functions in the BASIC language and-or interpreter:

SIN(rad)   :for the sine value of the radian angle as the argument. See notes at cosine (COS) and tangent (TAN) below.
COS(rad)   : to convert a radian (R) value to a degrees (D) value use: D = R * (180 / 3.14159265358979323846
TAN (rad)   : to convert a degrees (D) value to a radian (R) value use: R = (D * 3.14159265358979323846) / 180
ATAN(tan) : depending on which BASIC interpreter is being used, it may have ASIN(sin) and-or ACOS(cos)
The value returned is a radian angle.
LOG(n)   :for LN(n) in BASIC   , For LOG base 10 use: LOG = LN(n) / LN(10) = LN(n) / 2.302585093
EXP(n)   :for e^n   . (e) = epsilon = Euler's Number is also the base of the natural logarithms (LN)
e = 2.71828182845904523536028747135...
ABS(n)   :for absolute value
INT(float)   :for integer or whole portion of a value considered a potential floating point value
SQR(n)   :for square root   ,   for use, ex: root = SQR(n)   , if n=2 , root =~ 1.414
RND(n)   :for to get a random number , where n=1, 0 , or -1 and returns 0.0 to 1.0 , use: -1 to reseed first, 1 to reuse random numbers , 0 to use internal clock to seed the random number generator.
INT(n)   :to get just the integer portion of a mixed number value   , For use, ex: wholevalue = INT(3.14) , and then wholevalue = 3   , and to have the fractional value ,   For ex: fractionalvalue = 3.14 - wholevalue = fractional value = 3.14 - 3 = 0.14
DEF FN()   : to declare and define an inline math function, and of which can also be called elsewhere in the program
Ex. DEF FN F1(x) = (x + a) / 2   , for use, ex: n = F1(3)   , hence evaluated as: n = (3 + a) / 2

Relational operators: < , >, <>   for not equals   , <= , >= , =   : used to test or compare values to made decision.
used to make conditional statements with IF

Logic operators: AND , OR   , XOR   , NOT   : used to determine the truth (1 or 0) of two conditional statements

Some common or standard string functions in the BASIC computer programming language:

LEN   :string length   Ex.   L = LEN(A$)   ,   L will be set or assigned the number of characters in the A$ up to the NULL terminator character which is usually number 0 , a zero byte of data equal to 0
LEFT$: get the left portion of a string ,   format ex: S2$= LEFT$(string , number of characters)
MID$: get the mid portion of a string ,   format ex: S3$=MID$(string , first character number, last character number)
RIGHT$: get the right portion of a string,   format ex: S3$=RIGHT$(string , number of characters)
STR$: to convert a numeric value to a string ,   format ex: S$ = STR$(N)
VAL   : to convert a string to a numeric value ,   format ex: N = VAL(S$)

Some common BASIC interpreter commands: (These can also be part of your program.)

LOAD : load a filename.bas program into memory space assigned to the interpreter
SAVE : save the filename.bas program to a file such as located on a disk drive
LIST : display the current loaded BASIC program's text . Used by itself will list the entire program, but to list one line number, use this format: LIST line_number. To list from a line number onward use: LIST line_number-
To list a range of line numbers, use: LIST start_line_number - end_line_number
RUN : execute or process the program
NEW : clear memory to start over
FRE(0) : shows how much free program memory allocated to your program is left

Some common BASIC programming commands:

CLS : clear screen , deletes all text characters on the display screen
LET : An optional command to enter the value of a variable: N = 10 is the same as LET N = 10
LET essentially means "to assign" or "initialize or set this variable with this value"

PRINT : to display a string (array) of text characters or a numeric value
Format: PRINT value or string , Ex. PRINT A or= PRINT (A) , Ex. PRINT A$
PRINT TIME$ will display the current system time in H:M:S format

INPUT : to let the user enter a text string or numeric value to the program

IF THEN : to test or determine if a condition is true, and if so, the statement(s) following the THEN keyword will be executed.

ENDIF : if the condition was true, statements up to ENDIF statement will be executed. It is not always needed, but if there are related statements to be executed on further lines, it is a good idea to group them using this. The C programming language uses the braces pair (opening brace character, and closing brace character) of symbols to group related statements. Braces are also used to group the statements in a C function construct.

ELSE : can be associated to and used after the latest IF statements, and so as to perform a new statement if the condition was false

FOR TO NEXT This is for a looping programming construct for repeating code. Sometimes called a FOR NEXT loop.

```
Ex.  300 FOR  N = 1 TO 10         : default is STEP 1   or use:   FOR N = 1 TO 10 STEP 1
     305  PRINT N                  : here , N is known as the (loop) counter variable, or repetition variable.
     310  NEXT N                   : At 310, this is much like also saying.  NEXT N = (N=N+1; GOTO 300;)
     320                             Essentially then, the FOR command also assigns 300 as the label to
                                     return or go to.    NEXT N causes N to be incremented by the value of STEP,
                                     here 1 as the default if not used.  Here,when N>10, this loop will terminate and
                                     the program will continue to the  next statement in the program, perhaps on
                                     "(assigned) line  number or label 320.  The STEP  value can be a fraction and-or
                                     a negative value such as -1, and which then causes the variable, here N, to
                                     decrement by 1 for each iteration or repetition of the loop.
```

GOTO LABEL This is a programming construct that will cause program running or execution to resume at the location identified as LABEL, and for BASIC , it is a numeric value, usually considered the line number program following the specific value or identifier of the LABEL indicated such a line number. It is possible to create a homemade looping construct using GOTO.

GOSUB This is a programming construct that will allow the program to reuse the same code when needed. This is good for creating functions which are programming constructs, and of which may include math functions and-or statements. This function is essentially called using the GOSUB command. A line number or label identifying that function is needed, and so the format for this is: GOSUB LABEL . When the code of the function is executed, to resume program flow back to the next statement immediately after the associated GOSUB program flow command, use the RETURN keyword. GOSUB essentially stands for and means "goto subroutine" or "goto this subroutine". In C programming, a function is a subroutine, and it is called as: function_name(arguments_to_send_to_the function); and when the function is completed, the return; statement is used to send the program flow and execution back to the next statement(s) following the associated or corresponding function call.

END : terminates the program execution and gives device control back to the interpreter and-or computer system

REM This is to allow programmer comments and-or reminders, and of which will not be executed, processed or "ran" by the computer. It is also a method to "comment off" a section of code so it is not ran or executed, possibly for program testing. REM means "remark". If multiple lines are used, then each line must begin with the REM keyword. The C launguge uses: /* My comment. / , and may consist of multiple lines of comments, and only one instance of: /* and */ , the coment delimiters are used for each comment.

HOW TO MAKE A SIMPLE HTML WEBPAGE AND-OR EBOOK

The main concept of this article is to make a simple webpage having text, links and images (picture, graphics) to view on your or someone else's device.

When we click on or type in an internet address in a web or internet browser, a webpage will be sent (ie., "downloaded") to our computer and then be displayed on our device (phone,computer, etc.). The main language and-or specific code of to make a webpage is the HTML language. HTML means Hyper-Text Markup Language, and it could be thought of as using special defined text words and notation, often called commands or (document) "tags" within or as part of a text document so as how to display that document, etc.

Your webpage or HTML format document can even be sent ("uploaded") to a website for other people to view, and technically, it will be sent to a (data, webpage, storage) server computer assigned to that website(s). An alternative to uploading your webpage and-or its .html code to a website via a FTP (a standardize File Transfer Protocol) program for digital data communication) is to simply email it to an internet technician (IT) or webmaster assigned to that website. Often a default, initial or starting webpage of a website must be explicitly named index.html due to the internet standard. This webpage is the default webpage for a website. From this main or index webpage, other webpages, if available, can then be selected via what is called (hyper-text or html) links to those pages. An internal link can even be used to go to another part of the current document, and it is much like a "bookmark" used to go to a certain chapter and-or location in a book.

There are computer programs and-or internet browsers that con convert a webpage into an ebook such as with the public document format having the .pdf filename extension. These types or formatted ebooks can be viewed on both computers and-or modern phones with .pdf viewer program which usually comes freely with the device, and can even be sent via email as an email attachment. Further in this article is a method to easily make a PDF ebook from a .html file.

You can make and-or edit a webpage using a plain text editor, that is, one that is not a word processor editor which places its own proprietary formatting or display commands within the saved text document, and which are therefore not compatible with the standardized HTML language of a webpage or even a plain text editor. For a PC, Intel computer. or DOS type of computer system, the EDIT.com program will work if it is available, and-or the Notepad.exe program should work if you do not have another text editor. These programs will make text files with the .txt filename extension and which then needs to be changed to .html so as to be seen or recognized as a webpage by the (offline) HTML viewer and-or (online) webpage viewer such as the internet browser. To edit your .html file, right click on its filename and select "edit" from the menu options. If you make edits to your .html source code file, you can mouse right-click on the corresponding webpage to refresh or reload it so see the new edits. You can also double left-click with the mouse to display, or right-click on it and select a menu option. If you are further interested in learning much about making .html webpages, then you can purchase a book and-or take a course about it.

To view a webpage, you can use and internet browser like Internet Explorer or Chrome. You may also use another program that is able to view html documents. If you have edited the html code of a webpage, select refresh so as to display it with the new intended edits.

To keep your ebook source html code and other data such as the photos to include in your book organized, first create a folder (ie., a directory) for your ebook. For a PC type of computer, you can right click your mouse, and select the menu to create a new folder. Using this method also eliminates using filename directory paths in the .html code, Photo's, etc., will be assumed to be in the current directory as that of the .html file being created and-or edited. Once the .pdf ebook is made, the images are already included in it and there does not need to be a folder with the same images on the reader's computer or phone.

BASIC HTML LANGUAGE SYNTAX

Tags in HTML source code are essentially commands or instructions, and sometimes containing additional data that is sometimes called the (command's) arguments to currently use with it. HTML tags are placed within special characters so that they will be recognized as apart (delimited/denoted) from the regular text that is displayed on the screen. The delimiters (identifiers or markers) for HTML tags or commands are the < and > symbols. Tags tell the webpage browser or html viewer what to do with the following text, etc.

A tag is surrounded by a left angle and right angle bracket.
Format of start-tag: <tagname>

Tags are often paired, with an end tag containing the slash character. This signals the end of the element, and to distinguish it from an opening tag.

Format of end-tag: </tagname>

The text between the start and end tags is relevant to the tagname being used.

Tag attributes or simply attributes about the element follow the start tag. An unknown tag or out-dated (dropped from the standard) tag will be ignored, however, any text within it will still be displayed. A web page must have the HTML tag. This informs/commands the browser that this is a start of a HTML document. All the other commands, text images, links, etc, if any, will come between the HTML "opening" tag and the "closing" tag.

To put a comment (unseen text comments a programmer can later review, and which are not displayed on the screen) into the HTML source code, use the following format for the comment tag which uses the exclamation point character:

```
<! my comment goes here  >
```

The required, minimum tags a browser expects are the html, head, and body tags. Here is a simple template and a few extra tags of a webpage to copy so as to quickly create a webpage and begin editing it for what you need:

```
<!----------------------------------------------------------------------------------------------------------------------------------------------->
<html>

  <head>
        <title>My HTML Page</title>
  </head>

  <body>

        <h1>HTML IS EASY</H1>
        <b></b>
        <p>  A line of text here.  </p>
        <b></b>
        <p>  A line of text here.  </p>

  </body>

</html>

<!------------------------------------------------------------------------------------------------------------------------------------------------->
```

The title tag is optional, but is recommended. The text within it will be displayed on the top of the webpage on the title bar. The main viewable part of the webpage will be placed within the body tags.

In the body, you can see a headings tag indicated by h1, and there are 6 possible headings, 1 through 6. h1 is the largest size. These headings correspond to font sizes commonly available for a system font. h1 indicates the first heading size.

 is the Break tag, and it will start the following text on a new line.
<p> is the Page-break tag, and it is like the break tag: , however, page break will also insert a blank line before any more text is displayed. Be sure to use the opening and closing pair for tags: <p></p>

To include a hyper-text link in your document, use the Anchor tag: <A>

A general format for this type of tag is:

```
<A HREF="filename_or website_address_to_go_to">text_to_display_as_the_link_to_press</A>
```

HREF means Hyper_Text Reference, and the quotes should be used if there are any spaces in the filename. An example filename would be "my webpage 2.html". Without any directory or folder path to the file, the file will be assumed to be in the current directory, perhaps a pre-made folder containing the .html or webpage source code and some related images. You can use "../filename" to go back to a file in the parent (this root or current) directory or "../../filename" to go back two parent or previous directories. Use "\filename" to go to the next sub directory that is contained in the current directory.

If you want to execute or run a program by pressing a link in your webpage, here is an example:

```
<A HREF="dos.bat">Go To DOS Screen Here</A>
```

Here is an example of placing an image directly into the webpage:

```
<IMG SRC="myimage.jpg">
```

Here is an example of setting the horizontal space on the left and right side of the image, and the maximum width and height of the displayed image. The iimage will not be trimmed, but rather "shrunk" to fit this size:

```
<IMG SRC="myimage.jpg" hspace=50 width="150" height="150">
```

Here is an example of linking to an image, and it wont be displayed until the user selects the link:

```
<A HREF="myimage.jpg">Here is a  picture.</A>
```

In place of "myimage.jpg" can be another web page or mail address. If the object (image, webpage, etc.) is on another server computer someplace on the internet, the full URL (Uniform Resource Locator, for the internet) address to that file must be specified. For this example, the file will be understood to be local to the computer that the webpage is on, and therefore, the full URL or complete address does not need to be specified. Here is an example of using a complete address:

```
<A HREF="https://mywebsite1.edu/index.htm">Click Here For My Website</A>
```

To easily or quickly display text without any formatting codes, use the <PRE> or <pre> , pre-formatted tag, and this is useful when selecting and copying text already (controlled, such as with spaces, tabs, new lines, etc) formatted so as to be easily placed into your webpage:

```
<PRE>
   .   .   .   .   .   .   .   .   .

      Welcome
            To
               Here!
   .  .  .  .  .  .  .  .  .  .  . . .

</PRE>
```

Below is a more complete example to copy and paste into a blank or new text file, and then rename it with the .html filename extension. For organizing things, put the .html source code or document and the image in a new folder. The user can mouse left-click on the html file so as to display it.

Setting Colors

The html code below also shows a method and example of how to set the background and text color using a combination of RGB colors, each having a value of 0 to 255, however this value is entered in a hexadecimal format which goes from 0h to FFh, where FFh = 255d. The format for the color values is:#RRGGBB , and use 0's if no value is desired and it yields the darkest shade of that color, and FF yields the brightest shade of that color. The colors will be mixed together and produce a single resulting color. The example below shows how to set a black background with white text and purple links.

Setting Links

Also shown below is a link to a text file that is on the local computer such as in the folder created for the html webpage, and the filename can even be set to another html webpage. You must ensure the filepath or directory is correct for the user. Also shown is a link to another website such as the Google.com website.

```
<!------------------------------------------------------------------------------------------------------------------------------------------------>
<html>

<head>
        <title>My HTML Webpage or Ebook page.</title>
</head>

<body bgcolor=#000000  text=#FFFFFF  link=#0000AA>

<pre><h1>    WELCOME</h1></pre>

<pre><h2>    Here is the image:</h2></pre>

<IMG SRC="image.jpg"  hspace=50  width="150"  height="150">
<pre>

    I hope you like the above image.
    This ebook took me years to write.

   <A HREF="mytext.txt">Get My Text File Here</A>
   <A HREF="https://www.Google.com">Press Here For The Google Website</A>

</pre>
```

```
</body>

</html>
<!--------------------------------------------------------------------------------------------------------------------------------------------------->
```

Here is a line of html code so as the user can click on it so as to download a file such as an ebook or other file that you have sent to and stored on the website . The directory that the file is in will be the default and-or current directory, or one set by the programmer of the html page:

```
<A HREF="myebookname.pdf">Get the ebook here by clicking the right mouse button on this link, and then select Download from the menu..</A>
```

Converting a .html webpage to a .pdf document and-or ebook

With the Chrome (R) internet, web or other html browsers and viewers, you can make an ebook by right clicking in a webpage, and choosing the Print command, and then selecting to rather save or effectively print it as or to a file having the public document format and with the .pdf filename extension. This document is effectively an ebook. Chrome is a computer program made by the Microsoft company, of who also make the Windows, PC operating system or program.

To share your work with others, you can email them your ebook as an email attachment when creating your email message. There is a maximum size limit to all email attachments, and it is often a total of about 25 Mb. Your ebook can also be shared to others using a file hosting website that offers downloads of it.

mEq Units And Example

It was mentioned previously in this book that typical blood had about 3.22 mg of sodium per 1 mill-liter = 1 mL = 1cc volume of blood and which was equal to about 140 mEq of sodium per liter.

More correctly: mEq is the milli-equivalent = **mm**Eq **m**illi-**m**ol equivalent of an amount of mass.

The mol unit of mass was previously mentioned in ths book. A mol is a (quantity or amount) unit , and usually for a specific amount of mass - either atomic mass units (amu) or whole atoms composed of atomic mass units. A mol is used in chemistry so as to know the number of amu or atoms of, or for a chemical reaction. Individual atoms cannot be individually seen by human vision, counted and-or weighed, but a quantity of a mol of them has a corresponding mass and weight depending on the specific element considered since each element has more or less amu (mass particles) or "weight" per atom that of another element.

The atomic "weight" (g / mol) of sodium is 23, which means 23g / 1 mol of atoms of sodium atoms. or= 23g / 1 mol-atoms of sodium. Technically, this is 23 grams of mass as displayed on a weight (force due to gravity) scale and converted to its corresponding mass value which is often more important than its weight on Earth and its associated gravity value.

1 mill-mol = (1/1000) mol = 0.001 mol

23g sodium / 1 mol-atoms = 1g / 0.04347826 mol of sodium atoms = 1 g / 43.39 mill-mol of sodium atoms =
= 1g / 43.39 m-mol of sodium

It was found by experiment that there is 3.22 mg of sodium (ie., sodium atoms) / mL of blood =
= 0.00322 g / mL = 3.22g / L : (1 mL = (11cc) , and this is slightly less than ocean water being: 3.5g sodium / 1L

$$\frac{\text{1 g sodium}}{\text{43.39 m-mol sodium atoms}} = \frac{\text{3.22 g sodium in a liter of blood}}{\text{N m-mol sodium atoms}}$$

, solving for N, we have:

N = 139.758 =~ 140 m-mol units of sodium atoms in a liter of blood , and since this amount or count corresponds to a mass of 3.22 grams of sodium atoms, we can express the amount of sodium in m-mol units:

3.22 grams of sodium = 3.22 grams of sodium atoms = 140 m-mol of sodium atoms

The amount of sodium per mL of blood is equal to 140 mEq of sodium per mL =
= 140m-mols sodium per mL

Important: In general, there is no direct conversion between mol atoms and grams unless it is for the same the element in question and where there is a known relationship of grams and mols. If a certain element has (n mol / g) or (n g / mol), then there is a direction conversion such as by using an equivalent fraction.

Also, when a substance is evenly distributed in a volume of a mixture, any volume of that mixture considered will have the same fraction of that substance, and their ratio is the same in each volume, and it can be said that the (mass or count) concentration of that substance in each volume of that mixture is the same.

1 unit A / 10 unit B is a 0.1 (unit A / unit B) concentration = a 10% concentration of unit A per unit B

1 apple / 10 fruits = 0.1 (apples / fruit) = 10% concentration of apples = 10% of all the fruits are apples

50 mL / 1 L = 50 mL / 1000 mL = 5 mL / 100 mL = 5 cc / 100 cc = 0.05 and unitless= strict numeric =
a 5% concentration per volume = a 5% concentration per unit of volume = 5% of the volume

RDA AND %DV NUTRITIONAL VALUE

RDA = Recommended Daily Allowance value of a nutritional substance (vitamin, mineral, etc.) per or in a day. Here, allowance means the amount of the substance (vitamin or mineral, etc.) being considered.

RDA is a recommended daily allowance value or the amount of a particular substance (vitamin or mineral, etc.), and it is usually expressed as and amount of grams (g) , milligrams (mg), or micro-grams (mmg or ug) in 1 serving of the particular food substance. A **serving** is a typical and-or average recommended amount of that particular food substance to have during a meal. In general, people with less mass and-or weight will usually need a serving size with a lower amount.

1 milligram = 1 mg = one-thousandth of a gram = (1/1000) gram = 0.001 g
1 microgram = 1 ug = 1mmg = one-millionth of a gram = (1/1,000,000) gram = 0.000,001 g

Ex. It is recommended that you intake by mouth 3 grams a day of a certain substance, then you need to find out how many grams of that substance are in each meal and-or supplement that you eat and add them up so as to know you ate 3 grams during the day. The gram value you ate may be less or more, but on average over time, perhaps a weak, it should be about 3 grams per day. If your average intake of that substance is less, you need to consider eating more of it to prevent potential health issues. If your average intake is more, you need to consider any health issues that may develop from having too much. Many vitamins and minerals can become toxic if eaten too much, and then any perceived benefit of taking more than the RDA is dangerous unless it was prescribed by a doctor and- or nutritionist. If your total intake (eating) of the substance was 3 grams, then you had 100% of the RDA value:

(3g total intake during the day) / 3 grams RDA = 1.0 = 100% of RDA

Since it may be unclear to a reader what a certain number of grams of a substance on the labeling is in terms of RDA, the %DV nutritional value was created, and which gives a better indication of how much of the RDA is in one (recommended) serving of that substance to have during your meal of that food or supplement.

%DV = **Percent Of Daily Value** in 1 serving of the food substance =
= Percent Of RDA per serving of that food or supplement.

This value also assumes an adult doing moderate activity (ie., requiring energy) consuming a recommended 2000 calorie a day total intake (food, meals, diet), then for example if you eat more of it, you then had more than 1 serving of it, and you may of had more than the RDA of some substances in that substance or food item. Sedentary people and-or people who are smaller and have a lower amount of mass will require less calories per day, but then again calories do not generally correspond to nutritional content and-or its absorption into the body.

Ex. If the RDA of a certain substance is 4 grams, and 1 serving of a food you are eating contains 0.25 grams = one-quarter of 1 gram. You goal for the entire day unless told otherwise by a doctor and-or nutritionalist is to intake a total of 100% DV. The nutritional labeling on that item would indicate something like:

substance .... 0.25 grams per 1 serving : old way , here the RDA is unknown

substance .... 6.25 %DV : new way, here using %DV

6.25 %DV = 6.5% of the RDA : hence RDA is known

How was this value calculated?

%DV = (amount of substance in 1 serving) / RDA =
0.25g / 4g = 0.0625 = 6.25%

An Example Of The Nutrition In A Can Of Food, And Considering Magnesium

It is of note that if the ingredients list for the food substance is on the labeling, they will listed by the highest amounts first, and to the least amount.

It is of note that the nutritional content within a substance or food is not always placed on its label. For example, the author has noticed this on a can of sweet peas, and decided to see how much magnesium it has because many of us are at risk of magnesium deficiency and its potential health issues. Foods high in magnesium are often leafy green vegetables, beans and nuts. Here is some data about that can of peas and its magnesium content:

The RDA of magnesium for an adult male is: 410 mg/day, and for an adult female, 315 mg/day. For pregnant women, they will require about 355 mg/day. The average of these two values is: 363 mg/day

The net weight (NET WT) of the can of sweet peas was 15 oz = 425g. 1 serving of it was listed as 1/2 cup = 125g, and the label did not have RDA for the day and-or the %DV of 1 serving listed for magnesium. The number of servings in the can was 3.5 The serving size was mentioned as having 60 calories / serving.

After some research on a government food and nutrition website, 100g of peas will have about 33mg = 0.033g of magnesium available. The better it is digested, the more can be absorbed into the body. Babies who can eat, and older people should consider peas that are prepared by lightly pressing and mashing them using the underside end of a fork so as to help digestion and nutrition absorption.

$$\frac{\text{0.033g of magnesium}}{\text{100g of peas}} = \frac{\text{33 mg of magnesium}}{\text{100g of peas}} = \frac{\text{0.33 mg of magnesium}}{\text{1g of peas}} \quad \text{or=} \quad \frac{\text{0.00033g of magnesium}}{\text{1g of peas}} =$$

$$\frac{\text{330 mcg of magnesium}}{\text{1 gram of peas}} \qquad \text{: mcg = micro-grams = mmg = ug}$$

The 425g can of peas will contain a total of:

(0.33 mg of magnesium / 1 gram of peas) (425g of peas / can of peas) = 140.25 mg / can of peas

If 1 serving of peas is 125g, we have this much magnesium in each serving:

(0.33 mg of magnesium / 1 gram of peas) (125g of peas / 1 serving) = 41.25 mg of magnesium / serving

The % of the substance's, here magnesium, RDA in 1 serving of the food is the %DV value.
The %DV or= (% of recommended DV=RDA) of 41.25mg / serving is:

$$\text{\%DV} = \frac{\text{(amount of magnesium per serving)}}{\text{RDA of magnesium}} = \frac{\text{41.25 mg of magnesium}}{\text{363 mg magnesium / day}} = 0.11363\underline{6} \text{ / day } =^{\sim} 11.36\%$$

Note that the actual amount of magnesium or other nutrients in peas or in any other food item may vary due to a specific farm's growing conditions such as how fertile the soil is with nutrients, soil pH, sunlight, temperature and water (such as rain and-or deliberate irrigation) received for that growing season. The amount of magnesium or some other nutrient may also depend on the specific variety of the plant. Perhaps the variety grown at one farm actually grows better in a different climate and-or other growing conditions. Cooking (warming or heating, increasing their temperature) foods generally reduces the nutritional content in them, particularly the amount of each specific vitamin. Minerals (ie., natural elements) are generally not depleted to a lesser amount due to cooking them since it takes much energy to destroy, alter, change, the natural elements.. Washing, canning, refrigeration, and cooking foods is a good method to reduce germs (bacteria, viruses, worms, etc.) and-or if you are unsure if there is a problem it is better to heat it hot to eliminate dangerous germs.

[This space for book edits.]

GAS VOLUME AND PRESSURE EXAMPLE CONSIDERING SCUBA DIVING

Scuba diving and compressed air gas.

Being able to breath air underwater allows work and exploration that would otherwise be difficult. Before a diver could move or swim freely underwater using a compressed air tank (ie., a container, filled with compressed air) strapped onto them, various other methods to breath underwater were previously used. One common method used an air pump at the surface which supplied the diver with a fresh air supply via a flexible tube connected to a helmet about their head or suit that they wore that was somewhat like an astronaut's space suit. They could view what was in the water through a clear piece of glass that was part of the helmet. These suits and breathing methods are sometimes still used today.

For recreational or hobby diving, it is recommended that the experienced diver go no more than a depth of 130 feet =~ 40 meters. For divers to legally go to a depth of even 60 feet requires a training certificate by a certified diving instructor. The deeper a diver goes and-or the more inexperienced, the more the dangers and potential problems. Swimmers and divers should have at least one other person with them for teamwork and safety purposes, and who should also in be in good health and have some knowledge and experience. A swimming pool with an instructor is a good place to first test much of your knowledge you have learned about scuba diving and its gear.

An empty, unpressurized container or gas "**tank**" can be used to hold a fluid or (elemental, molecular) gas substance. This substance, particularly with gasses which have much space between the atoms or molecules, can be highly pressurized so as to store a larger volume of it within that relatively small container and-or volume as a compressed and more dense [density = mass / volume] form. Gas tanks are commonly found in hospitals, such as for compressed, pure oxygen and air mixtures, diver tanks, such as to hold much air to breath in a small volume, propane tanks for heating and cooking, welding tanks for various gases to melt and weld metal pieces together, for air for people to breath on high altitude mountains, planes and balloons, and for astronauts to breath in space. Tanks can hold compressed carbon dioxide for making some drinks such as soda pop. For astronauts, they will need much oxygen when having many hours of space flight, and therefore, liquid oxygen and nitrogen which is highly concentrated and-or very dense (mass/volume) is rather used than compressed air. Here, the liquid oxygen will be allowed to evaporate when having less pressure upon it, and it will become part of a breathable air gas mixture. Gas filled tanks are usually cylindrical or spherical so as to help (evenly) distribute the internal pressure and-or forces on the entire internal surface rather than being concentrated on a flat surface and-or joints at the edge of that surface, and then risking some deformation and-or a dangerous rupture and-or breakage of the tank.

The reader needs to understand and recognize that there is sometimes two general volumes being mentioned in discussion of tanks and gases. One volume (Vt) is the maximum volume of an empty tank, and another volume is amount or volume (Vg) of a gas remaining (usually under pressure [ie., compressed together into a smaller space]) within a tank. A new, empty metal tank has a constant amount of volume when it is made at a factory, and this volume (Vt) is the amount of empty space within it such as cubic inches, cubic centimeters, cubic meters, etc. This tank volume can also be measured and-or rated as an amount of water, such as liters of water, that it can hold at standard temperature and pressure (STP). Vt is a constant value even if it is empty or having any amount of gas in it. Due to the motion of gas atoms and-or molecules of gas, a gas such as an amount or volume (Vg) of compressed air will naturally (high pressure moving toward lower pressure) fill a volume such as that equal to the empty tank volume. When an amount of gas is removed from this tank, the gas pressure within that tank will then be reduced, and the volume of that (compressed) gas in that tank is reduced in a proportional manner. This concept is expressed as Boyle's law: P1V1 = P2V2 = a constant for a specific tank and-or system. It needs to be noted that a volume of gas in a tank can also be put at a higher pressure by physically reducing the volume of the holding tank or container it its in, and such as by using a mechanical piston that applies force and-or pressure to the gas. Here, the density (m/V) of the gas will increase since the volume is decreased, but the actual mass and-or weight of the gas will remain the same value. A common compressed gas is air which can be put into (via an air compressor) and stored in pre-filled tanks so as to fill (ie., "inflate") tires with compressed air, or to power (air powered) tools, and for spray painting using the Venturi effect (ie., a change in pressure) to draw or move a gas or fluid by using pressure differences.

Some tanks are made out of steel, and some are made out of aluminum. Aluminum is lighter in weight and is not as strong as steel, unless it is made thicker. Every pressurized gas tank is, or should be, tested to withstand at least the internal maximum expected pressure, and in fact for increased safety due to it accidentally being filled to have a higher pressure above its maximum pressure rating, a certified as safe tank is checked at 1.5 times the pressure of the maximum expected value and rating of internal pressure. For example, a tank verified for 1000 psi should be tested and certified as being as (reasonably) safe to hold an internal air pressure of (1000psi)(1.5) = 1500 psi.

Even though the pressure in the tank of compressed gas will be very high, and the density of the air in that tank will very higher, the air gas mixture in a diving tank will still be a gas and is not dense enough to be a liquid.

If the internal pressure doubles, such as by compressing and halving (dividing by n-2) the volume of the internal air gas, the density of the air gas mixture will double. From: density = mass / volume. We see in this equation that density is inversely related to volume and directly related to the amount of mass. If the volume decreases by a certain factor (n) and the mass remains the same, then the density will increase by that same factor: (n) density = mass / (volume / n) = (n) (mass / volume). If the volume increases by a certain factor (n), and the mass remains the same, then the density will decrease by that same factor: (1/n) density = density / n = mass / ((n) volume) = (1/n) (mass / volume).

> Ex. If the density of air at 204 ATM = 204 times the standard atmospheric pressure of 1ATM = 14.7psi at sea level, what is the density of that air? At 14.7 psi, = 1 ATM, the density of air is: 0.00124 g / 1 cc. At a pressure of 204 times that, the density of air is 204 times higher: (0.00124 g / 1 cc) (204) =~ 0.2530 g/1cc. The density of liquid air is about 0.87 g / 1cm. = 870g / 1L,, and that value is about 702 times greater than that of oxygen gas at 1 ATM of pressure.

The density of liquid water is 1000 g / 1L = 1kg / 1L It is of note that a liquid such as water is already as dense as it can be, and it cannot generally be compressed much so as to have a higher density. Deep water will be at a very high pressure and yet at the same density as that near the surface.

A volume of 1L = 1000 cc = 1000 mL. A mass or amount of water that has a volume of 1cc = 1 cubic centimeter = 1 cm^3 is defined as a having a mass of 1 gram.

The gas and-or fluid volume of a container or tank can be measured by filling it with water and then measuring that amount of water volume (WV). If a volume measuring container is not available, the mass of the water can be measured on a common weight scale which displays the result as the weight's corresponding amount of mass. The volume of that amount of water can then be calculated from that weight., for example: 1 gram of water = 1g of mass and has 1cc = 1 mL of volume. 1000g of water = 1kg of mass and has 1000cc = 1000mL = 1L volume of water. 1 cubic foot of water = 1 ft^3 = 1728 in^3 of water weighs 62.4 lbs 1L is roughly the volume of a quart or quarter of a gallon, and will weigh about 2 lbs if the internal substance is water. Given a 128 fluid-ounce gallon, a quart will be (128 fl-oz / 4) = 32 fl-oz. 16 fl-oz = 1 pint of water will weigh 1.0425 pounds =~1 pound of force. A gallon of water weighs 8.34 lbs. 1 gallon = 3.78L and if filled with water substance, it will weigh 3.78kg. (8.34 lbs water / gal) / (3.78 L / gal) = (8.34 lbs water / gal)(1 gal / 3.78L) = 2.206349206 lbs water / L. From this we have: 1 lb water / 0.45323741 L = 16 weight oz water / 0.45323741 L , and from this we have: 1 weight oz water / 0.028327338 L volume = 1 weight oz water / 28.327338 mL = 1 weight oz water / 28.327338 cc

Some of the most used units and conversions for volume measurement are given at the end of this article.

When a diver is below the surface of the water, they will need air to breath. A common method is to use a diving cylinder filled with air. This gas cylinder or tank is commonly called a "**scuba tank**" in terms of breathing ,or more generically as a "gas tank" in terms of any other gas such as methane or propane. The word "SCUBA" is composed of the first letters for a **S**elf **C**ontained **U**nderwater **B**reathing **A**pparatus. The scuba tank is generally credited in 1943 to **Jacques Cousteau**, (1910-1997) from France, and **Emile Gagnan** (1900-1984) from France. The scuba tank is also sometimes called an "aqua-lung", as coined by Cousteau. Cousteau is also very famous for his very entertaining, knowledgeable and educational undersea color movies made for public television, and which also inspired many others later in various ways. His research vessel was a boat named Calypso, and of which singer-songwriter John Denver wrote and sang a popular song about. Both Cousteau and Denver are also known for their Earth conservation and awareness efforts. Though high pressure tanks for various other use were already invented before Cousteau's time, they could not yet be used for independent diving and swimming underwater (ie., under or beneath the surface of the water, hence within water, submerged) until they also invented the diving regulator (a form of a gas demand-valve, were the gas in the tank is only released when needed, hence only during inhaling to breath) which is a (air) gas pressure regulator so as to give the diver the right amount of oxygen at about that of normal air and breathing pressure of 14.7 psi when inhaling at a shallow or low surface depth which has a pressure of about 14.7 psi, and then to also easily permit the diver to exhale carbon-dioxide or "used up air gas". Consider for example, at about 100 feet deep, the total water pressure is about 58 psi, and therefore, the tank must at least have a minimum of 58 psi + 14.7 psi for an air pressure difference so as the diver can breath easily, and which then equals about 73 psi left in the tank. As indicated, the pressure regulator redcues the high pressure in the tank to a safe and typical breathing pressure of 14.7psi. Note that it is recommended that the diver have (1/3) of the volume and-or air pressure remaining or left in the tank for various diving safety and-or potential emergency purposes. For example, if a diver gets stuck in a fishing line, it will take some time for the diver to cut that line.

Scuba diving can be very dangerous in many ways, and you must first get knowledge, training and certified by a certified instructor. One such danger for a diver is getting stuck in fishing line or a fishing net, and it would then be good for them to carry a sharp knife and-or wire cutters - possibly connected to a lanyard in case they drop it. Other dangers are due to pressure changes descending to a depth and ascending to the surface too fast. A properly prescribed breathing gas mixture needs to be considered with the aid of other professional divers and regulations before a dive is made. DO NOT DIVE OR EVEN SWIM UNANOUNCED, so tell others of the locations and times. Permission to dive may be also necessary. Do not dive alone, so consider including a surface or boat assistant crew and possibly another diver(s). Do not dive in dangerous conditions (including various potentially dangerous sea life such as sharks) and-or locations with strong currents, etc. Avoid cave diving, for you are simply asking for trouble and may easilly find it, and it could be deadly. When diving with others, consider hand, light and audio communication signals. Buoys can be created so as to mark a divers location, and or communication to the surface vessel. Get a proper diving education, training and certification, otherwise, avoid scuba diving at all costs.

Having a flashlight, and something to drink after a dive is always a good idea. **Hypothermia** as mentioned in this book is another danger that anyone in cool air or water can get when their body temperature get lows and cannot function as much physically and mentally. This temperature is not even very low by any means, and is about 95°F = 35°C. Most water temperatures are less than this value by many degrees, and so the body will start to loose heat when it is in contact with this cool water constantly absorbing some of that heat energy. Divers can consider "underwater clothing" to help stay warm and it is commonly called a "wet suit". The heat from the Sun due to its internal **fusion** or joining of elements such as hydrogen into helium and releasing energy such as heat and light, and heat from the air can warm and increase the temperature of the water near the surface of a large and-or deep body of water, and in general, the water beneath this warmer surface layer will then be cooler. Warm water, being slightly less dense than cold water will rise and-or remain at the surface region. Water expands slightly as the temperature of it increases. Through the year, the average water temperature at about the 45° latitudes is about 57 °F due to having less direct sunlight than at the Equator latitudes (0°) where the surface temperature of the water can average about 30 °F degrees higher in temperature. At the poles or 90° latitude, the surface temperature of the water can average 30 °F lower in temperature.

Scuba tanks are relatively small in size and-or volume, and surely this will not hold much air.. The average adult male doing average or moderate things and not much active work and-or exercise will breath in (ie., inhale) about 0.5L of air at about 12 times and-or 12 breaths per minute. A scuba diver having the tank and various other gear with them, and casually swimming near the water surface will take about 20 breaths per minute:

(0.5L air / 1 breath) (12 breaths / 1 min.) = 6L air / minute. : casual person, relaxing, sedentary, sitting at home

For the scuba diver-swimmer:

(0.5L air / 1 breath) (20 breaths / 1 min.) = 10L air / minute. : casual diver or swimmer

(US fluid ounces of volume will be considered in these calculations)

Since 1 US cup is 8 US fl-oz, and 1L = 33.814 fl-oz, a 0.5L per breath is 16.907 US fl-oz = US fl-oz = 2.113375 US cups =~ 2 US cups =~ 16 US fl-oz of volume =~ 1 US pint. This volume can be verified by breathing out through a straw or tube into a water filled, inverted measuring cup below the water surface. 1L is about 4.22675 US cups = 33.814 US fl-oz of volume.

1L of volume = a cube with a length,height and width of ten cubic centimeters =
10 cm^3 = (10 cm)^3 = (10)^3 (1 cm)^3 = 1000 cm^3

Half a liter is: (1L)(0.5) = 0.5L = (1000 cm^3)(0.5) = (1000 cm^3 / 2) = 500 cm^3

1 cubic inch = 1 in^3 = 0.55411 fluid ounces (fl-oz) , and mathematically, dividing each side by 0.55411 , we have:
1 in^3 water = 1 cu. in of water weighs 0.036127 lbs = 0.578032 oz

1 floz = 1.8046958 in^3 =~ 1.8 in^3
Taking the cube root of 1.8 in^3, we have a cube shape with sides of: 1.217497288 in =~ 1.2 in
Since 1 in = 2.54 cm , 1.217497288 in = (1.217497288 in)(2.54 cm / 1 in) = 3.092443112 cm , and
cubing this or raising it to the third power such as for a volume of a cube , we have:

1 floz = 29.57366557 cm^3 =~ 29.57 cm^3 =~ 29.57 mL =~ 30 mL

1 in^3 = (2.54 cm)^3 = 16.387064 cm^3 =~ 16.4 cm^3 , and mathematically dividing each side by 16.387064 , we have:

1 cm^3 = 0.061023744 in^3 =~ 0.061 in^3

1L = 1000 cm^3 = (1 cm^3)(1000) = (0.061023744 in^3)(1000) = 61.023744 cu-in =~ 61.024 in^3 =~ 61 in^3

Half a liter is: 0.5L = 1000 cm^3 / 2 = 500 cm^3 = (1 cm^3)(500) = (0.061023744 in^3)(500) = 30.511872 in^3
Taking the cube root of 30.511872 in^3 , we have a cube shape with sides of: 3.124805219 in
Taking the cube root of 500 cm^3 , we have a cube shape with sides of: 7.93700526 cm

1 ft^3 = (12 in)^3 = 1728 in^3
(12 in)(2.54 cm / 1 in) = 30.48 cm and (30.48 cm)^3 = 28316.84659 cm^3 =~ 28317 cm^3
(28.317 cm^3)(1 L / 1000 cm^3) = 28.317 L
1 ft^3 = 28.317L , and mathematically, dividing each side by 28.317, we have:
1 ft^3 = 1 cubic-foot of water weights : (1728 cu-in / 1)(0.578032 oz / 1 cu-in) = 998.84 oz of weight = 62.4275 lbs
1L = 0.03531467 ft^3

A scuba tank can hold a larger amount of air if that air is forced into it, and the internal volume of the air will then increase and it will become more dense (amount of air mass / volume). The pressure within the tank will increase due to the many more air gas atoms and their kinetic energy and collision force within it. This pressure (force / area) will also cause the same amount of pressure (= force / area) upon the inside walls of the tank, and the air is then said to be pressurized or compressed.

Can the tank be filled with compressed pure oxygen so as to last longer? Humans and many other life forms should not breath pure oxygen for very long, perhaps only a few minutes at a time because it can start to damage the body if used too much. Humans need to breath what their body is used to, and that is air which is a mixture of gasses, mostly nitrogen (about 78% of air gas) and oxygen (about 21% of air gas). About 1% of commonly available air is argon, and 0.035% of air is carbon dioxide. The cells in our body will use the oxygen so as to create energy molecules called ATP, and during this process carbon dioxide is created which needs to be eliminated from the body. The body will remove the carbon dioxide via exhaling it when we breath out. About 4% of the oxygen we inhaled will be converted to carbon dioxide, hence (21% - 4%) = 17% of the exhaled air will be oxygen, and 4% to 5% will be carbon dioxide. Plant life will use carbon dioxide during photosynthesis so as to create energy for it, and it will create and release oxygen. A regular, non-scuba diver person in a close room will most likely re-breath some of this air which contains the oxygen already exhaled, and hence the fresh supply of oxygen does not need to be as much as thought. The problem with a closed room, especially a small room having a small volume, is that the carbon dioxide level will continue to rise to a dangerous level, and the oxygen level will diminish to a dangerous level unless fresh air is routinely put into the room somehow such as opening a window or vent, either of which may have a fan installed. With a common scuba diver system, the diver will exhale all the breathed gasses into the water and will create "air bubbles" that will not be re-breathed and-or reused.

For each breath a diver breathes from the tank, the volume of air in the tank will decrease by 0.5L, and its internal pressure will also decrease since there is now less compressed air within it..

Given a common aluminum scuba tank that is about 30lbs of weight =~13.6 kg of equivalent mass that can hold a volume of about 80 ft^3 =~ 2265L of (compressed, into a smaller volume) air. How many breaths of air can this tank it hold?

Since each breath of a **non-scuba diver** adult male is estimated at 0.5L , and at 12 breaths per minute::

$$\text{Non-scuba diver breaths} = \frac{2265\text{ L}}{\left(\frac{0.5\text{L}}{1\text{ breath}}\right)} = 4530 \text{ breaths total available in the tank of compressed air}$$

(12 breaths / minute) (0.5L / breath) = 6L per minute

And:

$$\text{In terms of time: } \frac{2265\text{ L}}{\left(\frac{6\text{ L}}{1\text{ min.}}\right)} = 377.5\text{ min} = 6\text{ hrs} + 17\text{ min.} + 30\text{s}$$

$$\text{Or: } \frac{4530\text{ breaths}}{\left(\frac{12\text{ breaths}}{1\text{ min.}}\right)} = 377.5\text{ min}$$

Also:

For a scuba diver at 20 breaths per minute:

$$\frac{2265\text{ L}}{\left(\frac{0.5\text{L}}{1\text{ breath}}\right)} = 4530 \text{ breaths total available in the tank of compressed air}$$

(20 breaths / minute) (0.5L / breath) = 10L per minute

$$\text{In terms of time: } \frac{2265\text{ L}}{\left(\frac{10\text{ L}}{1\text{ min.}}\right)} = 226.5\text{ min} = 3\text{ hrs} + 46\text{ min.} + 30\text{s}$$

$$\text{Or: } \frac{4530\text{ breaths}}{\left(\frac{20\text{ breaths}}{1\text{ min.}}\right)} = 226.5\text{ min}$$

A diver needs to consider the time it will take to descend (go to the desired depth) and ascend (go back up to the surface, and it will take longer for deeper dives. For safety purposes due to various potential problems, a diver should consider surfacing with (1/3) of the compressed air and-or total time still available from that tank. A diver may even carry a small volume reserve tank of compressed air. It is recommended that a diver only use (2/3) of the volume and-or internal pressure during the entire dive, and have (1/3) of the volume and-or internal pressure as a safety reserve should any problem arise.

(2/3) of a 2265 L tank leaves the diver with an effective and safe tank volume of compressed air of:

(2265 L)(2/3) = 1510L

$$\text{breaths} = \frac{1510\text{ L}}{\left(\frac{0.5\text{L}}{1\text{ breath}}\right)} = 3020 \text{ breaths for a scuba divers when considering safety}$$

If there are 20 breaths per minute, how long can a diver remain underwater and-or use that scuba tank mentioned? First, this calculation will consider a depth of 0ft, because deeper dives will take longer, and the greater water pressure at deeper depths will also give less tank time:

$$\frac{3020\text{ breaths}}{\left(\frac{20\text{ breaths}}{1\text{ min.}}\right)} = 151 \text{ minutes} = 2 \text{ hours} + 31 \text{ min.}$$

: a rough estimate, safe dive time in low depth near the surface. For deeper dives, this value will decrease at a high rate.

$$\text{OR:}\quad \frac{1510\text{ L}}{\left(\frac{10\text{L}}{1\text{ min}}\right)} = 151 \text{ minutes} = 2 \text{ hrs} + 31 \text{ minutes}$$

If a dive is deep, the diver will also need to have a decompression time(s) for any nitrogen gas buildup in the body to be reduced by exhaling it. The diver will need to stop ascending at certain depths and allow the body enough time to exhale and get rid of any dissolved nitrogen gas that has accumulated in the body. The diver needs to do this before the diver reaches the lower pressure regions where the dissolved nitrogen gas in the body can develop into dangerous and painful nitrogen bubbles after it expands (ex., consider a ("fizzy") soda being opened, and the dissolved ("fizzy") and pressurized carbon dioxide bubbles come out of solution, expanding and float to the surface) when a diver quickly arrives at less depths which have a less pressure upon the body. This health and dangerous condition is commonly known as "the bends" or "**decompression sickness**". The term "bends" is used because the person having it will bend over in pain. Another health risk a diver must be aware of is that if they hold their breath and swim upward to less pressurized depths, their lungs will expand since they have a higher pressure volume of air in them, and this can cause a rupture in the airways and blood vessels of the lungs causing air to get into the blood stream which can block its flow in small veins and arteries. This is known as an **air embolism**. An air embolism can cause a stroke. Swimming to the surface too fast can also cause a rupture in the airways of the lungs due to the pressure difference in the body and water, and then potentially cause an air embolism. At depths of about 100 ft =~ 33m or more, divers can develop **nitrogen narcosis** and get physically and mentally numb, slow and-or confused from some inhaled gases, such as air, at those pressures. Special mixtures of breathing gases have been developed to help prevent this condition in some divers and for many diving to deeper depths, and this prevents (compressed) nitrogen from the compressed air tank from getting (unwantedly) absorbed by the lungs and then placed into the blood which can then cause "the bends" if decompression is not performed correctly. According to experienced divers, scientists and health experts, that for a dive less than 30ft =~ 10m deep, a decompression stops and times, of which are somewhat equivalent to a slow assent to the surface, is not required, but can be considered. As mentioned in this book, the water pressure will double for every 33ft =~ 10m deeper. The water pressure at 100ft =~ 33m deep is about (14.7psi)(1 + 33m/10m) = (14.7psi)(4) = 58.8psi =~ 60psi. The 1 valued term is included since the pressure at the surface is already at 14.7 psi due to the air pressure upon it. **Unhealthy, inexperienced, unfit, and untrained swimmers and divers, particularly being obese and-or with circulation problems** will have a much greater chance of **pulmonary (ie., blood and circulation) edema** (fluid buildup, swelling at a some location(s) in the body, including in the lungs) which can happen from either too much fluid in the blood and-or a high volume of blood in the body and the pressure of the water depth. It can also happen from being immersed in cool or cold water which can cause vascular changes when the body tries to maintain its core and head temperature, and which includes reducing blood flow to the extremities, increasing blood flow to the core and head, and raising blood pressure. Pulmonary edema can even happen to mountain climbers at high altitude due to the less air pressure. In general, divers should also be accustomed to or be used to the water, be able to swim, and be in fair health.

A diver or swimmer will also swim or dive with a diving or swimming partner who can provide assistance and-or seek help if an emergency happens. Having transportation and communication methods will help this process. New divers should also consider diving and exploring depths no greater than what they can stand in, in the case of a problem, the results will not be as problematic. Divers with minimal experience should consider diving to less than 10ft deep. A diver should consider having visible marked anchored safety ropes and-or lights, flotation devices and methods in case there is problems.

A typical 11 L = 0.39 cu.ft internal volume tank can hold about 80 cu. ft = 2300 L of compressed external air, and the tank will then have an internal pressure of about 3000 psi. 80 ft^3 / 0.39 ft^3 = a (compression or reduction) factor of about 205. Note also that 3000 psi / 14.7 psi = about 204 =~ 205. We see that the ratio of volumes is equal to the (inverse or reverse) ratio of pressures. 14.7 psi is the typical air pressure at sea level, and it is also called the pressure of 1atmosphere (atm). 14.7 psi = 1 atm. 3000 psi is 204 times greater than 14.7 psi = 1 atm, and this is said as being a pressure of 204 atm (or= 204 ATA). The tank will have a one-way value to keep the compressed air within it as it is being filled, and a valve for the tank to be stored with compressed air. The cylinder tank must be capable of holding a high internal air or gas pressure, and without a crack, leak or explosion. The pressure regulator must also be able to safely handle this high pressure and deliver the needed amount of air and air pressure to the diver. To have enough air to breath for many minutes underwater will require a high volume of air, and if this air is compressed, it can be put into a relatively small tank. The air in this tank will have a high pressure and is not safe to breath, and so a pressure regulator is needed. Before the scuba tank was invented, a diver could breath fresh air flowing via a tube from the surface boat, and which is attached to the divers helmet.

Water is much more dense than air will cause friction and therefore a loss of energy when moving through. Due to this, it will take much more energy for any object or diver to move through water than to move through the much less dense air. Like a plane moving through the air, the less surface area it has into the direction of travel, the less drag or friction forces placed upon it, and the less energy needed to travel through it. When a diver uses more energy to move, more oxygen will be needed and used by the body.

$\frac{\text{density of water}}{\text{density of air}} = \frac{(1\text{ g} / 1\text{ cc})}{(0.00124\text{ g} / 1\text{ cc})} =$ water is about 806 times more dense than air at STP (Standard temperature (ie., room temperature) and pressure (14.7 psi).

The deeper a diver goes, the less air time is actually available as was calculated for the surface and-or no dive at all and just breathing the gas without swimming or diving. The less time available is due to that the deeper a diver goes, there is more water pressure upon the body and this will make it difficult to breath or inhale for the lungs to expand in volume. Our lungs create a lower air pressure region to draw or effectively force in air that is at a higher pressure (14.7psi normally =~ 15 psi). The air pressure regulator for the tank will automatically increase the tanks output air pressure available so as the diver can expand their lungs and breath more normally, including having enough pressure to place the exhaust or exhaled air into the pressurized water. Consider at 33ft =~ 10m deep, the water pressure is already equivalent to that of 2 atmospheres (or= 2 bar units) of pressure = 2 atm = 2 (14.7 psi) = 29.4 psi =~ 30psi. Each breath at this pressure will amount to twice the normal volume of air taken from the tank, here 2 (0.5L / breath) = 1L / breath, and this will significantly reduce its available internal air volume and air pressure at twice the rate as that near the surface. This will therefore significantly reduce the amount of dive time of air available at that depth. The deeper and longer the time at an increased depth and its increase in pressure upon the body, the more nitrogen gas from the air gas mixture is absorbed through the lungs, and therefore, a longer decompression time and-or slower ascent to the surface is needed to avoid the "bends" and other health problems. A (1/3) rule is that (1/3) of the air should be kept in the tank at surfacing time for possible emergencies, (2/3) of the air remaining can then be used to descend, stay at the bottom depth, and ascend.

Another way to calculate air usage in the tank during or over a time, and at a certain depth is to find out how much the pressure in the tank is reduced while doing normal activities at the test depth. The diving tank system and pressure regulator will need to have a pressure gauge that the diver can see and-or record notes with:

At shallow depths near or at the surface: (PSI used) / (time in minutes) = (PSI used) / min.

Ex. 20 psi used / min

At a depth of 10m = 33 ft where the water pressure is twice (2) as much = 2 ATM = , the PSI depleted in the tank will be twice as much per minute and the time of breathable air use is essentially half the surface amount of time if the diver remains at that depth for a high percentage of the total possible dive time as that at the surface.

Ex. 2 (20 psi used / min) = 40 psi used / min

Here is a generalization and equation to consider, however, dive tables give better values to adhere to:
Time available = (2/3) of total air time available at the surface / ATM of the deepest depth :considering (1/3) of total air time remaining for safety

Again, as a safety rule, (1/3) of the volume of gas in the tank should be kept as an emergency reserve, and a diver needs to surface before any of that (1/3) amount is used or breathed. Due to this, (1/3) of the starting internal pressure needs to be kept as the reserve gas, and therefore with these considerations, (1/3) of the total possible dive time should not be used, and the diver needs to reach the surface by (3/3 - 1/3) = (2/3) of that total possible dive or air time.

Ex. If a tank is filled with air gas having an internal pressure of 3000 psi, the reserve amount will be:
(1/3) 3000 psi = 1000 psi , this leaves: (3000 psi - 1000 psi) = 2000 psi for a safe dive.

$$\text{total safe dive time at 33ft deep} = 2\text{ ATM} = \frac{\text{Safe psi available in tank}}{\text{Psi usage rate}} \quad , \text{Ex: } \frac{2000\text{ psi}}{\left(\frac{40\text{ psi}}{1\text{ min}}\right)} = 50\text{ minutes}$$

Considering a decompression time of 20 minutes to the surface:
safe time to travel to and stay at depth = total safe dive time - decompression time needed to the surface ,

Ex. 50 min - 20 min = 25 min

When the psi or bar pressure of the compressed air gas in the scuba tank is at half of its starting value, then that scuba tank contains half the volume of initial volume of compressed air. Due to this half of its total breathing time available was already used or breathed by the diver and only half of the total breathing time remains, and this value includes the (1/3) of tanks initial amount or volume of compressed air for safety. (1/3) amount of the initial volume also leaves (1/3) of the initial internal pressure, and (1/3) of the total breathing time available from the full tank.

Considering the decompression time needed

Generally, dives less than 30 feet deep, a short decompression time is optional. A diver can remain at some depths greater than 30 feet and not require a decompression time if the time at that depth is less than the time recommendation which is commonly known as the NDL = No Decompression (time, maximum value) Limit. The deeper a diver goes, the less time available at the bottom before decompression is needed. The deeper and longer at a depth greater than 30 feet,, the longer the decompression time will be. You will need to calculate and-or have a "look-up" (to find) chart and-or reference table available to find out a suggested and safe decompression time both for the depth you have gone and the amount of time you remained at that depth since both of these factors will determine the level of nitrogen gas absorption into your body. NDL is sometimes called the No-Stops Time (ie., no decompression ascent stops and times required).

A diver making repeated dives to the same depth will needs to also to consider a break time between each dive for health and safety checks, and to help eliminate any possible trace of nitrogen gas still in the body, and the deeper a diver goes, the longer the decompression time needed, and the longer the diving break time will be. Even when a diver is surfacing to a lesser depth but still greater than 30ft =~ 10m deep, there is still a possibility that more nitrogen gas can get into the body, and that is why decompression is a relatively, slow process.

Here are some rough estimated considerations for the maximum time limit values at depth till when a decompression time is required, and this will make calculations easier, and greatly improve the overall safety of the diver. The compressed air tank should have enough air to consider the descent time, the ascent time which includes any decompression time, the time at the desired depth, and (1/3) the maximum amount of air to be remain in the tank when the diver surfaces as reserve air for any emergency during the dive.

For a depth of < 60 ft, the maximum, no decompression time limit will double per 10 feet less:

NDL = (60 minutes) 2 ((60 ft - depth ft) / 10)

For a depth of 60 feet, the (maximum), no decompression required time limit (NDL) at depth is:.

NDL = 60 minutes : for lesser depths, the NDL will be at least 60 minutes as an easy reference

For a depth > 60 ft , the maximum, no decompression time limit will decrease by 1 minute per 1 foot deeper:

NDL = 60 minutes - 1 min (depth ft - 60 ft)

For a depth > 90 ft , the NDL time is 30 minutes and will decrease by 0.5 minute per 1 foot deeper:

NDL = 30 minutes - 0.5 min (depth ft - 90 ft)

At a depth of 150ft or more, the NDL time is about 5 minutes or less,, and the diver needs to consider decompression time. A general rule is that for any depth of dive, that when the diver ascends to every 15 feet less in depth which is a decrease in 1 ATM of pressure, that they take a stop in their ascent for at least 3 minutes and up to 5 minutes. This also needs to be considered if the dive time was longer than the NDL time, and can also be considered even if the dive time at depth was shorter than the NDL time

At about the last 15 feet of depth or less to ascend, a diver should do decompression stops every 5 feet due to that the ratio of the (ATM) pressure changes for every 33 feet deep is actually increasing as the diver ascends. In short, the pressure changes are increasing more rapidly than one might expect, and these increased pressure difference can cause the bends and therefore, the decompression process should go slower or longer in time at these less depths.

A diver not descend or ascend to rapidly due to the larger pressure changes upon the body. For health and safety, the body will need some time to adjust to pressure changes, and a slower descent or ascent will provide that. A typical and safe maximum descent or ascent distance rate is about 30 feet of change in depth / 1 minute. A dive should be planned, and can become a common routine that is easier to follow by an experienced diver.

How long in time will a diver need to decompress?

Since nitrogen in the body is both determined by the depth of the dive (ie., more pressure forcing nitrogen it into the divers lungs and then into their body) and time at that depth, both of these factors will increase the required decompression time needed for the body to "de-nitrogenize" or expel any remaining nitrogen via exhalation.

During this decompression time, the diver will be ascending to water depths at lower pressures so as to help expel the nitrogen and to help lessen any more nitrogen from being absorbed. When the diver is at more shallow depth and lower pressure, the compressed air which the diver breathes in from the pressure regulator will be set to a lower pressure, and this will also help prevent nitrogen absorption.

A divers ascent to the surface needs to be relatively slow due to that if the water pressure changes too rapidly such as during a fast ascent, the nitrogen in the body will have an increased chance of turning into painful bubbles in the body before it had a chance to be expelled or "gas out" in small particle size (ie., atoms) amounts through the lungs and out of the body when the diver exhales.

A typical rule of thumb for decompression time is that for every 15 ft deeper, that the total required decompression time will increase by 6 minutes:

Total Decompression Time = (Time the diver was at depth greater than the NDL time) + 6 minutes $\left(\frac{\text{Depth ft.}}{15\text{ ft.}}\right)$

Note, at 150 ft = 45m and greater depths, NDL (No Decompression [Needed, Maximum Time] Limit) is about 0 minutes.

The diver should stop for every 15 feet of ascent, and wait or stop for at least 6 minutes before continuing the decompression process. This activity is commonly called decompression stops.

The "120 Rule" is rule of thumb that for depths between 60 feet and 100 feet deep, that the sum of the NDL and depth is a unit-less value of 120. This was made from divers observations of the charts and data. From this, we mathematically have:

NDL = 120 - (depth in feet) : NDL will have units of minutes

Even if a diver has not exceeded the NDL time value at a given depth, they should still consider the decompression process.

Due to the possibility of a residual amount of nitrogen still being in the diver after surfacing, it is recommended that the diver wait at least a minimum amount time before diving again. This value of time, much like decompression time, depends on the depth of the dive and the time spent there. If unsure about this amount of no dive time, at least wait a full day before diving again.

Creating a condensed (ie., made denser) gas having a high pressure

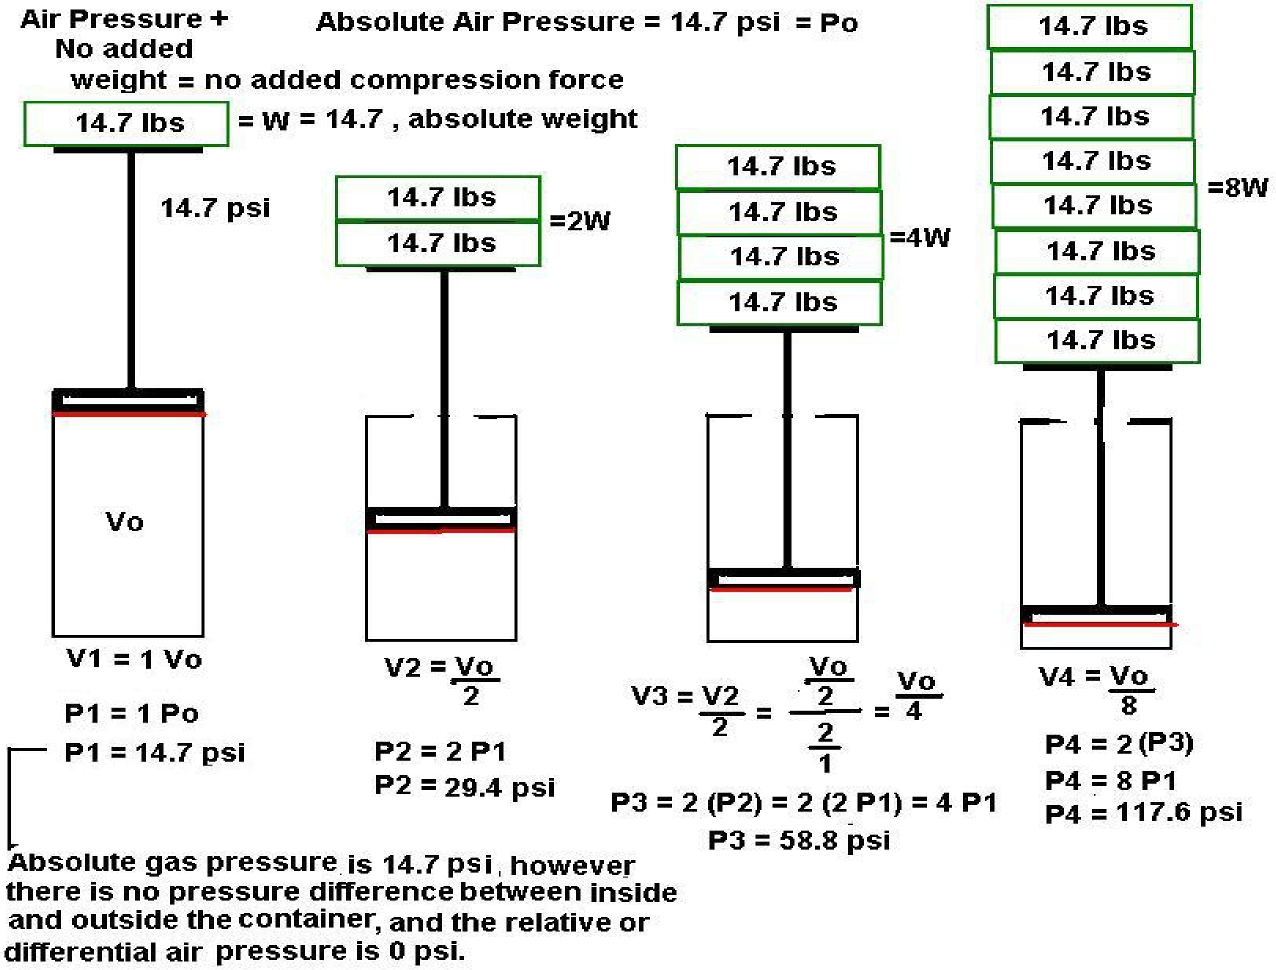
How can an air pressure machine make a very high pressure? First, it has to have a reasonably high force, such as being powered by an electric motor or a persons arms such as when using a tire pump for a bicycle or car.. Through a one-way valve mechanism that will only lets external air come in through it, an air compressor will gather external air and compress it using a force, therefore pressurizing that amount of air. When a tank is being filled with a compressed gas at a certain rising pressure, to get any more gas into the tank will require at least a slightly higher pressure to force it into the tank.

Ex. If a force is 30 lbs, and is applied to an area of 1 in^2:

P = F / A = 30 lbs / 1 in^2

If the output area is reduced to a small fraction of the initial area, say one-hundredth of the given area = 1 A / 100 = 0.01A such as a small opening or pinhole for all the internal pressure to essentially be applied to, the pressure at that hole will be very high, and in fact, it will be 100 times higher: P = F / A = P = 30 lbs / (0.01 in^2) = (100)(30) = 3000 psi. These are equivalent fractions.

Pressure and volume illustration in a tank [FIG 307]



In the above image we see that when the applied weight (W) or force is doubled or increased by a factor of (n), that the volume is decreased by that same factor of (n). We also see in the above image that the product of pressure and volume is a constant value for a particular system. Expressing these physical relationships numerically:

$$P1\ V1 \;=\; \frac{(n)}{(n)}\ \frac{P1}{V1} \;=\; (n)\ P1\ \frac{V1}{(n)} \;=\; P2\ V2 \;=\; P3\ V3 \;=\; P4\ V4 \qquad : n = \text{ratio of weights or applied force}$$

Letting subscripts (o) indicate a given, original or starting value, and (e) indicate an ending or resultant values, we have a general formula for the pressure and volume of a gas in a tank:

$$Pe\ Ve \;=\; Po\ Vo \quad , \quad \text{mathematically:} \quad \frac{Pe}{Po} = \frac{Vo}{Ve}$$

We see in above equation that the ratio of pressures is equal to the reverse (or inverse) ratio of the volumes, and this is so because of the inverse relationship between pressure and volume. Mathematically, for example:

$$Pe \;=\; Po\ \frac{Vo}{Ve} \qquad \text{and} \qquad Ve \;=\; Vo\ \frac{Po}{Pe}$$

When pressure, due to a force, is applied to a given volume of air, that air will get compressed into a smaller volume, and since density = mass / volume , the density will increase since it is inversely related to volume.

Notice in the above figure, that to hold the amount of weight in stable or equilibrium position without moving upward or downward, that the pressure applied to the plunger rod, say having a cross sectional area of 1 square inch, is equivalent to the weight per square inch. Also note that no matter what the pressure is within the container, to make the volume, for example half in value, that the extra weight (ie., a force due to gravity pulling on its mass) to apply will be twice (2) of what is already applied. Likewise,to make the pressure, for example double in value, that the weight will need to be doubled.

> From density = (mass / volume) = d = m / V , m = d V and V = m / d
>
> We see that density and volume are inversely related. When the volume of a gas decreases, its density increases and vice-versa.

As the air gets depleted in a divers air tank, it will have less mass and therefore, less density in that compressed air tank: density = (mass / container volume), and the tank will become more buoyant (ie., want to float to the surface more).

In a fire piston device, a volume of air is highly compressed so as increase in density, kinetic and thermal energy, and pressure so as to combust and ignite an ember so as to make a fire. Given Pe Ve is a constant, if the volume decreases during this compression process, the pressure is greatly increased. Likewise, the temperature of the air will be increased due to the energy applied and the increased kinetic and thermal energy of the air gas atoms. During combustion, the internal pressure will actually increase further.

Today with poles, ropes or "lines", RC (remote control) boats and submersibles, and with relatively inexpensive and "water proof" and "pressure proof" underwater cameras, a non-diver (or not) can experience what is beneath the surface of the water relatively inexpensively, easily and safely.

A Buoyancy Issue For A Scuba Diver

As a diver descends to greater depths and water pressure, any pockets of air will get compressed and have a smaller volume and the diver will then have a lesser or "negative" buoyant force and this could cause the diver to descend at an increasing rate unless corrective action is taken. The descending diver should add some air to their BCD (Buoyancy Control Device) so as to increase its volume and resulting buoyancy. In a reverse manner, as the diver ascends to water having less water pressure, any pockets of air will expand in volume and cause more or a "positive" buoyancy force and the diver will ascend at an increasing rate unless corrective action is taken. The ascending diver should release some air from their BCD (Buoyancy Control Device) so as to decrease its volume and resulting buoyancy. As a diver ascends, if they hold air of a higher pressure in their lungs it will expand in the lower water pressure and can damage their lungs, hence the diver needs to keep breathing regularly and-or rise slow enough so as to give the body and-its gasses time to adjust to the local pressure. **According to the pressure and volume relationship and formula, if the pressure of a gas increases by a factor of (n), its volume decreases by that same factor of (n).** Note also that the density (d = p = mass per volume) of that gas will also increase by the same factor of (n).

Does the buoyancy force change with depth?

This question is also related to the above topic of: A buoyancy issue for a scuba diver. The simple answer to this question is that according to the definition of buoyancy which does not have a depth variable, it does not, and only depends on the difference in pressure between the upper and lower heights of the object. No matter what depth, even at great depths where the water pressure is high, this difference is still the same value. In this sense, the buoyant force does not change with depth. If the object is compressible, as opposed to in-compressible (ie., can not be compressed easily and-or much), then the buoyant force can change. For example, at greater depths, where the water pressure increases, this high pressure will try to compress an object inward to itself, therefore it is trying to reducing its volume and increasing its density. If the object, such as a balloon or bubble, compresses it will have less volume and therefore it displaces less water (ie., volume of water). The balloon will then have less buoyant force, and this will be an issue if the balloon is being used to lift an object to the surface of the water. To overcome this problem, the balloon can be inflated more so as to have the original or intended volume of it, and which is needed for the desired buoyant force.

Some of the commonly used units and conversions for volume measurements

Units of volume and conversion have been previously discussed in this book, and here is perhaps some more to consider for this discussion. The general discussion about scuba diving will continue after this table.

Water has a known mass of 1Kg / 1L = 1000g / 1000 cc. 1Kg = 2.20462 lbs, therefore, after dividing both sides by 2.20462 , we find: 1 lb = 0.453592909 kg =~ 454 oz

1 cu. ft = (12 in)^3 = (12 in)(12 in)(12 in) = 1728 in^3 and 1 in^3 = 0.000578703 ft^3
1 cu. ft = 1 ft^3 = 28.3168 Liters , therefore, after dividing both sides by 28.3168 , we find:
1L = 0.0353147 ft^3 : this has a cube root or side value of: (0.328084092 ft). Hence (0.328084092 ft)^3 = 0.0353147 ft^3

0.328084092 ft =~ 3.937 in =~ 4 in , hence a volume of 1L in the shape of a cube with each side being 4 in =~ 10cm, hence a volume of 1L is a container with a volume of: (4 in)^3 = 4^3 in^3 =~ 61.0237 in^3 (= actual, using 3.937 in) =~ 64 in^3 = (10 cm)^3 = 10^3 cm^3 = 1000 cm^3 . 1cm^3 = 1 cubic centimeter = 1 cu cm = 1 mL of volume

1 cu. ft = 28.316846592 L = 28316.85 cc = 28316.85 mL
1 cu. ft = (12 in)(12 in)(12 in) = 1728 in^3 , and since 1 in = 2.54 cm , 12 in = 12 (1 in) = 12 (2.54cm) = 30.48 cm :
1 cu. ft = (30.48 cm)(30.48 cm)(30.48 cm) = (30.48 cm)^3 = 30.48^3 cm^3 =~ 28316.8 cc
1 cu. ft = 1728 in^3 = 28316.8 cm^3 , dividing each side by 1728, we have:
1 in^3 =~ 16.387064 cc

1g of water has a volume of 1cc. Since density = mass / volume:
The density of water is therefore: 1g / 1 cc
1000 cc = 1000 mL = 1L
1000 g of water corresponds to a volume of 1000 cc of water = 1000 mL of water = 1L of water

1L = 1 liter of volume = (10cm)^3 = 10 cm^3 = 1000 cm^3 = 1000 cc = 1000 mL
Since 1 in = 2.54 cm , 1 cm = 0.393700787 in. 10 cm = 3.93700787 in =~ 4 in
1 L = (10 cm)^3 = (3.93700787 in)^3 = 61.02374409 in^3

1 oz = 1 weight ounce = 1 w-oz = (1/16) pound = 0.0625 lb = 28.3495231 grams and 28.3495231 cc if water
16 oz = 1 pound = 1 lb

The US Customary units are (roughly) based on the (older) British units used in the United States (previously "New England" a British territory) before it became an independent country in 1776. Most countries now use the System International SI) which is commonly called the Metric System standard units of measurement.

1 US fluid ounce = 1 fl-oz = a unit for volume measurement

1 US gallon is based not on water weight, but of wine weight which is not as heavy as water . It has a volume of 231 in^3 = 128 fl-oz, and weighs 8.34 lbs = 3.78 kg if water. Note that (128 US fl-oz/ 160 Imperial fl-oz) = 0.8, and that (160 fl-oz)(0.8) = 128 oz.

The cube root of 231 in^3 = 6.13579244 in , such as the side of a cube having a volume of 231 in^3. 6.13579244 in = (6.12579244 in / 1)(1 ft / 12 in) = 0.511316036 ft on the side of a cube having a volume of 231 in^3. (0.511316036 ft)^3 = 0.133680555 ft^3.

231 in^3 / 128 fl-oz = 1.8046875 in^3 / 1 fl-oz

128 fl-oz / 231 in^3 = 0.554112554 fl-oz / 1 in^3

1 US gallon = 4 quarts has a volume of 3.78L = roughly 4L = roughly 4 quarts
1L = 0.2645503 US gal =~ (1/4L = 0.25L)

1 Imperial or British gallon is based on 10 lbs of water = 160 oz of weight , and has a volume of 4.54609L = 277.42 in^3
= 0.16054366 ft^3 , Canadians also use Imperial gallons, but also use metric liters in this modern age.

1 US gallon = 0.83263955 Imperial gallons , 1 Imperial gallon = 1.2 US gallons

1 US fluid ounce = 1/128 of a US fluid Gallon = 0.0078125 gallons , hence 1 US gallon = 128 US fl-oz
1 quart = 1/4 gallon = 128 fl-oz / 4 = 32 fl-oz = 2 pints = 4 cups
1 pint = 1/8 gallon = 128 fl-oz / 8 = 16 fl-oz
1 cup = 1/16 gallon = 128 fl-oz / 16 = 8 fl-oz

1 L = 4.22675 US cups = 33.814 US fl-oz **=~** 4 US cups = 32 US fl-oz
1 cup = 8 US fl-oz = 0.2365884 L =~ 237 mL =~ 237 cc **=~** (1/4 L = 0.250 L) , 4 cups = 0.946353 **=~** 1 L =~ 95% of a liter

1 US fl-oz = 0.96079599 fl oz in US Customary units
1 US fl-oz = 29.573529563 mL in International System (SI, metric) units =~ 30mL = 30 cc
1 US fl-oz = 0.02957353 L
1 US fl-oz = 29.57353 mL of water will therefore weigh 29.57353 grams =~ 30 grams = a common, "food ounce"
1 US fl-oz of volume will weigh as 1.04 oz of (dry, mass) weight , therefore mathematically by dividing each side by 1.04, we find that:
1 US oz = 1 weight ounce = 1 woz = 1 wt-oz of water and it will have a volume of 0.961538461 US fl-oz =~ 1 US fl-oz

1 US fl-oz = 1.040843 fl-oz in British Imperial units

1 British Imperial fl-oz = 28.4130625 mL in International System (metric) units
1 British Imperial fl-oz = 0.9607599 in US customary units

For British Imperial units , 1 fl-oz is defined as 1/20 of an imperial pint at 20 oz, It is also defined as 1/160 of an imperial gallon that is defined as an amount of water that weighs 10 lbs. 10 lbs / 160 oz = 0.0625 lb / oz = (1/16) lb / 1 oz = = 16 oz / 1lb in equivalent fraction form.

1 US teaspoon of volume = 1/6 a US fluid ounce = 0.16667 US fl-oz = 4.928921594 mL **=~ 5 mL**

Since 1mL = 1 cm^3 = 1 cc, multiplying both sides by 5, we have:
5 mL = 5 cm^3 = 5 cc

5 cm^3 = (1.71 cm)^3 = 5 mL = 5cc

1 US teaspoon of volume = 5 mL = 5 cm^3 = (1.71 cm)^3 = (0.67322 in)^3 = 0.305118719 in^3

Since 1cc = 1 cm^3 = 10mL, 5mL will fill or occupy half the volume of 1 cm^3. 1 cm^3 / 2 = 0.5 cm^3
Since 1 in = 2.54 cm , dividing both sides by 2.54, we get:
1 cm = 0.393700787 in , raising each side to the third power:
(1 cm)^3 = (0.393700787 in)^3
1 cm^3 = 0.061023744 in^3 = 1 mL = 1cc = 0.001L
1L = 1000 mL = 1000 cm^3 = 1000 cc 61.023744 in^3
1 cc = 1 cm^3 = 0.061023744 in^3 , mathematically:
1 in^3 = 16.38706403 cc or 16.38706403 mL = 0.01638706403 L

Since 1 mL = 0.061023743 in^3 = 1cc = 1 cm^3 , multiplying both sides by 5, we have:
5 mL = 0.305118719 in^3 = (0.6732$\underline{2}$ in)^3 = (1.71 cm)^3
10 mL = 0.610237439 in^3

1 cm = 10mm = 0.393700787 in
(1 cm)^3 = 1 mL = (10mm)^3 = 1000 mm^3 = 0.061023744 in^3 , mathematically:
1 mm^3 = 0.000061023 in^3 , mathematically :
1 in^3 =~ 16387.$\underline{1}$ mm^3 : mm^3 = cubic millimeters

1 US tablespoon = 3 US teaspoons =~ 15 mL commonly

1 US gallon = 128 US fl-oz = 3.78541178 L =~ 3785 ml = 3785 cc, , Mathematically:
1 US fl-oz = 0.029573529 L , hence mathematically:
1L = 33.81402274 US fl-oz = 1000 cc , hence mathematically:
1 US fl-oz = 29.57352953 cc = 29.57352953 mL = 0.02957352953L
If the fluid substance is water: 1 US fl-oz will have and weigh as a mass of 29.57352953 g =~ 30g

For finding volume of a container using water as the mass substance which has a simple relationship between mass and volume in the metric system:

1 gram of water = 1g of mass and has 1cc = 1 mL of volume.
1000g of water = 1kg of mass and has 1000cc = 1000mL = 1L volume of water.
1 cubic foot , volume of water = 1 ft^3 = 1728 in^3 and weighs 62.4 lbs
1L is roughly the volume of a quart or quarter of a gallon, and will weigh about 2 lbs if the internal substance is water.

Given a 128 fluid-ounce US gallon, a quart = (1/4) gallon = 2pints will have a fluid volume of (128 fl-oz / 4) = 32 fl-oz.
16 fl-oz = 1 pint of water will weigh 1.0425 pounds =~1 pound of force.
1 cup of water = 8 fl-oz of water will weigh about 0.5 lbs

A US gallon volume of water weighs 8.34 lbs.
1 US gallon = 128 US fl. oz = 3.78L , and if filled with **water** substance,
it will weigh 3.78kg since 1L water = 1 kg of water

$$\frac{\text{1 gallon water}}{\text{3.78 kg}} = \frac{\text{0.264550264 gal}}{\text{1 kg}} = \frac{\text{(0.264550264 gal)(128 floz/gal)}}{\text{1 kg}} = \frac{\text{33.86243386 floz}}{\text{1 kg}} = \frac{\text{1 floz water}}{\text{0.02953125 kg}}$$

If the substance is water: 1 floz water / 0.2953125 kg corresponds to a volume of: 1 floz water / 29.53125 cc =
1 floz water which corresponds to a mass of: 1 floz water / 29.53125 g , therefore:
1g mass of water corresponds 0.33862433 floz = 1cc = 1mL

(8.34 lbs water / gal) / (3.78 L / gal) = (8.34 lbs water / gal) (1 gal r / 3.78L) =
= 2.2063$\underline{5}$ lbs water / L = 1 lb water / 0.45323741 L = 1 lb water / 453.23741 cc = 1 lb water / 453.23741 mL
Since 1cc volume = 1mL volume , and 1 cc water = 1 mL water:

1 lb water =~ 453.2$\underline{4}$ cc = 453.2$\underline{4}$ mL = 453.2$\underline{4}$g

Be sure to note:

1 ounce of weight of any substance = (1/16 1lb) = 0.0625 lb = 28.3495231 grams of mass = 0.0283495231 kg
From this we have mathematically:

1g = 0.03527396$\underline{2}$ weight oz
If the substance is water: 1cc water = 1g water = 0.03527396$\underline{1}$ weight oz of water , and this is the amount of weight oz of water and not floz of water even though 1g corresponds to exactly 1cc of water.

The corresponding amount of US fluid ounces (floz or fl-oz) is close to the shown value, and is actually:

1 cc of volume = 1 cm^3 = 1 mL 0.0338140227 US fl. oz. and mathematically from this:
1 L of volume = 1000 cc = 1000 mL = (1 mL) (1000) = (0.0338140277 fl.oz)(1000) = 33.8140277 fl.oz =~ 1 US quart (32 fl.oz)

1 US fl.oz = 29.573533018 cc and if the substance in the volume is water, it will weigh:
1 US fl.oz of water weighs **29.573533018 grams = 0.029573533018 kg**
and will have a volume of **29.573533018 cc = 0.029573533018 L**

The result shows that a 1 US floz of water weighs slightly more than 1 ounce of weight:
1 US fl-oz weighs 1.04317568 oz = 29.573533018 grams

The above issue of the 1 US fl. oz being (slightly) greater than 1 weight ounce is due to how the US defined their fl.oz.

A note about calculating mass, density and volume

First: Force = (mass)(acceleration) = ma

Weight = (force due to gravity) = (mass)(gravitational acceleration) : gravitational acceleration = g = 9.81 m/s^2, g = 32.2 ft/s^2

We see that the mass of an object can be calculated from the corresponding and proportional weight of that object:

mass = (weight / a) : here for weights on Earth, a = g and mass = weight / g

Density or density of matter can be thought of as the concentration of matter such as the amount of matter or substance n a unit of volume. Since some substances salt grans, sand or foam have much space between particles which have no relevant matter in it and will cause an incorrect calculation of density, it is better to first weigh the amount of matter so as to find its density by calculation.

density = (mass / volume) : d = m / v , m = d v , v = m / d : m = mass in units of grams
v = volume in units of cc or mL
density = (mass / volume) = (weight / g) / volume
d = density in units of grams / cc or g / mL

weight = the force of an object in gravity = (mass)(a) = d v a = d v g = (density)(volume)(acceleration)

1 gram of water is defined as the amount of water in a volume of 1 cc , and any mass or object that has the same amount of weight as 1 gram of water is then also said to have a mass of the same value of 1 gram.

The density of water is defined as:
density of water = (mass / volume) = (1g / 1 cc)

1 cc of lead or gold for example, will weigh more than the reference mass of 1g of water when given the same size and-or volume such as 1cc. These elements are then said as being denser than water. Since they are denser than water, an equivalent volume (V) of it will weight more than that of the same volume water. To have 1 gram of these elements corresponds to having a less volume tan 1cc.

V = m / d , if (d) increases , (v) decreases

Ex. If a certain element is listed as having a density of (5g / 1cc) and weighs 100 g, how many cc of volume corresponds to that amount of mass? We can first set up an equivalent (and proportional) fraction and problem to solve:

$\frac{5g}{1\ cc} = \frac{100g}{x\ cc}$ solving for x, we have: $x\ cc = (1\ cc)\frac{(100g)}{(5\ g)} = (1\ cc)(20) = 20cc$

If you had a volume of 7cc of this element, how much will it weigh?

weight = d v a = (density)(volume)(acceleration) = (5g/1cc)(7cc)(9.8 m/s^2) = (0.005 kg/1cc)(0.07m)(9.8 m/s^2) =
= 0.00343 Newtons

mass = d v = (5g/1cc)(7cc) = 35g : finding total mass by knowing the density and volume

The volume of an object can be found by submerging it in water and measuring the increase in volume. The volume of the object or mass is
Vm = (ending volume of water) - (starting volume of water) =
Vm = difference or change in water volumes

1N = 101.9716212978 =~ 100 equivalent grams-force (gf) = (grams)(a) in Earths gravity of 9.8 m/s^2
This would be the force that 100 grams of mass will exert or weigh due to gravity

In Earth's gravity, the weight and-or force of 1Kg is:

Weight = Force = (mass)(acceleration) = 9.8N = (1kg)(9.8 m/s^2) = (1000g)(9.8 m/s^2) , solving for 1N, we have: 1N =~ (101g)(9.8 m/s^2) =~ 100 gf = 0.1 kgf
If you had a mass of 100g, it would weigh about 100 gf = 0.1kgf = 1N of force.
If you had a mass of 1kg, it would weigh about 1000 gf = 1kgf =10N of force

Calculating The Buoyant Force Of An Object In Water

From : Pressure = Force / Area = P = F / A , mathematically: F = P A

Pressure can be thought of as the average amount of force applied to an area, or force distribution to an area whereas, force can then be thought of as the total amount of pressure applied to the total amount of area.

If the force is due to a weight (W), and weight is a force due to gravity, then P = W / A = F / A.

Whenever a force is applied, there is a contact and-or surface area associated with it, and therefore an amount of force per unit of area, and this is the pressure value. If the pressure is high enough upon an object, it can cause an object to compress (get pressurized) and deform its shape and reduce in volume. If the material is flexible, the deformity will not be permanent if the force is removed, much like how a spring can change shape. The amount of deformation is directly related to the pressure that was applied to that area. If the force was distributed over a large surface area, then the pressure or amount of force per unit of area will be low and the deformation low.

For a given amount of force applied, and regardless of the size of the area, the product of P A will be a constant value for a given system and initial amount of force, and that value is equal to: F = P A :

$$F = P1\ A1 = P2\ A2 = P3\ A3 = \frac{n}{n} P\ A = nP\ \frac{A}{n} = \frac{P}{n} nA$$

If the area is made to be a very low, then the pressure or effective value of the applied force will be very high. The tip of a nail to be hammered into a piece of wood has a small area, and when the force is applied to the nail, it will have a high pressure upon that area of the wood and it can be driven into it. High pressure can be thought of as the force, energy or ability to do something as being concentrated, or the effective value of the force, and which equals the pressure, as being increased, here, as if the initial force of the hammer was amplified. As seen in the above equations, force remains constant, however, pressure can be amplified by a factor (n) if the area is reduced (ie., de-amplified or de-magnified) by that same factor of (n).

If the water pressure is higher at deeper depths, and the force and pressure upon an object will be higher, and if the water pressure is lower, the force and pressure upon an object will be lower. If an object, such as a bubble of air gas is put in water having a high pressure, it will get compressed by the surrounding forces upon it, and it will decrease in volume, but density of the air gas will actually increase. density = (mass of air / volume).

For an object in water, and since there is greater water pressure at greater depths, there will be more force upon the lower (deeper) part of the object than upon its upper (less deep) part. The difference in forces or pressures will result in a net, effective or unbalanced, active, non-neutralized force upon the bottom of it. This force is called the buoyant force. An unbalanced or net force will give kinetic energy to an object, and the buoyant force is this unbalanced force value and will cause an object that weighs less than the water it displaces to rise upwards in the water.

Buoyant Force = weight of the displaced liquid = mg = dVg : **Bouyant Force upon an object in a liquid**.
d = density of the liquid = mass of liquid / volume of liquid
V = volume of the liquid displaced = volume of the object
g = gravitation acceleration = 9.81 m/s^2 = 32.2 ft/s^2

The density of water = mass of water / volume of water = 1g / cc = 1g / 1ml = 1kg / 1L

Apparent weight of an object due to its buoyancy = Weight of the object out of the water - Buoyancy force in water

We see from the buoyant force equations that the mass of an object does not determine the buoyant force, and only the volume of it does because this is what displaces the equivalent volume of the liquid.. The object might be made be of any material(s) or element(s), and therefore be of any mass and weight, yet for all these objects of the same mass, weight, and technically, volume dimensions, they will have the same buoyant force applied to them due to a water pressure difference. The buoyant force of a solid steel ball is the same as a hollow aluminum ball because they have the same amount of volume, and an average person might think that the aluminum ball is more buoyant because it weighs less. Another viewpoint is that even though the solid steel ball has some buoyant force upon it, it will still sink to the bottom due to that its average density (total mass / volume) = [(weight / g) / (volume)] and-or its weight is greater than that of the water it displaces and the buoyant force is not enough to raise it upward or maintain its depth and have equilibrium where the average density (mass / volume) of the object is that of the water it displaces which has a density of (mass / volume) = 1g/cc.

A strong balloon with a large volume of air (which is less dense that the water it replaces is capable of lifting a heavy weight objects from the bottom to near the surface of water. The higher pressure of the water around the balloon or has compressed that inner volume of air to be at the same pressure, but more importantly, the water pressure at the top of the balloon is slightly less, and therefore, there is higher pressure upon the bottom of the balloon. Since there is difference in pressure (P = F/A = W/A) upon the balloon , there is a difference in forces upon its surfaces, and a net force (F = PA) is developed on the lower part of the balloon. This force is effectively applied to the bottom of the balloon in the direction of the surface and causes the balloon to move vertically. This force (the buoyant or "(vertical) flotation" force) must be greater than the weight of the balloon for it to be moved upward, and the balloon surely does not weigh too much being filled with air, and using a lightweight balloon material.

The difference in the pressures (P = FA) and-or forces (F = PA) upon an objects vertical surfaces will cause an effective or net pressure and force (ie., weight) and it is actually equivalent to the weight of the water displaced.

For the object part at lower depth: F1 = P1 A and water pressure1 = P1 = F1 / A : assuming similar areas:

For the object part at high depth: F2 = P2 A and water pressure2 = P2 = F2 / A

Difference in pressure = (P1 - P2) : extra, this is also what causes a planes lift force, a difference in pressure upon the upper and lower wing surfaces.

Difference in force = (F1 - F2) = buoyant force : extra, this is essentially the lift force for a plane

Force = F = weight = ma = mg = dV g = P A
Pressure = P = F / A = ma / A = mg / A = weight / A = (dV)g / A = dVg / A = Weight / Area

The concepts of buoyancy of a water bubble or object can also be applied to a **hot air balloon** that rises vertically in the air due to its buoyancy in the air. For the balloon to rise vertically, the buoyancy force developed must be greater than the weight of the balloon system and passengers. Large balloons are capable of lifting several hundred pounds. The minimal amount of buoyancy force needed will be the weight of balloon system plus the weight of the passengers, and any extra buoyancy force is the effective (vertical) lift force which is effectively applied to the bottom of that balloon. Since air is much less dense than water, the balloon must be very large in size (ie., volume) so as to displace a large amount or volume of air which has total mass and its corresponding weight. To lower the weight of the balloon so that the buoyancy force is greater than the weight of the balloon, a low density (d = m / V) gas such as hot air can be used and therefore, that amount of air in the balloon has a low corresponding weight. Shown further below is an equation that we can use to can find the (minimal) volume of the balloon needed.

From: **Buoyant Force** = weight of the displaced liquid or gas (here air) = **W = dVg** , we mathematically have:

For the weight of 1 m^3 volume of water which has a density of (1g/cc) = (1000g/1L) = 1 kg / 1L
W = F = ma = mg = dVg = (1 kg/1L) (1 m^3) (9.8 m / s^2) = 9.8 (kg m^2 / s^2) = 9800 N

The weight of a 1 kg mass of water is: W = F = ma = mg = (1 kg)(9.8 m/s^2) = 9.8 N

Most weight scales which measure mass in the presence of gravity, should display W=F=(mg), for example pounds of weight , but commonly "metric weight scales" usually display the weight's corresponding mass. m = W / g , and are actually "mass scales".

F = PA = ma = mg = W = dgV and d = m / V = W / gV and m = dV , V = m / d = (W / g) / d = W / dg

The volume of 1 kg of mass of water is: V = m / d = 1 kg / (1kg / 1L) = 1L = 1000 cm^3

The mass of 5 L of water is: m = dV = (1 kg / 1L) (5 L) = (5 L) (1 kg/1L) = 5kg

Since the minimal amount of buoyant force needed must be at least equal to the weight of the balloon, the minimal volume needed will be derived and calculated :

: d = density of unheated air at STP is 0.001225 g / cm^3 = 1.224 kg / m^3 = 2.69846 lbs / m^3
: d = density of the hot air at 100°C is 0.000946 g/cm^3 = 0.946 kg / m^3 = 2.08557 lbs / m^3
g = a = 9.81 m/s^2

Note that the ratio of volumes of air at two densities is also equal to the ratio of their corresponding densities. After dividing the values , the ratio is about: 1.2294

Note the mix of metric and English units in: 2.69846 lbs / m^3 ,and this may help some, and to make the full conversion of system units we will first convert: 1 m^3 to its equivalent volume and expressed with units of feet: 1m^3 = 10.7639 ft^3.
2.69846 lbs / 1 m^3 = 2.69846 lbs / 10.7639 ft^3 , and using division of both the numerator and denominator by 10.7639 to create an equivalent fraction, we have: 0.2506954 lbs / ft^3

Also since d = m / V , m = dV , after multiplying both sides by g, we have: W = mg = gdV = F

Also, from W = dVg , (W/V) could be described as "weight density" and

(W/gV) as we commonly know is "mass density" = d = m / V = W / gV

Note that some products may be labeled: as "weight / volume", rather than "mass / volume", or simply as "sold by weight" (such as lb = pounds, or: oz = dry ounces), rather than "mass".

Each 1 m^3 of volume of the inflated or expanded hot air balloon will replace 1 m^3 of typical air. Since buoyant force is equal to the weight of the substance (here, air) displaced, 1 m^3 of balloon will displace 1 m^3 of typical unheated air which has a corresponding (mass) weight of 1.225 kg/m^3.

Since 1m^3 of air will be displaced, the buoyant force upon a 1m^3 balloon will be able to lift a total mass of 1.225 kg.

To lift a mass of 300kg mass (which has a corresponding weight value), and of which includes the mass of the balloon material, system and the passenger or object to be nearly lifted into the air vertically, will require a buoyancy force applied beneath it, and having the equivalent value of that of the mass of 300kg and-or its corresponding weight. Since volume and mass are proportional, we can use an equivalent fraction and-or equation to solve for the corresponding (minimal necessary) volume needed to create the (minimal necessary) buoyant force to just begin to lift that amount of mass.

$$\frac{1\ \text{m}^3}{1.225\ \text{kg}} = \frac{V\ \text{m}^3}{300\ \text{kg}}\ ,\ V\ \text{m}^3 = \frac{(300\ \text{kg})(1\ \text{m}^3)}{(1.225\ \text{kg})} = 244.9\ \text{m}^3 \approx 245\ \text{m}^3 = V\ \text{balloon} = V\text{air displaced}$$

If we take the cube root of this amount of volume, we can find the side length of a cube having the same volume. The cube root of 245^3 =~ 6.26m . The radius of a sphere (ie., like a balloon) with this amount of volume is:

r = cube root of (3 V **/** 4 (pi)) = cube root of (0.238732414 V) = cube root of **[**(0.238732414) (245m^3)**]**

$r \approx 3.88\underline{2}$ m , $d = 2r \approx 7.763\underline{5}$ m

Any extra buoyant force more than the minimal amount needed will then cause the balloon (or thing in water) to rise up vertically and no longer be **neutrally buoyant** where it is neither rising upward or sinking downward. If the weight of the volume of gas or liquid displaced by the object is not equal to the weight of the object (such as a solid stone, and of which is a denser material than water per volume), then the object will sink even though it has some buoyant (or upward force) on it. An object will appear to have (some) less weight due to buoyant force.

A related concept is called **relative density** and which is also called **specific density, specific density ratio,** or the **specific gravity** for a given mass or substance. In simple wording, the relative density of an object and-or mass is how many times more dense it is than water which has a density of (d = m / V = 1 g / 1 cc):

$$\text{relative density} = \frac{\text{density of object}}{\text{density of water}} = \frac{(\text{g} / \text{cm}^3)}{(1\text{g}/1\ \text{cm}^3)} = \text{g} / 1\text{g} = \text{ratio of how many times denser the object is greater than that of water.}$$

If the relative density of the object is greater than 1, it is more dense than water and will sink in water. What this also means is that if the density (d = m/V) of the object is more than the density of water, the (average) weight of the object per same volume of water will be more. Weight is directly proportional to mass. Surely, the metal of a submarine or boat is much more dense than water, but the average density for the same volume of water that is displaced then needs to be considered. The submarine can rise upward in the water if its average density is less than that of water, and it can do this by removing the water in its ballast tanks (which caused it to dive or sink deeper in the water) with air which is less dense than water, and thereby making the **average density (= total mass / total volume)** per unit of volume of the submarine less than that of the same volume of water of which it has displaced (ie., replaced).

From: Buoyant Force = Weight of water displaced = dVg , and if V remains the same, such as for the submarine, then the buoyant force depends upon the average density of the object such as a submarine. If the submarine takes in water, its average density will increase, and its relative density will be more than that of water and it will go deeper. Many types of fish have what is called an (internal) air-bladder (ie., sack) which the fish can inflate (ie., expand in volume, like our lungs) with a gas, or deflate (ie, remove) the gas, and therefore change the buoyancy of the fish so as to rise upward, or to easily remain at the same depth (neutral buoyancy), or sink downward.

Vertical or effective lift force due to buoyancy = (buoyant force) - (weight of object(s) being lifted)

Note that for the minimal amount of buoyant force to cause upward motion (and not just some lesser value making it appear as slightly lesser in weight), the weight of the displaced gas or liquid is equal to the weight of the object, but the volume of that gas or liquid is not equal to the volume of the object, and we see that the volume of the balloon is much greater than volume of the (much greater amount of) mass it is lifting. $d = m / V$, $V = m / d$, and for any given amount of mass [which also as a corresponding weight] at STP (standard temperature and pressure), if the density (d) decreases by a factor of (n), the volume (V) will increase by that same factor of (n).

Avogadro, while studying gases surely noted that given: $d = m /V$, and when he had two balloons, each filled with a different type of gas, and having the same volume, that they weighed slightly different, and therefore, the mass of each type of gas particles or molecules in each balloon must be somehow different, and that the densities of the two different types gases must be different. Today, we know that the two different types of gas particles are actually different atoms of gas particles, and with each type of gas atom having a unique number of atomic mass particles (protons,neutrons). Avogadro theorized that each type of gas at the same temperature (ie., thermal to KE of the particles) and pressure, and in the same sized balloons (ie., volume) had the same number of particles. Avogadro did not know that specific number, but later, he was honored for is work by having this value named after him, and that is Avogadro's constant or Avogadro's number.

A certain number of particles, such as those of hydrogen gas and which sum to a mass of 1 gram, is used as the reference unit for an amount of particles (amu's, atoms, molecules) and it is called a mol. Each type of gas, of which each particle or atom of it has a unique amount of mass, and therefore having a unique number of grams of mass per 1 mol count unit, and-or a unique number of mols per 1 gram of mass.

The number of particles in a mass of 1 gram of hydrogen gas was assigned 1 mol. 1 mol of atom particles of hydrogen has a mass of 1g. Since hydrogen has 1 proton and no neutrons, 1 mol of protons is 1 gram of mass, or it can be said that 1 mol of amu (ie., protons or neutrons) is 1 gram of mass

A Note On Avogadro's Theory

What may have inspired Avogadro do his scientific study of matter?

Consider that two different metals, such as aluminum and copper that having the same volume have different amounts of weight, and therefore, the mass ($m = F / a = W / g$) of each is also different. It was understood since antiquity, that the smallest indivisible particles of each type of element was an atom of the same element, and therefore, Avogadro must have considered that there is something different about each type of atom of the two different metals. Since the mass of each element was different per same unit volume, and is known as the density ($d = m / V$) of that matter or element, it is reasonable to first conclude that the atoms of one metal are packed together more closely. As mentioned previously, the atoms or smallest particles of two different types of metals are not similar because they atom sized particles of each different element still have the qualities of that element or metal. If it was simply a matter of the density only of similar atoms, then it would be possible to turn cheap lead into expensive gold by putting much pressure ($P = F/A$) upon it so as to compress it and increase its density. Many have tried to do things similar to this but never succeeded, other than advancing the science of alchemy (ie., a type of experimental chemistry). Avogadro must of realized that it was not the atom or particle count per unit increasing the density ($= m/V$) and weight ($= F = ma$) , but rather it had something to do with each different type of atom particle of that type of matter or element. In Avogadro's balloon experiments with gasses, he proposed that given the same volume of two different types of gasses at the same temperature and pressure (STP) each, that they must have the same number of particles which caused the balloons to expand to the same volumes. What was different about the two seemingly similar balloons? The weight of each balloon was slightly different, indicating that the mass of each different type of particle (ie., atom) or molecule of that gas was causing the weights of the balloons to be different. The hydrogen gas balloon weighed less than all the other gasses, and the number of particles corresponding to 1 gram of it was called a mol or 1 mol of particles. Avogadro did not know the quantity of particles equal to 1 mol unit or count of particles, but it was later found after years of research by others, and they honored Avogadro for his work by naming this constant as Avogadro's constant or Avogadro's number.

Because different metal elements have different densities (m/V and W/V) due to that the different types of element atoms or particles having a different amount of mass, 1 mol of particles or atoms of that element with more density and mass (or its corresponding amount of weight) per unit volume will have more grams of mass per 1 mol count of those denser, more massive (ie., in amu) particles. By knowing how many grams of atoms corresponds to and-or are needed for 1 mol of atoms, if we need to have n mol of atoms for something such as a particular chemical reaction or some medical formula, and we surely can not count them all, we can rather weigh the needed amount of it for 1 mol of atoms by using a weight to its corresponding mass displayed scale, (ie., finding mass via its corresponding weight). For example if a particular element is noted as having 10 grams per 1 mol of atoms, how many grams are needed so as to have 2 mol of it? For the solution, we can set up a proportion type of equation using similar fractions and mathematically solving for the value we are trying to find. The number of grams and the number of mol are directly related (ie., as in higher grams means higher mol) and are mathematically proportional (ie., each changes by the same factor or ratio value) in (relative, or ratio) value to each other.

> If 10g corresponds to 1 mol of atoms of that element, then the equivalent fraction of Ng to 2 mol of atoms of that element can be expressed as:
>
> $\frac{10\text{ g}}{1\text{ mol}} = \frac{N\text{ g}}{2\text{ mol}}$, mathematically: $Ng = 2\text{ mol }(10g / 1\text{ mol}) = 20g$: $Ng = (x\text{ mol}) (g / \text{mol})$.

Continuing onward with the discussion about compressed air tanks for scuba diving :

Besides using a weight scale, it is possible to calculate the amount (weight or volume) of air in a tank if you know the weight of the empty tank without the compressed air in it.

Weight of tank filled with compressed air = (weight of the empty tank) + (weight of the compressed air in the tank) .

(weight of the compressed air in the tank) = (weight of tank willed with compressed air) - (weight of the empty tank)

(Weight of the air in the tank) = (mass of the air)(g) = (density V)(g) = dVg = W , for the volume of this weight of air:

V = W / dg = ma / dg = mg / dg **= m / d** : V = volume , W = weight , d = density , g = gravitational acceleration

From: d = m / V , we have: m = dV and V = m / d = (F / a) / d = (W / g) / d = W / dg
: it is of note that most modern scales are calibrated to display the mass, and in grams, of an object.

W = dg V **:** extra: g = W / (V d) = a = F / m = W / m

The ratio of volumes is equal to the reverse or inverse ratio of the pressures or densities.

$$\frac{V1}{Vo} = \frac{Po}{P1} \quad : \ V1\,P1 = Po\,Vo$$

The ratio of the weights (W) of the air is also equal to the ratio of the volumes of air in the tank:

$$\frac{V1}{Vo} = \frac{\text{V of air compressed in tank}}{\text{V of air in empty tank}} = \frac{\text{(W compressed air in tank / dg)}}{\text{(W of air in empty tank / dg)}} = \frac{\text{W compressed air in tank}}{\text{W uncompressed air in tank}} = \frac{W1}{Wo}$$

$$\frac{V1}{Vo} = \frac{Po}{P1} = \frac{W1}{Wo}$$

: For this example, Po = the absolute air pressure at sea level =~ 14.7 psi
P1 = pressure of the compressed air in the tank = Po Wo / W1
P1 = Po Wo **/** W1 = (14.7 psi)(dg Vo) **/** (dg V1)

The ratios of the weights to volumes are proportional:

$$\frac{W1}{V1} = \frac{Wo}{Vo}$$

: these can be thought of as "weight densities" , where as "mass densities" = mass / volume = m / V
: Wo = weight of uncompressed air and W2 = weight of compressed air

How many grams does a volume of 1 liter of air weigh?

F = weight = ma = mg = dVg , and when finding just the mass value, m = dV , and since the density of air is about:
d = mass / volume = 0.00124 g/cc and 1L = 1000cc:

m = dV = (0.00124 g/cc)(1000cc) = 1.24 g , hence the density of air can also be said as being :
1.24g / 1L = 1.24g / 1000 cc = 1.24g / 1000 mL :at 14.7psi

d = 0.00124 g / 1 cc = 1.24 g / 1000cc = 1.24g / 1L : equivalent and proportional fractions

A tank with a volume of 80 ft^3 of air = 2265.348 L of air will weigh an equivalent mass of:

(2265.348L of air) (1.24 g / 1 L) = 2809 g = 2.81 kg

Since 1L = 0.0353147 ft^3 and 1g = 0.035274 oz:

1.24g of air / 1 L = 1.24 g of air / 0.0353147 ft^3 = 0.04373976 oz air / 0.0353147 ft^3 =

$$= 1.238571 \text{ oz} / 1 \text{ ft}^3 = 0.07741 \text{ lbs} / 1 \text{ ft}^3 = \text{roughly about } 0.08 \text{ lbs} / 1 \text{ ft}^3$$

As the air gets depleted from the tank, it will weigh slightly less and be easier to carry. It is as if it became more buoyant, however the buoyant force is still the same value because the volume of the displaced air due to the volume of tank is the same.

$$80 \text{ ft}^3 = 2265.348 \text{ L} \quad \text{will weigh about: } 80 \text{ ft}^3 (0.08 \text{ lbs} / 1 \text{ ft}^3) = 6.4 \text{ lbs} = 6.4 \text{ lbs} (0.453592 \text{ kg} / 1 \text{ lb}) = 2.90\underline{3} \text{ kg}$$
$$=^{\sim} 3 \text{ kg}$$

When compressing a substance such as air, if the volume Vo is decreased by a factor of (n), the pressure Po will increase by that same factor:

$Vo\, Po = V1\, P1 = k$: **Boyle's Law** , and from this we have: $\frac{V1}{Vo} = \frac{Po}{P1}$ of which are reverse or inverse ratios and equivalent fractions or equivalent ratios

k = a constant value

Boyle's Law applies only if the temperature is held constant because a change such as an increase in temperature will cause the internal pressure to increase, even if the volume of gas or other substance remains the same such as in a closed container. If the temperature decreases, the internal pressure will also decrease.

While a scuba tank is being drained of compressed air, by using Boyle's Law, various volumes and corresponding pressures can be calculated. This can also be used to determine how long a full tank or one being emptied of air can be used. It is already known how much volume of air is inhaled on average, and then the volume of the tank will be reduced by this much for each breath, and the corresponding pressure left (P1) in the tank can be calculated:

After breathing the air in the tank, the volume of air in the tank will be:
starting volume of air - volume breathed = ending volume = Vo - Vbreathed = V1 , and using substitution:
V1 = Vo - **(**n breaths**)** **(**volume per breath**)** = Vo Po / P1

The remaining pressure in the tank will be: (Po - Preduced) = P1 = Vo Po / V1

Extra: Another note on Avogadro's theory.

Avogadro's theory is that given any gas at standard temperature (32°F = 0°C = 273 °K) and air pressure (14.7 psi), that they will fill a known volume, such as a balloon, and have the same number of particles (today, we know these as being atoms of that gas element). Unlike a metal, the gas particles are relatively very far apart. Since the gas substances he used were different, the balloons have a different weight (W) for each. By knowing the volume and weight (ie., force created upon the mass of gas by the force of gravity) of the gas in the balloon, the density (m/V) and mass of that gas can be found.

As an extra note, surely when Avogadro made his gas theory in 1811, he must of known that when the gasses in the balloons were higher in temperature, perhaps by taking them into a heated room of twice the temperature, that they expanded to twice their size (volume). The actual amount (mass and-or weight) of gas within each remained the same value such as 1 gram. The balloons were now less dense (d=m/V, or even the related value of: "weight density" =W/V) per unit of volume is less. **Charles Law** which relates the volume of a gas to temperature was discovered in December of 1787 when **Charles Prairie de Nesles** from France was experimenting with his hydrogen balloons for manned flight shortly after the first manned flights made by the Montgolfier brothers were made in France on November 21, 1783. To Avogadro, it also indicated that the gas particles must be energized and traveling faster when heated, and so as to expand the balloon to its new larger size, and rather than having an increased amount (mass and-or volume) of gas placed in the balloons to expand their size. He reasoned that there is probably the same number of particles in each balloon if their volumes are still the same. Though there was the same number of particles in each balloon, due to the slightly different weight of each balloon of the same size or volume, it indicated that the size and-or weight (ie., hence mass) of each different type of particle (here, unknown atom structures at that time) of gas in each balloon was different. It also then indicated that the structure of each particle (here atoms yet to be formally discovered) was somehow different, and of which we know today as each element having atoms which have a different number of atomic units (protons and-or neutrons = amu = atomic mass units), and normally, with 1 orbiting electron of opposite electrical charge per 1 proton in the nucleus (ie., center) of the atom. This one to one, proton and electron count or ratio makes atoms electrically neutral (no net electrical charge) and electrically stable (no general movement due to the force of an eternal electric charge).

Avogadro found that in 22.4 L = 0.792 ft^3 = $5.91\underline{7}$ US gal of volume, nearly 6 US gal, that hydrogen gas weighed 1 gram and that another gas of the same volume, temperature and pressure would weigh more. The number of hydrogen particles (today known as atoms) to make 1 gram of mass was defined as 1 mol unit in reference to the word molecule which meant a tiny particle at that time. Since other gases weighed more, by reasoning, they had more mass each. All the gases have a volume at nearly 22.4 L of gas per 1 mol unit of atoms. In general, all gases will have the same volume when having the same number of particles and at the same pressure and temperature.

From: density = d = mass / Volume = m / V , mass = m = dV , and

Weight = a force = (mass)(acceleration) = ma = mg = dV g , we have:

d = m / V = (W / g) / V = W / Vg

By knowing the density and weight of the gas, we can then find its mass:

m = W / g = dV : If the volume is 22.4L, then this gas has a total amount of mass of 1 mol unit of atoms of that gas. Here, density of the gas is: d = (1 mol / 22.4L) = (1 gram / 22.4L) at STP

Since antiquity, it was known that the same volumes of two different elements such as metals had a different weight, and therefore their substance or matter must be different in some way as if they had more matter per unit of volume, perhaps compressed together in some way into a smaller volume, and this was called the density (d) of the substance, mass, matter or element:

density = (amount of matter) / Volume , and then calling (amount of matter) as the (mass) of matter:
density = mass / Volume = m / V , and mathematically, m = dV

It was also known that if the volume of each substance changed by a factor (n), that its weight also changed by that same factor of (n), hence by reasoning, the quantity of mass also changed by that same factor of (n). Now if density is related and proportional to weight, we can find the amount of mass of an object from its weight. The weight of a cubic centimeter amount or volume of water was standardized as a reference mass and having a mass of 1 gram. 1000 grams of water was defined as having the reference mass of 1000 grams = kilogram (kg), hence its volume is 1000 cc of which was then standardized as 1L of volume.

Today we know that different elements, it does not mean all atoms in the universe are the same and are simply compressed together more closely than another elements atoms so as to increase its density. We know today that atoms of different elements have a different structure, particularly the number of atomic mass units (ie., protons and neutrons). In general atoms having more mass, weight, and size will occupy a larger volume, and this actually results in having less atoms per unit of volume, and so it therefore takes more of these same atoms, such as in grams of atoms, so as to have 1 mol unit or count of those atoms.

Extra: A note on Newton's force and gravity equations

Isaac Newton knew that if a weight is pushed by a force, that it will move. The more force applied, the more distance it moved,hence Newton figured that the distance an object moves is related to force. The more the object weight, the less distance it moved for a given force. When a force was no longer applied to the object, such as a box on the floor, it would slow down in speed, and this is called a deceleration. If the force is constantly applied, the object would accelerate. Newton knew the basic distance equation of distance = (speed) (time). Newton realized that acceleration (change in velocity / change in time used) is directly related to the amount of force applied to a mass, hence acceleration is directly related to the amount of constant force applied to the mass. Once a force is not applied, there will be no increase in acceleration and no increase in velocity:

$$\text{acceleration} = \frac{\text{force}}{\text{mass}}$$, and mathematically, Newton made his this equation:

force = (mass)(acceleration) = ma , and in terms of distance and velocity:

$$\text{acceleration} = \frac{\text{force}}{\text{mass}} = \frac{\text{(change in speed or velocity)}}{\text{(change in time)}}$$

Associating weight as a force due to gravity:

weight = (mass)acceleration due to the force of gravity on Earth) = mg : g = 9.81m/s^2 = 32.2 ft/s^2

Galileo and later, Isaac Newton knew that gravity must be some kind of force which caused objects to move downward, he also knew that a constantly applied force applied to an object will cause an acceleration in its motion and-or velocity, and it will get faster in the same direction of the applied force. By doing experiments such as releasing a still (no force applied, therefore no acceleration, and therefore no initial velocity) ball from a height, it took say 1 second for it to reach the ground. But was it accelerating due to this constant force of gravity? Newton figured that it should be if the force is constant, that is, a constantly applied force will cause a constant increase in acceleration (change in velocity), and the object will then be traveling faster and faster (ie., or greater and then greater) in velocity. After dropping the ball from at twice the height, the ball did not take twice as long (2s) to reach the ground, but took less time, say 1.5 seconds, The ball took the same amount of time to first go, move or travel a distance equal the original height, but it must of kept accelerating due to the constantly applied force of gravity upon it, and giving it more kinetic energy and increasing in speed, and then the time to travel the remaining height to the ground was less than the first.

acceleration = (change in velocity) / (change in time) , and mathematically:

(change in velocity) = (acceleration) (change in time)

Since distance = (velocity) (time) , a change in velocity = acceleration, will cause a change in the distance traveled per unit of time. (change in distance = (change in velocity) (change in time)

(acceleration) = (change in velocity) / (change in time) =
[(change in distance) / (change in time)] / (change in time) =
(change in distance) / (change in time)^2

Ex. If an object such as a motor vehicle is traveling at a distance of 10 feet per second of time, its velocity is said to then be: v = d / t = 10 ft / 1 s. If more energy and-or force (the application of energy) is then constant applied to the object, it will have a constant increase or change in velocity during that time, and this is its value of acceleration. If after 5 seconds of time, its velocity was 15 feet per second of time, then the change in velocity was (15 ft / s - 10 ft / s) = 5 ft / s , and its (average, if not consistent) acceleration was: acceleration = a = (change in velocity / (change in time) = (5 ft / s) / 1s = 5 ft / s^2 =
a = (change in distance) / (change in time)^2 = (change in velocity) / (change in time)

From the above equations, we mathematically have:

(change in distance) = (change in velocity)(change in time) , and also:

(change in distance) = (change in velocity) (change in time) = (a) (change in time)^2

(change in velocity) = (change in distance) / (change in time) = (a) (change in time)

(acceleration = a or g) = (change in velocity) / (change in time) = (change in distance) / (change in time)^2

Newton knew that heavier weight objects did not reach the ground any faster than lighter weight objects, hence, he knew that the weight and-or mass of the object did not determine or affect its velocity and-or its acceleration. It was rather the (relatively. locally, here Earth's gravity) constant value of the force of gravity being constantly applied to the object and causing (ie., forcing) it to accelerate (ie., travel faster, increase) in velocity and have more kinetic energy.

By conducting many experiments and calculations, Newton found that an object will accelerate downward at 32.2 ft/s^2 = 9.81 m/s^2 due to gravity. This value is called the gravity acceleration value of Earth and is given the variable name of (g). A ball dropped from a height of 9.81 meters will reach the ground in 1 second of time. A ball dropped from a height twice a high = 2 (9.81m) = 19.26 meters will reach the ground in this many seconds or units of time:

(change in time)^2 = (change in distance) / (a) = 19.26 m / (9.81 m / s^2) = 1.9633 s^2 and ,
after taking the square root of each side of this equation, we have:

(change in time from 0s) = (time of reaching the ground) = $1.401\underline{2}$ s : and not 2s

Also: 1g of mass has a weight of: 0.009806652 N , and 22.4L = 22400 cc of hydrogen gas

Dividing each side by 0.009806652 to isolate N as 1 unit of N, we have:

1N = 101.9716 g rams

1 kg of mass has a weight or force of: (weight of 1 gram)(1000) =
(0.009806652 N) (1000) = 9.806652 N =~ 9.81 N = 2.20462 lbs and from this we have:

1 N = 0.224808629 lbs =~ 0.25 lbs which is a quarter of a pound of weight
1 lb = 4.448227813 N =~ 4.5 N

If Avogadro's gas filled balloon was not expanding or deflating, then its internal pressure from the pressurized gas and upon its inner surface was that of the standard atmosphere which is 14.7 psi at sea level. Avogadro also used gases that were at a standard temperature of 32°F. Avogadro found that a hydrogen filled balloon weighed 1 gram (ie., of equivalent force or weight of 1 gram of mass), that the volume was 22.4L, but other gasses at the same volume were heavier and therefore, it took less volume to fill them to weigh 1 gram , and since d = m / V , or , considering d = W / V since weight and mass are proportional, If the amount of substance remains the same, its mass and weight will remain the same when the volume it is in changes in value, however the density (m/V) of that substance will change by the inverse factor that the volume changed. Given the same amount of mass in a larger volume, its density will decrease.

Of mention is that Avogadro did not know the (atomic) structure of the hydrogen gas particles in his balloon, and we now know that the type of hydrogen he used is known as of the most common structure of hydrogen which is **diatomic** (ie., two atoms joined as 1 molecule) hydrogen rather than single atoms of hydrogen which are called mono-atomic hydrogen. Diatomic hydrogen (H2) is a molecule consisting of two hydrogen atoms which share their electrons which creates a covalent bond due to the nearby electric charge attractions of the protons and orbiting electrons. If Avogadro's 22.4 L balloon was filled with diatomic hydrogen and it had a mass of 1 gram, what is the density of this diatomic or common hydrogen? First, today we know that his balloon had twice the amount of matter than he thought (but still one mol of it as defined). Avogadro called this 1g of matter or mass particles as having 1 mol of gas particles. By measuring the weight of a substance, it can be determined how much mass it is, and-or the number of mol units it is if we know the (g/mol) of that substance and-or element. The mol unit is a certain number of particles, and is often used various fields of study such as chemistry and-or electro-chemistry, biology, medicine, electrolysis and electro-plating.. If something weighs 2g, it therefore has 2 mol of atomic mass units, but not necessarily 2 mol atom units unless it is monoatomic hydrogen which is sometimes called protium. By using mass, a total sum of matter can be found by weight: W = mg and m = W / g . Using the concepts of (mol / gram) or (grams / mol) = molecular weight of an element, the total number of particles such as atoms or molecules can be found by weight rather than counting each particle of which would be nearly impossible. If diatomic hydrogen which has a molecular weight of (2g / mol) is weighed and measured, and if there is 2g of it, then we have 1 mol of diatomic hydrogen (not exactly atoms, but molecules for this somewhat rare instance of gases):

density = d = m / V = 2g / 22.4L = 2g / 22400 cc = 0.000089285 g / cc = 0.089$\underline{3}$ g / 1L : diatomic hydrogen

Since 1 mol of mass of mono-atomic hydrogen has and-or corresponds to a mass and-or weight of 1g , 2g of matter is the weight per 1 mol unit of diatomic hydrogen, and this is called the molar mass of diatomic hydrogen. Its molar mass is 2g / 1 mol. Since 1g of pure hydrogen atoms is essentially 1 gram of protons, there is 1 mol of protons in 1 gram of pure (mono-atomic) hydrogen atoms which have only 1 proton and 1 electron (which has negligible mass) in each.

1 proton or neutron has a mass defined as 1 atomic unit of mass or 1 atomic mass unit (1 amu). The number of particles such as atoms in 1 mol is called Avogadro number, and its value was later found by extensive experimentation, measurement and calculations by many to be about: 6.0221408 (10^23) particles (ex., protons and-or neutrons, or atoms, or molecules). For diatomic hydrogen, each of these particles with 2 protons corresponds to the number of grams of that substance per mol unit. This value of 2 is also called the atomic number of (diatomic) hydrogen, and which is therefore also equal to the number of protons (and the number of electrons) in each particle (here for diatomic hydrogen, it happens to be a particle that is a molecule of two atoms, but in general, for single atom particles of other elements). The **atomic mass** or **molecular mass** or weight (ie., mass that which will give it a corresponding and proportional weight [force] in a gravity field) of an atom or molecule (joined atoms into a molecule particle or unit) is the total number of atomic mass units (**amu**), hence the number of protons and neutrons in an atom of a certain element or molecule; for example: 10 amu. **Atomic weight** is the number of grams per mol amount of atoms or molecules of the substance, and which is also called the **molar mass** (ie., mass per mol of a substance). Ex. If an element has a atomic mass or molecular mass of 10 amu, its molar mass will be (10 grams / 1 mol).

A pure elemental hydrogen (and the molecule diatomic hydrogen) does not have a neutron in the nucleus of its atom, and therefore it has just 1 proton and 1 neutron for or in its atom particle. Its atomic number is therefore 1 and its atomic mass is 1 amu or as 1u. Its molar mass is 1 gram / 1 mol. This could also be stated as: (1 gram of substance or particles such as hydrogen atoms / 1 mol of that substance). For hydrogen, this can also be stated as (1 gram of protons) / 1 mol, and from this using division by the actual numeric value of a 1 mol, we can find the mass of a single proton or neutron.

The gasses that are commonly found in their diatomic molecule form are: Hydrogen (H_2), Oxygen (O_2), Nitrogen (N_2), Chlorine (Cl_2), Bromine (Br_2) and Fluorine (F_2). One form of oxygen even has 3 atoms joined together and is called **ozone** (O_3), and it is mostly found in the upper atmosphere. Ozone helps block UVB (light-photonic) radiation. Concentrated ozone is also used by industries so as to produce some chemical reactions because it is highly reactive (ie., here, "oxidizing"), and it is sometimes used to reduce germs, hence it is not generally safe for lifeforms, especially when breathing it and-or "smog" (smoke containing various chemicals and-or pollutants such as from combustion engines and-or factories).

The more mass (ie., amu's) a particle such as in its atom of a particular element has, the heavier 1 mol of those atoms will be, such as in grams of mass "weighed" (weighed and calculated as mass) on a scale, hence its molar mass value will be greater. For example, an atom with twice the number of amu's than that of another atom will have a mass and weight of two times more and 1 mol of it will be twice as much grams.

The mathematical inverse or reciprocal of (grams / mol) is (mol / gram). If a substance has 10 grams / 1 mol of atoms, how many mol is 1.5 grams of that substance? After dividing the numerator and denominator of (10g / 1 mol) by 10 so as to create an equivalent fraction, we have: 1g / 0.1 mol. Now multiplying both the numerator and denominator by 1.5 so as to create an equivalent fraction, we have: (1.5g / 0.15 mol). 1.5 gram units of that substance corresponds to 0.15 mol units of the substance.

Extra. This is example how to count the number of grains of rice in a container by a known (rice grains / volume) unit rather than a known (rice / weight) unit such as used when weighing a quantity of rice and then finding the number of grains. If a particular type of rise has an average of a count of 30 grains per 1 cc unit, how many grains of that rice are in a container with a volume of 1L ? We know that 1L = 1cc (1000) = 1000 cc , creating an equivalent fraction:

$$\frac{\text{30 grains of rice}}{\text{1 cc}} = \frac{(1000)}{(1000)} = \frac{\text{30000 grains of rice}}{\text{1L}}$$: hence, associating a number of grains with a liter

Much like a mol is associated with a specific number of particles, we can assign a unit for 30 grains of rice, such as 1 ric unit of rice. 2 ric units would be: (2 ric) (30 grains / ric) = 60 grains of rice.

What is the mass (grams) of air needed per day by a relaxed person, and what is the mass (grams) of oxygen needed per day by a relaxed person?

For this question, there are many factors to consider such as weather the person is working or sedentary. For this analysis, we will consider a sedentary adult person breathing at a rate of 12 breaths per minute as mentioned previously in this main article about scuba diving. Let us call this the minimum rate needed. You may then wish to do the calculations for a diver breathing say 20 breaths per minute. At 0.5L volume of air per breath from a sedentary person, the volume of air per minute is: (12 breaths / min.) (0.5L / breath) = 6L of air per minute. This results in: (6L air / min.)(60 min. / hr.) = (360 L air / hr.) , and this results in: (360L air / hr.) (24 hr. / day) = 8640 L air / day = 2286 gallons / day

Since: 1 ft^3 = 7.48052 gal , (2286 gal air / day)(1 ft^3 / 7.48052 gal) =~ 305.6 ft^3 of air / day : is breathed

1L of **air** at STP has a mass of 1.24g and (8640 L air / day)(1.24g / L) =~ 10714 g air / day =~ 10.7 kg air / day

Given that typical air is about 20% **oxygen**, and we use about 5% internally and convert it to carbon dioxide, then in terms of just oxygen, we would need about: (10.7 kg / day) (0.05 oxygen) = **535 g oxygen / day** : about half a kg
For a quick calculation, a diver would need about twice as much , hence: 1070 g oxygen / day =~ 1kg oxygen / day
We must also save (1/3) of this value for emergency usage or add in (1/3) more for that purpose.

1 L of air at STP has a mass of 1.24g and (1.24 g / L air) (0.20 oxygen) = (0.248 g oxygen / L air) =~ (0.25g of oxygen / L air) = about a quarter of a gram of oxygen per liter of air = 1g oxygen / 4 L of air =~
=~ 1 g oxygen / U.S. gallon of air

Since 1L =~ 0.26455 gallons =~ 0.25 gallons , 0.25 gal will have 1.24 g of air and 1 gal will have 4.96 g of air =~ 5g
1 gallon = 3.78L =~ 4L , and 8640 L air / day =~ (8640L air / day) / (4L / gal)) = 2160 gal air / day and if we rather used the more accurate value of 3.78L as the divisor,we would have 2286 gal air / day as previously mentioned.

Since 1 gallon = 0.1337 cubic feet = 0.1337 ft^3 , 2160 gal air / day = (2160 gal air) (0.1337 ft^3 / gal) / day =
=~ 290 ft^3 air breathed / day . Taking the square root of this, the side length of this volume is: 6.62 feet

Much of the shores and ocean of the Earth have still been unexplored as of the year 2024, and due to the oceans great distances, depths, visibility, and pressures that makes exploring it an inpractical venture on a large scale. General sonar (**SO**nic **N**avigation **A**nd **R**anging) images are the best images available of the larger unexplored portions of the oceans, and these images have a relatively low resolution as compared to a photograph. Just like the remote control drone vehicles in the air, there is a high potential use for remote controlled water submersible versions with lights and cameras.

Sonar is like the sonic (acoustic) version of Radar that uses radio waves and its reflection from objects in the air, however radio waves do not travel far in water and then sonar must be used. Basic electronic sonar began in about 1906.

Some Properties Of Water (H2O)

Water is the **liquid** physical state of H2O (2 Hydrogen atoms, and 1 Oxygen atom joined together as a 1 molecule, the smallest particle of water, and with two or more molecules being called the compound name of water), composed of many water molecules. Each water molecule is composed of 2 Hydrogen atoms and 1 Oxygen atom. The chemical name for water is H2O. At room temperature, hydrogen and oxygen atoms are a gas, and water is a liquid. When water is reduced in temperature, the water molecules will loose kinetic or thermal energy. Their motion is getting reduced. At 32°F = 0°C , the water molecules will arrange themselves in a cubic, grid-like pattern and form a solid that we call **ice**. This structure is actually less dense (d = mass / volume) than liquid water because in liquid water, the water molecules tend to get closer in distance to each other due to their kinetic energy, and this makes liquid water actually slightly denser than ice.

What keeps the water together and not split apart into drops or a gas? Water molecules can become electrically attracted to each other and form what is called a hydrogen bond (bonding, connection). When a hydrogen atom looses an electron, it becomes positive in charge. When a hydrogen ion of the water molecule is electrically attracted to the outer, more distant orbiting electrons of a oxygen atom with its negative electric polarity influence when nearby, an atomic bond, here called a hydrogen bond is created. An individual water molecule is said to be electrically polarized where one side has a net positive charge, and the other side has a net negative charge. Water can therefore ionize itself and the result is regular water molecules mixed with both hydrogen ions (H+) and water molecules having a net negative charge which are called hydroxide ions (OH-). Water is considered as a chemically neutral (ie., "in the middle", of neither extreme) substance that has a pH value of 7.0 which is half-way between that of a strong acid (pH of 0) substance and a strong base (pH of 14) substance. In short, water is both a weak acid and a weak base. Water can dissolve some substances such as salt and sugar.

The outer electrons of an atom are called its **valence electrons**. Molecules can be formed when two or more atoms share the same outer orbit electron(s). This type of chemical element bonding is called a **covalent bond**.

The **density** (mass/volume) of water is generally considered as normally being 1g/cc , and even when a very high external pressure is applied to it, its density will only increase by a very small amount or fraction, say 1%. Due to this stable density, it is possible to use water in a hydraulic jack that can be used to lift very heavy weights a relatively short distant, however due to the potential of rust issues with iron, some type of oil is rather used instead. The electrostatic forces of the water molecules are much stronger at close, molecular distances, ant its is very difficult to move and-or force the molecules any closer.

Water does expand when heated, and this is called **thermal expansion** of an object. When water is heated from 72 °F to 212 °F, it will expand by about 4%, hence its density = (mass / volume) actually decreases due to the thermal expansion when he water molecules gain kinetic energy from the applied heat or thermal energy. For a large body of water such as an ocean, thermal expansion will cause the sea level to rise to perhaps several feet higher and causing flooding issues along the coasts or sea-shores.

The weight of a gallon of water is 8.34 lbs, and the weight of a cubic foot of water is 62.4272 lbs. 1 ton = 2000 lbs of water will therefore be: 2000 lbs / (8.34 lbs / gallon) = 239.81 gallons =~ 240 gallons. 2000 lbs / (62.4272 lbs / ft^3) =~ 32.03732 ft^3 , by taking the cube root of this value, this would result in a side of the cube of about: 3.176 ft and this is slightly more than 1 yard, and is also slightly less than 1 meter = 3.28084 ft.

When water is heated, the water molecules will gain kinetic or thermal energy, and move more rapidly about and collide with each other more. At 212 °F = 100 °C, which is the water boil (boiling) temperature, this temperature will cause much kinetic energy that will break apart the hydrogen bond of water molecules. The water will become less dense due to thermal expansion and will rise upward toward the less dense and less pressure water and-or substances. The hot water will form into (low density) steam (hot, microscopic or small water drops) at the surface of the water, and which is water molecules acting like a low density gas, and with their high kinetic energy, they can rise upward into the air of which is less dense and of less pressure. This process is called **boil**, and the steam has a higher pressure (force/area) than that of the atmosphere pushing down upon it, usually 14.7 psi at sea level. At higher altitudes with less air pressure upon the water, the water will boil at a lower temperature. Note that the water molecules do not split apart into their oxygen and hydrogen atoms parts when water boils, and for that to actually happen requires much more energy and-or force of which can be done with an electric force such as during the process of electrolysis.

When steam cools to 212 °F = 100°C, it will start to condense (ie., get denser) and attract itself into hydrogen bonded water molecules, then small drops or even snow flakes of frozen water made in the high cold air, and then a liquid when the air and ground is warm above the freezing temperature of ice (a cold, frozen [non-liquid] - a solid , crystallized form of water). A snowflake is hexagonal (6 sided, having "branches" or "arms") in shape and this is due to other water molecules attaching themselves via hydrogen bonds to an initial molecule of water. Each branch can even develop other branches later, and the shape of a snowflake is determined by the weather and-or environmental conditions.

At 39.164°F = 3.98°C =~ 39 °F = 4°C , water is at its most dense state and standardized value of (d = 1g / 1 cc). It will become less dense for temperatures lower than this till the point it freezes at 0 °C = 32°F and its density then remains constant at (0.9168 g / cc) and that is a difference of (1.0 g/cc- 0.9168 g/cc) = 0.0832 g/cc and which is 8.32% less than when it is most dense at 1g / 1 cc.. At the temperature when water freezes from liquid to solid, water then becomes at its least dense point. At temperatures colder than waters freezing temperature, the crystal structure of the water molecules of ice will begin to compress slightly, and hence its density will slightly rise slightly.

Ice is slightly less dense than liquid water and will float when in water. Water will also become less dense for temperature higher than 4°C = 32°F , and until it boils at 100 °C = 212 °F and turns into steam (ie.,"water gas") which has a very low density.

When water freezes, it creates a solid crystal of water ice, and expands in volume by 8.32%. Expanding ice will cause a pressure on any external surface and may damage it, and this is also a form of natural erosion of which also includes glaciers, rain and flowing water. From density = d = mass / Volume = m / V , we have V = m / d, If volume increases by a factor of (n), the density will decrease by that same factor. From d = m / V , and after dividing both sides by (n):

d / n = (m / V) / n = m / (nV) and nV = m (d / n)

Heated water will expand in volume, and therefore it also gets less dense. Water can also become what is called **super-heated water** that is above the water boil or steam temperature (212 °F = 100 °C) if it is pressurized in a container such as in a pressure vessel and-or cooker, such as in a (locomotive) **train engine.** Here, any would be steam having less density cannot then rise like it would to a lower pressure region such as it does in Earth's atmosphere at 14.7psi. Super heated water and resulting **super heated steam** will contain more kinetic energy and pressure (P = F/A) to do things. If the air or container pressure drops, then the water will boil faster - including into a lower pressure region such as that at standard air pressure. In a heated container full of water with practically no room to expand, the water will essentially try to expand into itself and compress itself, and the internal water pressure will then rise, and this pressure (force / area) could cause a dangerous rupture (hole, leak) or breakage of the holding tank and the release of high pressure hot water and steam.

The density of water at its boiling temperature of 100°C = 212°F is 0.958 g/1cc and which is (1 g/cc - 0.958 g/cc) = 0.042 g/cc less. (0.042 g/cc) / (1 g/cc) = 0.042 = 4.2% less and its volume will be 4.2%.more.

Heater water that is greater than 0 °C = 32 °F will have a fairly linear expansion in its volume until it boils. The total amount of expansion for this temperature range is about 4% as shown above: The change in volume per degree Fahrenheit is:

A pot full of water will overflow when it is near boiling, and when it boils, the bubbles in the water will cause the volume of the water to increase even more and cause more water to overflow. Some waters heaters, such as a solar water heater may use this expansion of water concept to place the hot water made that rose to the upper water surface and into another tank that is insulated and can then recycle any cool water at the bottom of that tank back into the water heater so as to be reheated and in a continuous loop of making hot water available.

The density of water at room temperature (~ 68 °F = 20 °C to 75°F = 23.89°C , and with 72 °F = 22.222 °c being more common) using 72°F is about 0.998 g/cc, and the density of water near its boiling point is about 0.958 g/cc. This change in water density between these two temperatures is found by taking their difference, and it is: -0.04 , and here using the negative sign because it also indicates a decrease. The volume of water will expand by the same absolute value of 0.04.

With this data and using a linear or line [y = mx , m = y / x = (change in y) / ((change in x) , (change in y) = m (change in x)] approximation, we have this for the approximate or typical (constant) slope (m) or rate of changes in the two values:

Change in temperature = 100 °C - 22°c = 78°C or 212 °F - 72 °F = 140 °F

m = line slope rate = (change in density) / (change in temperature) = - (0.04 g/cc) / 78 °C or
-(0.04 g/cc) / 144°F

From this we can create an equivalent fraction for the (change in density) / (1 degree change in temperature).
For example, dividing each by the denominator value we have:

Change in water density per degree change in temperature from room temperature to boiling temperature =~
- (0.00051$\underline{3}$ g/cc) / 1°C or =~ **-** (0.000277$\underline{8}$ g/cc) / 1°F

To find the corresponding density of water for a given temperature between room temperature and boiling:

From: (density at final temperature) = (density at starting temperature) + (change in density) , we have:

$$\text{density at final temperature} = \text{density at starting temperature} + \left(\frac{\text{change in density}}{\text{degree}}\right) (\text{change in temperature})$$

The above equation has the general form of: y2 = y1 + (change in y) : from (change in y) = (y2 - y1)
And this form: y2 = y1 + m (change in x) : (change in y) = m (change in x)

A person might think that a pot of boiling water will weigh less since the water is now less dense, but this is not actually so, and the pot will weigh the same amount if no water has yet boiled away and made that pot of water lower in weight. Consider a given amount of mass such as water or a gas, it will be a constant amount regardless of its temperature. What does change is its density and volume, and if one of these values changes by a factor of (n), the other value will change by a factor of the reciprocal of this which is (1/n), and since they are factors of the result. Density and Volume are physically and mathematically, inversely related, and are not necessarily reciprocal in actual values, and where the product, here mass, would always be 1:

density = (mass) / (Volume) = m / V , mathematically: : extra: Weight = F = m a = (d V) g

$$m = d\,V = \frac{(n)}{(n)}\,\frac{d\,V}{1} = \frac{(n)\,d}{1}\,\frac{V}{(n)} = \frac{d}{(n)}\,\frac{(n)\,V}{1} \quad \text{or=} \quad ((1/n)\,d)\,(nV)$$

: n = a multiplying factor (<1 or >1)
(d) is often identified as (p).

We see in the above equation that if density decreases by a factor of (n), the volume will increase by a factor of (n).
If the density increases by a factor of (n), the volume will decrease by that same factor of (n).
If the volume increases by (n), such as for a gas that can expand and fill a space, its density will decrease by that same factor of (n). If the volume has air spaces in it, unlike that of a liquid, then the equation is no longer valid as is. In short, there is two different densities involve - that of the material, and that of the air, and the average density is actually less than that of the solid material. For these reasons, it is often better to weigh a substance than use its volume. .

The graph of water density versus temperature is approximately linear or like a line, however the curve is actually a slight downward curve, and this implies that the slope is changing to a slightly lower value. Although
m = dV = (ndV / n) is a constant, the value of (n) is not necessarily a constant and is rather a variable when considering the curve on the graph.

From: m = d V , we mathematically have: V = m / d , and this and-or both equations show the inverse relationship between volume and density such as for an easily compressible or expandable substance such as a gas, and of which is at a certain temperature. If the temperature of the gas changes changes, the pressure of that gas will change if the volume is held constant, and therefore, the mass and density of that gas will still be the same.

When water is heated to its boiling temperature, the liquid water has much thermal and kinetic energy in its molecules and the hydrogen bonds of water molecules begin to break apart into separate water molecules. At the surface of the water, these water molecules will rise upward in the air as (cloudy, foggy, misty) steam which is also called water gas, and this has a very low density and a high thermal or kinetic energy. Some train engines use steam to turn its wheels which then moves (here, pulls) its heavy load of train cars on the train tracks. The steel train tracks have a hard, low friction surface.

Extra: The density of the space in a pure vacuum having no matter in it is 0.

density in a vacuum = m / V = 0g / V = 0

Even though a perfect vacuum has 0 mass within its volume, it may have energy traveling through it such as heat (ie., infra-red light), invisible radio waves (RF) and other various types of radiation, and visible light.

Ocean or sea water has on average 35 grams of **salt** (table salt, sodium chloride) per (1000g = 1 Liter). This is said as being: 35g salt / 1000g sea water = 0.035 salt = 3.5% salt by mass and-or weight since weight and mass are mathematically, directly related and proportional in values. 1lb of ocean water will have: 1 lb = 16 oz , and 16 oz (0.035) = 0.56 oz = slightly more than half an ounce of salt. 1 cubic foot of ocean water will have: 1 cubic foot of typical ocean water weighs about 62.4 lbs. 62.4 lbs (0.035) = 2.184 lbs of salt.. 1 gallon (= ~4 liters) of typical ocean water weighs about 8.34 lbs. 8.34 lbs (0.035) =~ 0.292 lbs = almost 30% or about 1/3 of a pound of salt. Salt can be obtained from ocean or sea water by evaporating the water while leaving minerals such as salt. If the evaporated water is condensed by cooling it and then collected in a container, it is vital and healthy drinking water which is typically called distilled or evaporated water.

Ocean or sea water contains many dissolved mineral and gas elements. The weight of these minerals is about 40g/kg mass of sea water, hence about 40g/L volume of sea water. Mathematically, this is about 4% of the sea water being dissolved minerals. 1L = 1000cc =~ 1000g sea water. 1000g (0.04) = 40g. Some of these elements and-or minerals come from land and-or soil erosion due to weathering, and some are from deep in the earth being expelled by volcanoes and undersea vents. Deep water also has different amounts of minerals than near the surface. About 86% of the dissolved (about 4% of the total weight of the water) elements are sodium (55%) and chloride (31%) which compose the (table or food) salt or sodium-chloride molecules. There is then about (100% - 86%) = 14% of other dissolved elements which have a total mass of about 0.57g/L, and some averaged values for that 4g of minerals are: magnesium (3.7%), sulfur (7%), calcium (1.2%), potassium (1.1%, and bromine (0.2%). There are many lesser or trace values of other elements in the water, such as gold, silver and uranium. Iodine (50ug / 1L. An iodized fortified (additive) salt has 45ug of iodine / 1 gram of salt , and the **RDA of iodine is typically noted as about 140 mcg of iodine / 1 day for an adult**, however twice as much and-or slightly more is often consumed by some people. Many of these minerals such as lithium metal are obtained after the evaporation of the plain or fresh water ($H2O$) from the sea water and-or its dense brine (high in salts such as created after desalination to make fresh water) at large and shallow depth ponds in hot, sun heated surface regions on the Earth. Brine is obviously much higher in mineral content than common sea water. **Selenium** is often taken with iodine if needed, and at about the same RDA dosage or amount. To be safe in terms of health, ask your doctor about taking each specific nutritional supplement.

Most sea life usually contains higher levels of iodine than land based life. **Seaweed** absorbs and effectively concentrates the iodine atoms so as to have a high amount per gram of it, especially when dried with its water content greatly reduced by drying (evaporating) it, and then it having about [(1000 mcg = 1mg, or more) / 1 gram] = (1g / 1 kg) of dried seaweed. Due to the high levels of iodine in seaweed, too much of it can eventually cause iodine toxicity and thyroid problems if intake (ie., eating of) is greater than that of the RDA. 1g of dried seaweed contains abut 12.5mg of potassium, 3.7mg of calcium, and 0.25mg of iron. Kombu Kelp is said to be the seaweed highest in iodine at nearly 3000 mcg = 3 mg of iodine in its dried form at 1 gram = 1000 mg.

When ocean water is evaporated so as to make (food grade) sea-salt, many of these elements or minerals will be in that salt. Some companies even sell fortified salt for nutritional needs. The majority of the iodine will evaporate or "gas out" since it is so volatile, and it be lost unless it is somehow collected, and due to this fact, even sea-salt that is purchase if often fortified with iodine.

Because of the (dense) minerals in sea water, its density (m/V) is greater than that of plain or pure water which is 1kg/1L. The pH of sea water averages at about 8.0, hence it is slightly alkaline. (base). Just like freshwater, sea water which contains salt still has bacteria in it, and potentially dangerous bacteria in the areas of raw sewage disposal into the ocean. Due to this, filtering, boiling and or using chlorine in the water will reduce and-or eliminate any possible and dangerous germs, however the chlorine in the water then needs to then be removed by heating it or letting it sit for several hours, say 8 hours or more, and "gas-off" (evaporate out from).

RELATIVE SIZES OF AN EQUAL AREA CIRCLE AND SQUARE

In the figure below, a square and circle are both centered about the same point which is the center point of the circle.
[FIG 308]
By observation, we can see that the circle is sometimes wider than the square, and the square is sometimes wider than the circle, yet their areas are the same. Note also that neither is completely within the other and-or completely surrounded by the other. Notice that all of the 8 overlapping segments are equal in area. The radius of the circle is slightly longer than half the side of the square, and which is then S/2. $r > (S/2)$. The radius of the circle is slightly shorter than half the diagonal of the square, and which is then D/2 . $r < (d/2)$.

To help make the analysis slightly easier, lets make both the areas equal to 1 square unit of length = 1 unit^2 .

$Ac = 1 \text{ unit}^2 = (pi)\, r^2$ solving for r, the radius when the area is 1 unit^2, we have:

$r = \sqrt{1 \text{ unit}^2 / (pi)} = \sqrt{0.318309886 \text{ unit}^2} = 0.564189583 \text{ unit}$

Dc = diameter of the circle= $2r = 2\,(0.564189583 \text{ unit}) = 1.128379167 \text{ unit}$

$As = 1 \text{ unit}^2 = s^2$ solving for (s), we have:

$s = \sqrt{1 \text{ unit}^2} = 1 \text{ unit}$

Half of s = 1 unit / 2 = 0.5 unit , and this length is shorter than (r), and the difference is:
0.564189583 unit - 0.5 units = 0.064189583 unit, and twice this distance is: 0.128379166 and this value is also the difference between the diameter of the circle and the side length or diameter of the square.

The diameter of the square is Ds = s =1, and this is shorter than the diameter of the circle by a value of:
1.128379166 unit - 1 unit = 0.128379166 unit , and this is equal to two of the widest parts of the circle that are opposite of each other, and is longer than the square. Each part is half of this value and is:
0.128379166 unit / 2 = 0.064189583 unit

The diagonal of the square is: $z = \sqrt{(s \text{ units})2 + (s \text{ units})^2} = \sqrt{2\,(s \text{ units})^2} =$

$\sqrt{2}\ \sqrt{(s \text{ units}^2)} = (1.414213562)(1 \text{ unit}) = 1.414213562 \text{ unit}$

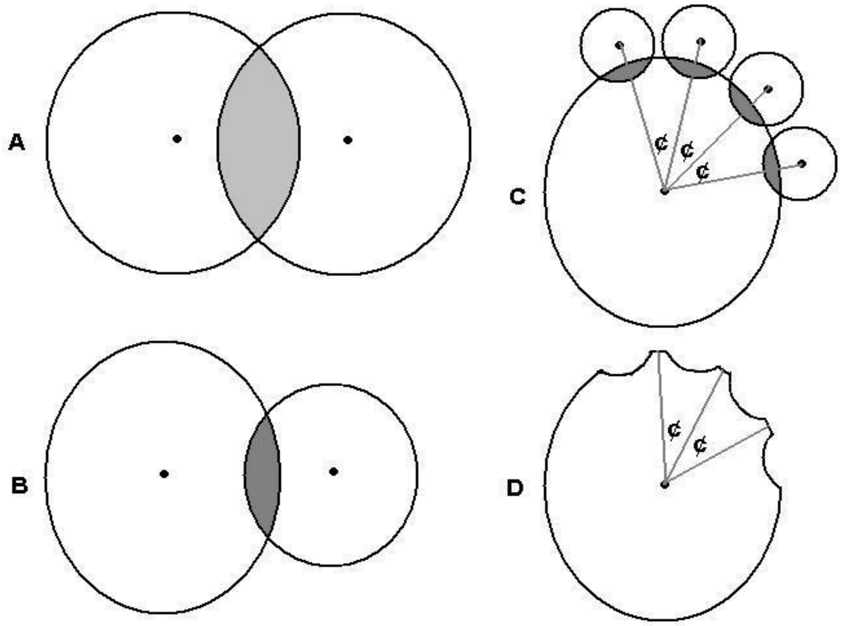
The diagonal of the square is larger than the diameter of the circle by:

1.414213562 unit - 1.128379166 unit = 0.285834396 unit , and half this distance is the longest distance between the circle's circumference and the corner of the square. 0.285834396 unit / 2 = 0.142917198 unit

Extra: If the 4 corners of the square were removed, and the 4 edges of the circle were removed, the result is a rectangle (here, a special instance of a rectangle called a square with 4 equal side lengths)with rounded corners who radius of curvature is that of the radius of the circle. A square with rounded corners is called a **squircle** which is a word created by the combined words of: "square" and "circle". The curved corners can have any radius of curvature. A squircle is a special instance of a **rounded-rectangle**.

Extra: The following geometric shape is created at the intersection of two circles, usually of the same diameter, however, they need not have the same value. The portion of each circle not overlapping is called a **Lune** (ie. Moon) or crescent shape. **Venn diagrams** use these shapes to show and compare amounts in a simple and relative way.

[FIG 309]



A: Intersection of two circles having the same radius. The intersection of the two circles that coincide is colored gray and it is formally called a **Vesica Piscis** which is the Latin words for "bladder" and "fish", hence "fish bladder" shaped, and which can alternately be called the "**fish-shape**". When the radius of each circle is the same, the same portion or area (here the fish-shape or fish-shaped area) of each circle is intercepted.

B. Intersection or overlapping of two circles not having the same radius. The radius of curvature of each side of the fish-shape is therefore different.

C. Shows a basic example of how a certain type of gear shape can be drawn, here a sprocket gear for a bicycle chain to transfer the input power to the wheels. The centers of each smaller circle are offset by the same angle.

D. Shows the intersections of the two circles removed so as to obtain the gear teeth shapes.

A STUDY OF CHANGES IN AREAS OF CIRCLES AND SQUARES, AND INTEGRATION TO FIND A SQUARE AREA

Note the different equations for circle area or square area when a value has changed:

Area of a square = As = A1 = s1^2 **,** after solving for s: s1 = $\sqrt{A1}$ = and in general: s = $\sqrt{As}$ **:**

If the area of the square has changed by a factor of (n), we need to multiply each side of the equation for the area of that square by the factor of (n):

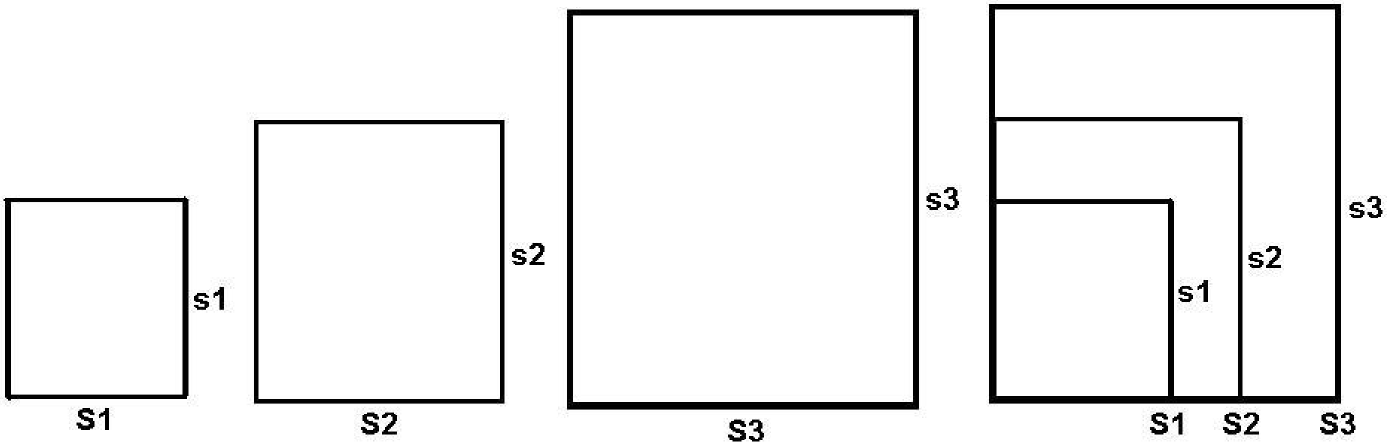
n (Area of a square) = n A1 = n s1^2 = A2 = s2^2 , after solving for (s1): s2 = $\sqrt{n\ s1^2}$ = $\sqrt{n}$ s1

We see that if area of a square has changed by a factor of (n), then the side of that area will change by the square-root of that factor = $\sqrt{n}$

If the **side (s1) of a square** has changed by a factor of (n), we need to multiply (s1) by that factor of (n):

A2 = s2^2 = (n s1)^2 = n^2 s1^2 = n^2 A1 , and the result is that area of the first square = A1 = s^2 had increase by a factor of n^2 when its side (s1) has increased by a factor of (n).

A2 / A1 = n^2 , mathematically: A2 = n^2 A1 , and we see that when the side (s1) of a square changed by a factor of (n), that the area will change by a factor of n^2. [FIG 310]



If the side length increases by a factor of (n), the area will increase by n^2

A1 = 1 unit^2
A2 = 2 (A1) = 2 (1 unit^2) 2 unit^2
A3 = 2 (A2) = 2 (2 unit^2) = 4 unit^2

If area increase by a factor of (n), the side has increase by $\sqrt{n}$

s1 = 1 unit
s2 = (s1)($\sqrt{2}$) = (1 unit)(1.414214) = 1.414214
s3 = (s2) ($\sqrt{2}$) = (1.414214) (1.414214) = 2

Area of a circle: Ac = A1 = (pi) r1^2 , after solving for r1: r1 = $\sqrt{A1 / (pi)}$: (pi) = 3.141592654
In general: r = $\sqrt{Ac / (pi)}$

If the area of the circle has changed by a factor of (n), we need to multiply each side of the equation for the area of a circle by the factor of (n):

n (Area of a circle) = n A1 = n ((pi) r1^2)) = n (pi) r1^2 = A2 = (pi) r2^2 : also, A1 = A2 / n

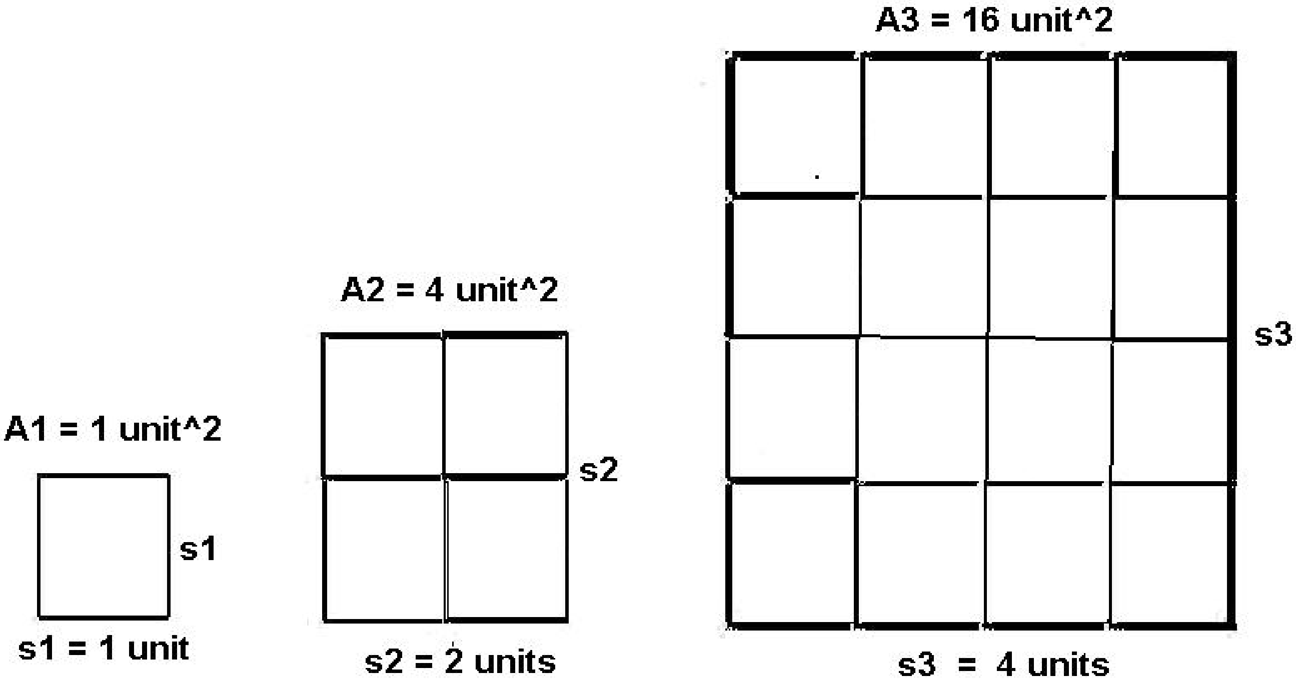
After solving for (r2): $r2 = \sqrt{n\ r1\text{^}2} = \sqrt{n}\ r1$, and we see that if the area of a circle has changed by a factor of (n), then the radius has changed by a factor of:

$$\sqrt{(n)}$$

If the **radius (r) of a circle** has changed by a factor of (n), we need to multiply (r) by that factor of (n):

A2 = (pi) r2^2 = (pi) (n r1)^2 = (pi) n^2 r1^2 = n^2 (pi) r1^2 = n^2 A1 , and the result that if the radius changes by a factor of (n), then the area will change by a factor of n^2 .

An analysis of the rate of changes between the sides of squares and the corresponding areas.



The equation for the area of a square is: Area = side^2 , or simply: A = s^2

When s=1: A = s^2 = side^2 = (side)(side) = (1 unit)(1 unit) = (1 unit)^2 = (1)(1)(unit)(unit) = 1^2 units^2 = 1 units^2
= "one unit square" or "one unit squared"

When s=2: A = (2 units)^2 = 4 units squared = (2 units)(2 units) = 4 units^2 = "four square units"

When s=3: A = (3 units)^2 = 9 units^2

When s=4: A = (4 units)^2 = 16 units^2

The equation for area has a general equation form of: y = x^2 or y = f(x) = x^2

The above equation is a second order equation like a parabola is. The equation is also called a power equation, and here the indicated power is 2. As the independent variable, here it is (x), changes when it is greater than 1, the value of the dependent variable, here it is (y) of this equation changes or increases in value rapidly.

When the side (s) changes by a factor of n=2, the area changes by the square of that factor: n^2. = 2^2 = 4
When the side (s) changes by a factor of n=3, the area changes by the square of that factor: n^2 = 3^2 = 9
When the side (s) changes by a factor of n=4, the area changes by the square of that factor: n^2 = 4^2 = 16

When the side (s) changes by a factor of n= 1.5, the area changes by the square of that factor: n^2 = 1.5^2 = 2.25

Since this equation is not a linear (ie., a line equation) equation having a constant slope or rate of change in the dependent variable with respect to the independent variable, the rate of changes is not constant for similar increases in the independent variable (here s = side length).

$$\text{slope} = \text{rate of changes} = \frac{\text{change in dependent variable}}{\text{change in independent variable}} = \frac{\text{(change in area)}}{\text{(change in side)}} = \frac{\Delta A}{\Delta s}$$

Ex. $\text{slope} = \dfrac{(1 \text{ units}^2 - 0 \text{ units}^2)}{(1 \text{ units} - 0 \text{ unit})} = \dfrac{1 \text{ units}^2}{1 \text{ unit}}$: When s = 0, area is changing by 1 units^2 for each unit increase in (s). When s=1 unit, A = 1 unit^2

Ex. $\text{slope} = \dfrac{(4 \text{ units}^2 - 1 \text{ units}^2)}{(2 \text{ units} - 1 \text{ unit})} = \dfrac{3 \text{ units}^2}{1 \text{ unit}}$: When s = 1, area is changing by 3 units^2 for each unit increase in (s). When s=2 units, A = 4 units^2

Ex. $\text{slope} = \dfrac{(9 \text{ units}^2 - 4 \text{ units}^2)}{(3 \text{ units} - 2 \text{ unit})} = \dfrac{5 \text{ units}^2}{1 \text{ unit}}$: When s = 2, area is changing by 5 units^2 for each unit increase in (s).

Ex. $\text{slope} = \dfrac{(16 \text{ units}^2 - 9 \text{ units}^2)}{(4 \text{ units} - 3 \text{ unit})} = \dfrac{7 \text{ units}^2}{1 \text{ unit}}$: When s = 3, area is changing by 7 units^2 for each unit increase in (s).

Since the slope is constantly changing along the curve that graphically shows the relationship between the variables , it is not even a constant for a change of 1 in the independent variable, and is in fact, here with a non-linear equation, the slope is for only two very close points on the curve, and of which the change in co-ordinates and-or changes in values is very small, and is a just small fraction of a unit.

When the changes are very low in value, and approaching a value of 0, this is called the instantaneous rate of changes, hence the (instantaneous and-or unique value of) slope on the curve. The small change in (x) is named dx for the differential or difference in (x), and the corresponding small change in (y) is named dy. This instantaneous rate of changes is formally called the derivative of the equation, and this book shows how to find it given the equation or function. For a linear equation, the derivative is a constant numeric value, but for an equation such as y = x^2 or area = side^2 , the derivative is not constant, but depends on the specific value of (x), the independent variable. For higher order equations other than the linear equation, the derivative is another equation. The derivative of a parabola, quadratic or second order equation is a linear equation.

The derivative of a function of (x) with respect to (x) $= \dfrac{d\,f(x)}{dx} = \dfrac{dy}{dx}$ = "instantaneous slope" at a point on curve

The equation or function of the area of a square with respect to the side of that square is: A = s^2

The derivative of the function of the area of a square with respect to the side of the square is: $\dfrac{dy}{dx} = \dfrac{dA}{ds} = 2\,s$

For example, when s=3, A = s^2 = 3^2 = 9 and the slope at (y, x) = (A , s) = (9 , 3) is dA / ds = 2s = 2 (3) = 6

Given: dy / dx = dA / ds = d(s^2) / ds = 2s , mathematically:

dA = 2s ds , integrating both sides = summing (S) up all the small bits of, so as to have the whole thing:

$A = S\,dA = S\ 2s\ ds$: indefinite or "unbound" (no boundary values) integral, or sum producing the whole thing and not a bound portion, section or part of it, here the area.

$A = S\ 2s\ ds$, hence the value on the right side is equal to the function or equation for A, hence it is equal to the anti-derivative of this given derivation that is also multiplied by (ds).
In the process of converting this derivative to the original function or anti-derivative, the value of (ds) will be converted to s^1 and the value of 2s ds will get converted to s^2.

$$A = S\,dA = S\,d(s^2) = S\ 2s\ ds = s^2$$

On the curve for $A = s^2$, a small bit of area is dA . If this is considered as a thin rectangular region, it each region will have a width of ds, and a height of $A = s^2$. When all these small areas (dA = 2s ds) are summed or integrated so as to be 1 whole value, it will equal the whole area A.

For the area between s=0 and s=2, this is a bound area, and the summation or integration is called a definite integral of summation, and these limits are expressed as:

$$\underset{0}{\overset{2}{A}} = \underset{0}{\overset{2}{S}}\ dA = \underset{0}{\overset{2}{S}}\ d(2s)\,ds = \underset{0}{\overset{2}{(s^2)}}$$ = area at upper limit - area at lower limit = area in between limits =

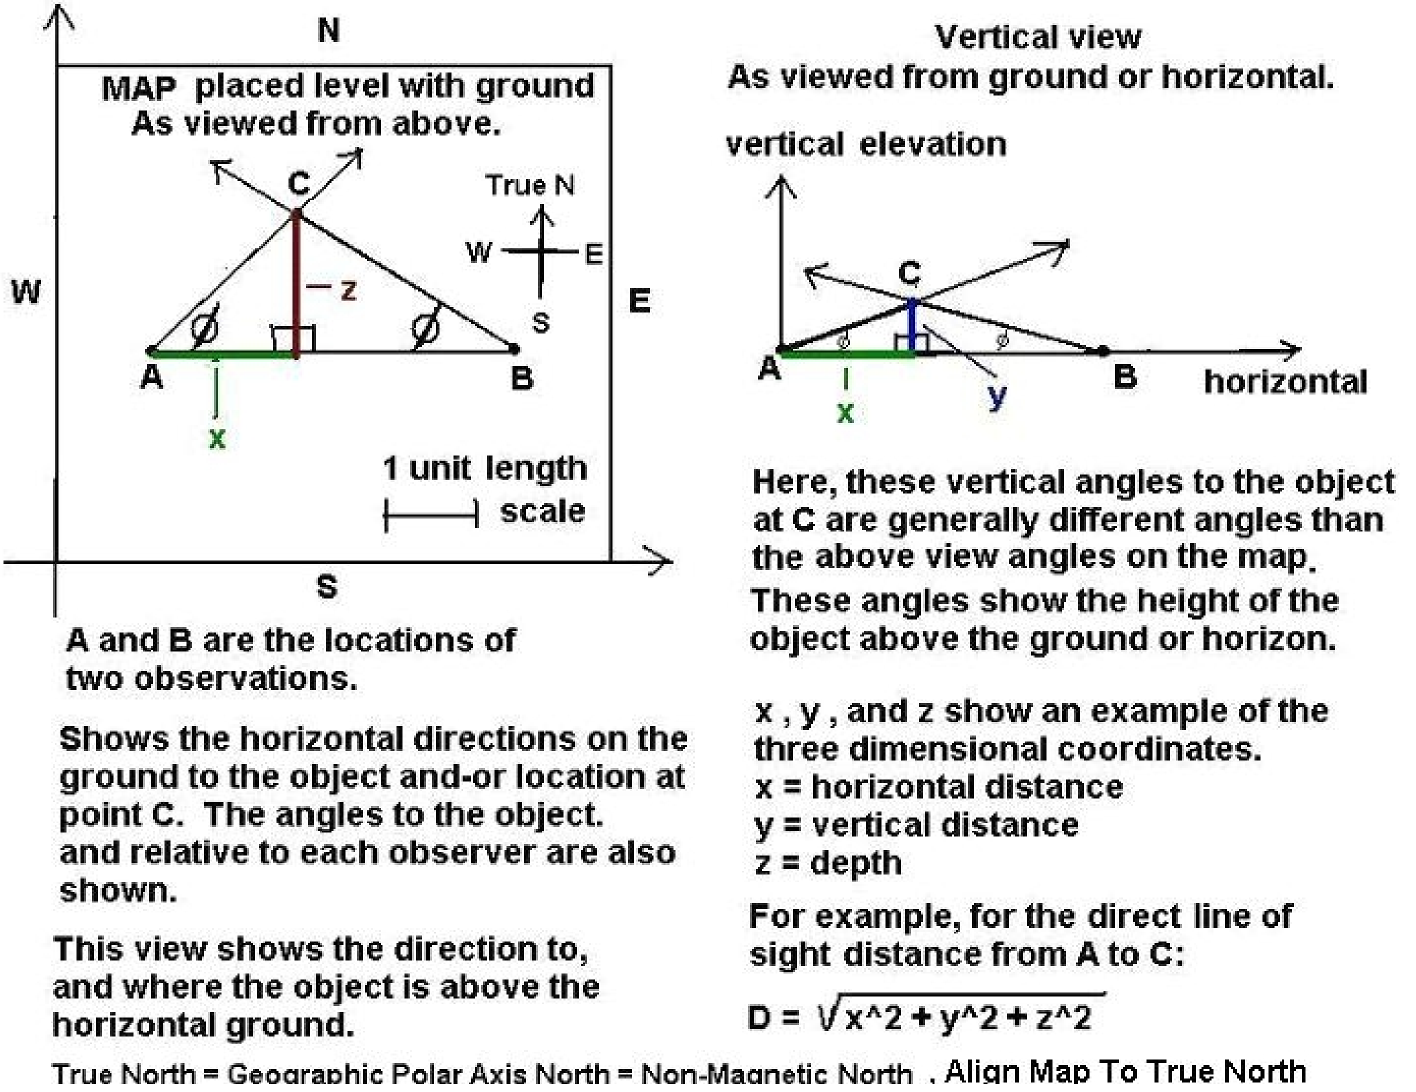
A(at s=2) - A(at s=0) = (s^2 at s=2 units) - (s^2 at s=0 units) =

(2 units)^2 - (0 units)^2 = 4 units^2 - 0 units^2 = 4 units^2

Extra: The area of a circle is: $Ac = (pi)\,r^2$ and $dA / dr = 2\,(pi)\,r$ = a linear equation, and with a length equal to the circumference of that circle. $Ac = (pi)\,r^2$ is a second order, quadratic or parabolic equation.

SOME CONCEPTS OF TRIANGULATION

Triangulation is using two or more observers to locate where an object and-or location is such as if placed on a map, and to find the distances to it. The basic concepts of trigonometry can be used for this analysis.   [FIG 310A]



A and B are the locations of two observations.

Shows the horizontal directions on the ground to the object and-or location at point C. The angles to the object. and relative to each observer are also shown.

This view shows the direction to, and where the object is above the horizontal ground.

Here, these vertical angles to the object at C are generally different angles than the above view angles on the map. These angles show the height of the object above the ground or horizon.

x , y , and z show an example of the three dimensional coordinates.
x = horizontal distance
y = vertical distance
z = depth

For example, for the direct line of sight distance from A to C:

$$D = \sqrt{x^2 + y^2 + z^2}$$

True North = Geographic Polar Axis North = Non-Magnetic North . Align Map To True North

If each observer has a directional compass, they can state the horizontal (ie., ground level) compass direction (N,S,E,W, degrees, etc) that the object is seen at. They will both need to measure or estimate the angle the object is seen above the horizon, hence the vertical angle. If possible, these compasses should be adjusted to true north since the magnetic north pole of which a mechanical, magnetic compass and-or a phone APP (ie., an application = program) compass senses is usually several degrees off from that true value. True north is in the same direction of the North Star, Polaris. The distance between the observers can be calculated by the map and-or calculated using the longitude and latitude coordinates of each. Many modern phones are capable of using an APP for an electronic compass device, however the value or direction returned is usually in terms or in reference of the magnetic north pole. It is possible some APP's might be able to convert this value to be in reference to true north if their longitude and latitude is known - perhaps indicated by a map and-or by GPS (Global Positioning Satellite) of which many phones can activate (a setting and-or an APP) and receive.

THE EFFECTIVE RESISTANCE OF A DIODE

A typical diode circuit consists of a supply voltage and the diode in series. If the supply voltage is equal to the diodes junction or barrier voltage or conduction (ie., considered "on") voltage, then no series resistance is needed to limit the current to it, otherwise if its is greater, then a current limiting, "safety resistor", is needed or the diode will be destroyed by having too much current flow through it, causing much power and thermal heat energy in it. A typical, non-light emitting, silicon diode has a turn-on voltage of 0.7v, and it will actually produce some low frequency light of which we cannot see, but possibly feel as an increase in temperature. This "invisible light" is called infra-red light and-or thermal radiation, and of which can be seen by special cameras that have thermal image sensors.

In general, the lower the frequency of color, the lower the led turn-on voltage. Red LED's have a turn-on, conduction or forward voltage of about 2v, yellow LED's have a turn-on voltage of about 2.25v, green LED's have a turn-on voltage of about 2.5v, and blue LED's have a turn-on voltage of about 3v and up to 4v. The higher the frequency and its resulting color emitted, a higher amount of energy (Joules) is needed by an electron to produce a photon (ie., a light particle and-or wave, hence a single wave of RF [Radio-Frequency = electro-magnetic] energy), and so the LED is then designed so as to have a higher turn-on voltage and-or electric field across the junction. When an electron gains kinetic energy due to the electric field it is in and leaves its orbital position about the atom, it will loose its gained kinetic energy as a photon of light energy when it falls back into an orbit about an atom.

White is not a color, but is a combination of colors such as red, green and blue (RGB) as seen when white light passes through a glass prism and produces a rainbow of colors. To produce a white light LED, three tiny LED's - red, green and blue, and of which are very close to each other, can be used to effectively combine or mix their output colors and-or frequencies and which will effectively appear as white light. Another method to produce white light is by doping (including) the LED semi-conductor material with various trace amounts of certain elements and-or using certain layers of material on the semiconductor so as to be used as light and-or filters, and-or to re-emit or radiate the input light energy as another color (ie., frequency).

White LED's typically require a turn-on or forward (ie., properly biased) operating voltage of 3V and 20 mA of current for a reasonable amount of light. Up to about 4V and 35 mA may be possible with some white LED's. Voltage higher than about 5V can damage a white LED. As compared to many standard, non-light emitting diodes, the reverse bias breakdown voltage (ie., where it starts conducting when reversed biased) is a fairly low value at only 5v. Placing a standard 0.7v or regular (non-light emitting) diode to be biased in reverse, and also having a high reverse bias breakdown voltage in series and-or parallel with a LED will help protect that LED. When the reverse bias is applied to this circuit, the 0.7v regular diode will behave like a very high resistance and will protect the LED by not allowing current to flow through it.

Because there is a voltage drop across a diode, and there is a (limited amount) current flowing through it, there is therefore an amount of power supplied and-or used by that diode and its will have an increase in temperature. The limited amount of current through a diode indicates that it has some amount of resistance, and when the forward bias or operating voltage is applied across it.

When the forward bias applied to a diode is less than its rated turn-on voltage, it will still be partially on and a lower amount of current will passing through it. The lower the applied voltage across it, the lower the resulting current through it.

Effective resistance of a diode = $Rd = \frac{Vd}{Id}$: The slope of the Id with respect to Vd curve is the conductance (Gd mos) value of the diode, and this is equal to (1 / Rd ohms)

Effective resistance of a white LED = $Rd = 3\text{ v} / 0.020\text{ A} = 150$ ohms

At 0v across a diode, it is completely off, and its resistance is very high and is similar to an open circuit. As the supply voltage and-or forward bias voltage across the diode increases, it begins conducting, but the slope or rate of change of current through it with respect to the voltage across it is low and is almost linear in nature. Once the turn-on voltage is reached, the junction region of the diode will drop significantly in resistance and this will allow much more current to flow through it in an exponential like manner . As the bias voltage increases further, this junction and-or semiconductor resistance remains at nearly the same value, and this effect is sometimes used to provide a stable ("reference") voltage and-or voltage regulation for devices across and-or in parallel to it.

The theoretical luminous or light conversion efficiency from electricity energy to light energy is about 325 lumens / 1 watt = 325 lm / W. A typical 5mm white light LED will produce about 100 lm / W, and is about 40% to 50% efficient at converting the input electrical energy to light energy, and the remaining 50% is wasted as thermal energy (heat). By slightly increasing the current to an LED, it will produce more light, but if too much current goes through the LED and or it exceeds (I max. = maximum current) of the LED, it can burn out.

energy conversion efficiency of an LED at producing light = P out / P in = output light energy / input electrical energy =
= light or luminous efficiency of an LED.

Ex. If a 3v LED is rated at 40 lm at 30 mA of current, how many lumens per watt does it have?

First, lumens is a measure of the total amount of light produced by a device. Also what needs to be considered that with a light concentrator (ex. lens) and-or reflector (mirror, director near the LED chip), a high percentage of all that light can be formed into a more narrow beam of light and having a beam angle of emission, radiation or dispersion and therefore concentrated upon an object or surface, and it will then appear brighter as if the source or flashlight was actually a brighter or intense point source, and the illumination from a certain flashlight or lamp may be rated this way, and its rating is actually then the apparent or equivalent amount of light intensity and-or brightness, yet the power to the LED and the total amount of light energy produced remained the same.

Also: 20 lm at 30 mA could be expressed as: 20 lm / 30 mA = 0.67 lm / 1 mA or= 667 lm / 1A

Pled = P in = (V led) (I led) = (3v) (0.030 A) = 0.090 W in : input electrical power to the LED =
power used and-or lost by the LED

lm out / P in = 20 lm / 0.090 W , after dividing num. and den. by 0.090, we have
lm / W = 222 lm / W : electrical energy to luminous energy conversion efficiency

Series and-or parallel LED's.

LED's can be placed in series and-or parallel electrical connection and both have their own advantage. If the LED's are all the same, and generally should be, then each will require and-or use the same amount of power, say 60mW each:
If one series LED burns out, the entire string or branch of LED's will not receive any current and will be useless. LED's in series require a higher supply voltage. LED's in parallel require more current, hence more drain of charge from a battery.

Pled = (Vled) (I led) = (3v) (0.020A) = 0.060W = 60 mW

Total power used for (n) LED's equals the sum of the power of each, and since the power of each is the same value, we can use multiplication to represent this repeated addition of the same value. If there is an array of 10 LED's:

Pt = (n LED's) (60 mW / LED) = (10 LED's) (60 mW / LED) = 600 mW = 0.6 W

If the voltage supply is 120v, how many LED's can be placed in a string or series of these LED's, and how much current will be needed ?

120V / (3v / LED) = 40 LED's

Since the LED's are in series, the current going through 1 LED will be the same amount of current going through them all. A typical LED will need about 20 mA to 25 mA of current to produce, perhaps about 90 lm to 100 lm.

The total power needed by these 40 LED's is: Pt = (40 LED's) (60 mW / LED) = 2400 mW = 2.4 watts
The total amount of lumens at 90 lm / LED = (40 LED's) (90 lm / LED) = 3600 lm
3600 lm / 2.4 W = 1500 lm / W : compare this to many incandescent bulbs at only 15 lm / watt

[This space for book edits.]

Exploring The Energy Conversion Efficiency Of A Light Emitting Diode (LED)

An LED converts electrical energy and-or power (energy/time, a usage rate) to light energy and-or power. The better or more that LED can convert its input power to output, light power, the better its (energy) conversion efficiency. We should desire LED's with a high conversion efficiency because they will produce more light, be brighter and produce less wasted energy (usually as heat or thermal energy). The conversion efficiency an LED light (ie., "a bulb") is much higher than that for an incandescent light (bulbs). A high conversion efficiency also means less input power will be needed to produce the same amount of light, hence there will be an energy and cost saving with the lowest (total system cost / watts output) ratio.

Scientists have done analysis, experiments and calculated that:

1W of power = 643 lm : lm = lumens, a unit of light energy per unit of area, hence an "energy density" or "energy concentration". 1W = 1J / 1S. This value indicated is a true energy equivalency, and does consider conversion efficiency and any energy losses. Therefore, this value does not mean that 1W of input electrical power will produce 643 lumens of light, and this is so when the conversion efficiency is less than 100%.

From the above equation, mathematically:

1 lm = 0.001555209 W =~ 0.001555 W =~ 1.5mW light power

For a common 5mm wide, clear plastic white light LED, a typical rating is:

100 lm LED , multiplying both sides of the above equation by 100:

100 (1 lm) =~ 100 (0.001555W) = 0.1555 W of light power if there was 100% conversion efficiency , hence

0.155W / 100 lm = 0.00155 W / 1 lm

Input power for a common 5mm wide, clear plastic white light LED =

Pw = (V led)(I led) = (voltage across the led) (current through the led) = (3V) (0.020A) = 0.060W = 60 mW

100 lm / 0.06W = 1667 lm / W = 1 lm / 0.0006 W : actual light amount created and corresponding power used

From : (actual output light power) = (conversion efficiency) (ideal light power)

$$\textbf{conversion efficiency} = \frac{\textbf{actual output light power}}{\textbf{ideal light power}} = \frac{0.0006\text{ W / 1 lm}}{0.001555\text{ W / 1 lm}} = \frac{0.0006\text{ W}}{0.001555\text{ W}} = 0.385\underline{9} \;=^{\sim}\; 38.6\%$$

If an LED can be made to have a lower internal resistance, there will be less heat energy loss in it, and it will have a higher lumen rating with the extra current going through it. Technically, if an electronic device has a lower resistance, the voltage drop across it will be less, but this is not so with an LED because the (PN semi-conductor diode junction) barrier voltage is still the same at about 3v for an LED to function. With a slightly lower internal resistance of the LED, a slightly higher amount of current will flow through it, and this will produce an increase in the electrons flowing through it and the photons being created by those electrons, and therefore, the number of lumens will increase. Given the number of lumens per watt = (lm / W) = lm / (Vled I led), and if the voltage across the LED is the same, and the current increases, the amount of power used will increase. An LED with a higher lumen and-or brightness rating might not even have a higher conversion efficiency, but rather it uses more battery power (perhaps with a slightly higher than 3v applied), and therefore, it will drain the battery in a shorter amount of time, and the only benefit is a brighter LED and-or flashlight, but for a lesser amount of time of use. For any flashlight or energy consuming device, the less time it is used per instance, the more total time span of potential use and the number of instances it can be used before there is not enough battery power for it to function.

White light LED's can obtain a higher conversion efficiency by using more efficient phosphors, etc. in the LED's construction.

A white light LED can be powered by using two 1.5v batteries in series, and therefore having a total voltage of 3v, but that LED will not function until the battery is drained of charge and is 0v, but perhaps will it will function to as low as to 2.5v, and then the LED will not have enough voltage across it to function, and it will become a high resistance or like an open circuit with very low current through it. If the LED was replaced with a resistor, the terminal voltage of the supply battery will remain fairly high if the current or charge drain is low, but the voltage and charge available will eventually decline at a rapid rate, and the power available may be insufficient for some electrical device to function, even if the output voltage of the battery is only 1 or 2 volts less than the rated version of the battery. Many lead-acid batteries are considered drained at this point and need to be recharged before being damaged by further use and-or excessive current. Lithium-ion or Lithium-iron batteries are known for supplying more energy and-or power, hence watt-hours (wH) at or near the rated voltage of the battery for longer than many other batteries, and this is due to the low internal resistance of lithium batteries, and of which will waste less power as the circuit current must also pass through it.

An LED can be pulsed by a higher voltage, say 6v and appear as brighter, but only if the pulses are quick, hence if a low duty cycle (= on time of use / total time) of energy and-or power is used. The pulses of energy will be brief, but powerful (P = VI) and temporarily more brighter since the number of photons produced is directly related to the current flowing. The average power loss in the LED should still be kept lower than its maximum rated power and-or thermal ability. Will the LED appear to flicker? Yes if the pulses are slow, but some remedies are to use a capacitor (that stores some charge) in parallel to the LED to help reduce the flicker, and-or increase the frequency of the pulses, and of which will require some type of oscillator circuit. Humans have a persistence of vision for about (1/60) of a second, hence if the pulse rate is over 60 cycles per second, we will not generally notice it. A "joule-thief" (ie., voltage booster, here, a basic type of "switching regulator") LED light circuit can boost the voltage and apply it across LED, and from a low supply voltage supply of say 1.5V or even less, and so as to be 3v or more volts, and it creates at pulsed signal at a frequency of tens of kilohertz.

Part of the inefficiency of an LED is also due to internal absoprtion and-or reflections of where the light is converted to heat energy. Modern (as of the year 2000) LED's are now being redesigned and manufactured to help reduce internal light or photon losses, and this will increase the lumen output of an LED, and decreaae the heat losses. The end result is greater electrical conversion (here, electricity to photons) efficiency of an LED.

BATTERY BASICS CONSIDERING THE GALVANI-VOLTA CELL

In 1600, **William Gilbert** invented the first **electroscope**, and of which was like a magnetic compass, but it rather sensed electric charges rather than a magnetic field and-or direction to the north. Charged metal plates will attract each other if they have the different electric polarity and-or charge, and if they have the same electric polarity and-or charge, they will repel each other. An electroscope can be used to sense and-or measure an amount of charge, and the polarity or type of charge. Because the needle or foil can move in an electroscope, it also shows that (electrostatic, charges at rest, not moving) electricity can apply a force and induce (ie., cause) the motion of another object (even if its not charged, and this is called electrostatic induction, and is analogous to magnetic induction of a piece of metal), and this is similar to how magnets can attract or repel depending on their magnetic polarities used of the magnet's two ("North" [so called because that end of the magnet point or gives direction to the north (magnetic) pole of the Earth] or "South" pole) (magnetic) poles, and of where the magnetic field was more concentrated. The electroscope made measuring small amounts of charge practical, unlike for example measuring the length of a high voltage spark. Practical circuits use relatively small amounts of voltage and therefore charge (ie., later found to be electrons with and-or carrying that charge in a wire). **Electricity** and-or electric power eventually got its name from the fact that electrons, each with kinetic energy, transfer that energy and-or power from one location to another.

By the 1700's people began experimenting more with the mystery of electricity, and knew that non-metallic items such as amber, silk, fur could produce a charge when friction was applied to them and-or when these materials were rubbed together. In 1745 a practical way to store charges was invented, and it was called the **Leyden Jar**, and of which is basically two metal plates with a non-metallic, item such as glass in between them. Today,we call such a device a capacitor or charge capacitor since it has the ability to can store an amount of charge. The amount of charge it is storing is called the capacity or capacitance of charge. This non conductor between the plates ensured the charge could be maintained on those plates and not neutralized or vanish as would happen if they made contact. This "insulator" material between the plates is also called a dielectric material and-or a dielectric plate, and this description is due to it not promoting the flow of electricity, however it could very also mean that each side of the plate will l have a different electric polarity. Even though it does not conduct charge and-or electricity well, if any, it can be charged to have an electric polarity (positive or negative) on each side. Charged metal plates will attract each other if they have the different electric polarity and-or charge, and if they have the same electric polarity and-or charge, they will repel each other.

After the discovery of the Leyden Jar and its ability to store charge, more people began became interested in electricity, and particularly with charges on metal surfaces, and the amount of charge. One new inspired device was called the electrophorous which was essentially a metal plate having a wooden handle in the center, and one plate made of wax type substances resting on a table, and this device could be used to create charge and store it. This was created in 1762 by **Johan Wilcke**, from Sweden. The famous **Alessandro Volta** was inspired by this and began a study of electricity.

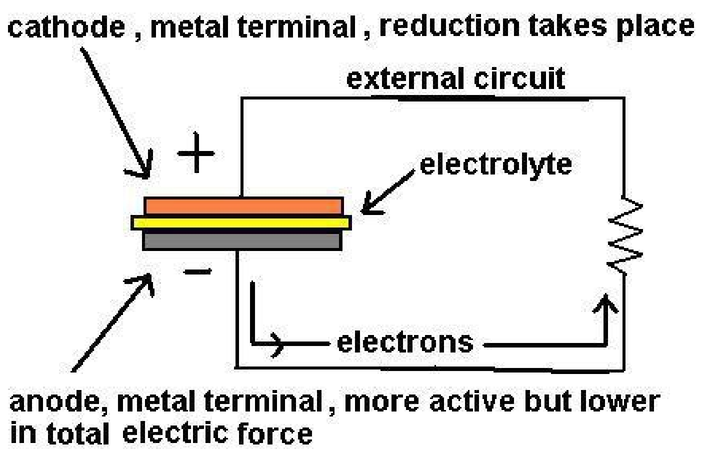
In 1782, **Volta** studied the relative amount of force of attraction or repulsion of charges on two electric plates and-or a Leyden Jar (capacitor) using an electroscope and concluded that more charge caused more force and-or motion of the electroscopes plates. Later, Coulomb would also studied the force due to electric charges separated by a distance and made his famous equation for the electric force due to charges, and this force is called the electric force. Volta also concluded that the amount or quantity of charge is directly related and proportional to the voltage which caused it to move, and this value is a constant which is called the capacity (C) of that specific (size, construction) Leyden Jar (capacitor). The **law of capacity or capacitance** is: **$C = Q / V$ =** (mathematically reduces to) **charge per unit volt**. Mathematically, the relative or comparative amount of charge in a capacitor can then be determined by its capacity (C) rating and the voltage applied: **$Q = VC$**. Later, voltage (electric potential energy) was found as also determining the amount of the flowing charge and giving that charge the energy to do work (ie. apply force , work = (force)(distance) = joules of energy). The total amount of energy in that charge is: (total energy) = (amount of charge)(voltage applied to the charge) = (amount of charge)(voltage [electro-motive force] causing the charge to move) = **Joules = $J = (Q_c)(V)$** , and mathematically: **$V = J / Q_c$ = (electric potential) energy per unit of charge** . The general capacity rating of a capacitor was later defined by its physical properties and was given the units of measurement called **Farads** and this rating is also a constant for a given capacitor if its physical dimensions and construction materials remain constant.

In 1785, **Martinus van Marum** , from the Netherlands, used a (high voltage) electrostatic generator to extract tin, zinc and antimony from their respective (chemical) salt forms, and this is similar to a process used later in 1807 by **Michael Faraday** for extracting and discovering sodium and chlorine gas natural (non-reducible, not a molecule) elements from sodium-chloride (a compound) which is commonly known as table salt that we put some on food and eat.

Just before **Alessandro Volta**, from Italy, invented his battery, it was noted in 1791 by **Luigi Galvani**, also from Italy, that certain muscles would have a quick movement when two dissimilar metals were applied across the nerve(s) of that muscle. This indicated several things such as what nerve signal could be, and that dissimilar metals were causing this signal, and the general concept of using two different metals for some type of (electro-chemical) reaction is called galvanic, galvanic action or galvanic-electric action. Soon afterward of this, in 1799 and 1800, Volta invented and presented the first known battery which was a stack or series of (Galvani-Volta, electrical) cells, each being two dissimilar (such as zinc and silver, zinc and copper, silver and copper, etc) metal disks with each separated by a liquid (now called an electrolyte) that aids in the current (electrons and ions) transfer between each dissimilar metal. For this to happen,there also needs to be an external circuit for the electrons to flow, and their gained (kinetic , [(mv^2)/2]) energy can be used to do power an external electric circuit.

The electrolyte liquid might be a weak acid or base (such as sodium bicarbonate) and-or simply some salt water. To retain the liquid in place, pieces of material were soaked in the liquid first, and then placed onto the "Voltaic pile" or battery. The electrolyte serves as a type of barrier that promotes the conduction of electricity and without having the two metals being in direct contact with each other which would prevent the electricity from flowing through the electrolyte substance(s). Galvani's experiment surly inspired Volta's to create the battery which is composed of many galvanic cells connected in a series arrangement to increase the voltage. If the plates were made to have a larger area, and-or several batteries were placed in a parallel electrical arrangement or connection, the current could be increased by the same factor that the area was increased. [FIG 310B]

Galvanic - Volta Cell



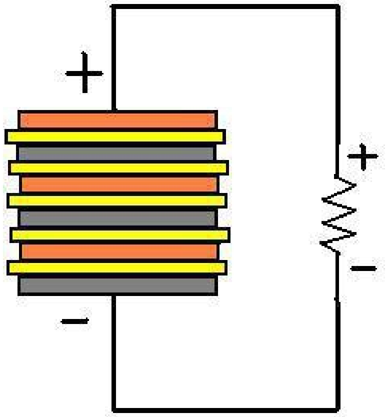
When an anode atom looses an electron, it becomes oxidized. The electron now having gained potential energy from the electrolyte and the postive electromotive force of the cathode attracting it can travel through the external circuit and power it.

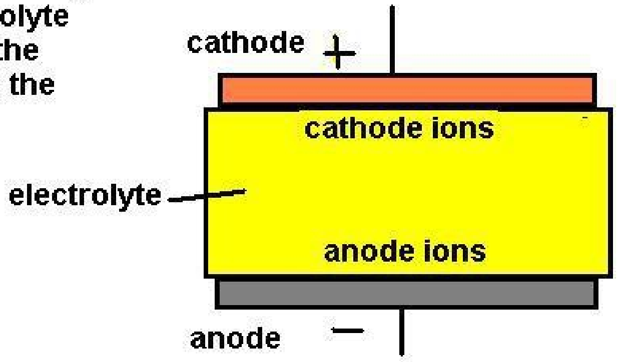
P = V I = Joules / second = watts

Example materials:

cathode: copper
anode: zinc
electrolyte: vinegar and salt water

Volta's battery or array of cells.





The word **catalysis** means to dissolve, remove, cut down, cut off, cut from or out from, and a chemical can be or cause a catalysis to happen and initiate or help promote a chemical reaction take place, hence it also causes it to happen in less time. Generally, the catalysis remains unchanged during this process, and the chemical and-or process to cause a chemical reaction is then called the (specific or particular) catalysis. Consider that even heating a substance to a higher temperature can speed up a chemical reaction.

The word "**ion**" was made by Michael Farday and Reverand William Whewell, and it basically means a particle that moves or travels from a location, and in electricity it is due to the electrostatic forces upon that (electrically charged) ion. Faraday also made the words: "electrode", "cathode" and "anode" to describe electricity.

The word "**electrode**" means an initial or terminal access point or location for the flow or movement of electricity.

Cathode is the negative pole or terminal, and this is the terminal electrons travel from. **Cat**hode **ions** are also called **cations**, A positive charged ion will move toward the negative charged cathode.

Anode is the positive pole or terminal. Anode is based on the words "path", "way" , and "up" or "to take up" (ie., or collect) and in terms of electricity, it means where the electrons are going to. A negative charged ion will move toward the positive charged anode. **An**ode **ions** are also called **anions**.

The word "**volt**" that we commonly use as a unit of electric potential energy of an amount of charge or a difference in electrical potential energy at two specific points in a circuit (which allows electricity [electrons]or current to flow) is named after Volta. Voltage = Joules of energy / Coulomb of electric charge. The more cells, placed alternately on top of each other, more voltage could be produced and the more (mysterious) electricity (today, known as electrons) would flow. Volta created a practical source of electricity. The voltage was not particularly high and useful for most experiments and purposes, but it was not as high as the (static) electricity machines already available that would rotate and accumulate a high amount of charge so as to eventually produce a high voltage spark across a short distance.

It is of note that water, which is often considered by the average person as being non-active in terms of electro-chemistry, is slightly active. Water is not a complete base (= pH of 14) or a complete acid (= pH of 0), but has a pH of 7, hence like a perpetual weak acid and a weak base of the same substance, and this helps it in terms of being used as one of the main substances in an electrolyte (semi-conductive) liquid, and it is commonly available and inexpensive. During electrolysis, the electrolyte substance will heat up due to its internal resistance, and this represents a power loss (P=VI) in the battery and it will be unavailable as power to and for the external circuit.

Each different metal used in a galvanic cell has an electric or electrode potential (ie., ability to create an electric force = electromotive force = emf). The electric potential of zinc is about -0.75v, and the electric potential of copper is +0.35v, and when constructed to be an electric cell, the sum of their voltages will be about 1.1 Vdc Making a stack of 3 of these cells in series will create a battery voltage of their sum, and since multiplication is repeated addition: V = 3 (1.1v) = 3v . There are tables of the electrochemical potentials of metals and these are known as galvanic or (metal) electrode potential. A particular table may be associated with a particular reference metal and-or electrolyte such as sea-water with its particular amount of sodium and other elements. Still, regardless of a specific table, the difference in potentials when using any electrolyte should still be the same. Metals that are more electrochemically (ie., cause and-or affected by electron and-or chemical activity) active, hence not exactly stable in the electrochemical sense, such as being able to become and-or produce ions, will have a higher voltage (ie., energy, V = J/Qc) rating, and these more active metals such as zinc are used as "sacrificial anode (source of ions)" that will eventually oxidize and disintegrate to ions in the water, while protecting another metal such as steel (here, being considered electrochemically like a cathode), from rusting (ie., galvanic corrosion [slow destruction], oxidizing, becoming ions and falling apart) by obtaining free electrons from the zinc, and this is common with boats made of steel which would otherwise oxidize to rust when its atoms oxidize in the water and loose an electron. Whenever two different metals contacting each other and-or in the in the presence of moisture (ie., as an electrolyte), galvanic corrosion can happen. Galvanic corrosion can sometimes be reversed by using a sacrificial metal of lower electric potential so as to electrically transfer (via the electrolyte in surface contact with the oxidized metal) and donate its electrons to the oxidized metal ions which lost an electron.

Though the zinc-copper battery was good, it was non-rechargeable, and another problem is that even by sitting over time and with no load current, the zinc electrode will slowly react with the electrolyte solution, and the battery essentially self-discharges and will eventually produce no power (V I). A solution to this is called the **Daniel Cell** and it used two electrolytes separated by a conductive path for the ions. The Daniel Cell is also non-rechargeable, but has a good shelf life and will be available for use when needed. It is also possible to store the electrolytes and metal electrodes away from each other and assemble the battery when it is needed.

Noble metals such as platinum and gold have "heavy atoms" having a large nucleus mass, and with a large number of protons (ie., a high amount of positive force) and orbiting electrons, however, they have relatively few valence (far orbit, with least electric force upon them from the nucleus) electrons and these metals are therefore said as being more electrically stable and-or it would take much energy to free an electron from gold than it does for copper. Noble metals may be said as being more inert, stable, and non-reactive. Noble metals are also described as being immune to oxidation (ie., turned into ions, "rust") and-or corrosion. A metal that is more reactive than another will have a loosely bound electron in its atom. As a metal looses electrons and oxidizes into ions, it become even less (electrically and chemically) reactive. An element that is more reactive than another has electrons that require less energy (including electromagnetic force =emf, voltage) to break free from their orbits, and this metal is called the anode or negative terminal, and even if it is another noble metal. The other terminal and-or metal will be called the cathode or positive terminal which attracts the electrons. Again, for these electrons with gained energy are to be useful for an external electric circuit, they need to travel to and through that (usually of a low resistance wire) external circuit and then back to the battery - although now having less energy available and near the "ground state" of no energy. The less reactive metal with much positive charge and-or protons and less negative charge and-or electrons in the outer, valence region is able to attract (due to electromotive forces of attraction) the electrons from the anode terminal.

Commonly seen and-or mentioned oxides are iron oxide, aluminum oxide, copper oxide, zinc oxide, lead-sulfide (galena, lead and sulfur), silver oxide (usually silver-sulfide due to sulfur atoms) and iron-pyrite (iron and sulfur crystal). People have made diodes to be used in electrical circuits such as radio receivers with the help of an oxidized metal. These oxides are not good conductors of electricity since they have lost a loosely bound, outer (ie., valence) electron that could be used for conduction, and are said as being semi-conductors, and for a diode in a radio receiver, it is critical or necessary to have so as the audio can be heard and not effectively canceled out by other halves of the waveform. Some oxide coatings or layers are sometimes said as being like an insulating layer that could prevent further oxidation corrosion (ie., pitting, degradation). To avoid corrosion in a metal, an insulation barrier to the flow of electricity (electrons) and-or ions (atoms that lost an electron) is needed, and may be a coating of an oil based substance, a wax, or paint, plastic or electroplating of a non-reactive metal onto it such as gold, chromium or nickle. **Stainless steel** is made to be less corrosive than regular or plain steel, and it usually includes chromium (10.5% minimum) and-or nickle. The surface of the stainless steel may corrode some iron particles very slightly at first, but that will cease once it reaches the non-reactive, non-corrosive metal(s). Stainless steel products are often used in the food processing , medical, manufacturing, and sanitation industries so as to reduce organisms and-or to increase the quality and usage time of the product(s). The surface of stainless steel can then be relatively, easily cleaned and-or sterilized without worry of corrosion and-or rust. Since galvanic action is essentially due to electric potentials and-or electric current, galvanic corrosion can sometimes be prevented with an applied voltage and with nearly no current necessary.

The galvanic potential and-or difference in (voltaic, electric) potentials between two metals in an electrolyte such as saltwater can be measured by a voltmeter, and if the metals are connected by an external wire, electric current will begin to flow and the less electrochemically active metal will experience galvanic corrosion. The amount of current created by using two different metals in an electrolyte will be determined by the size of the metal surface or plate area, and the type and (electrochemical) strength (ie., concentration of substance(s)) of the electrolyte. Temperature can also affect an electrolyte and can make it more active or less active, hence alter its internal resistance, hence it will be a factor in the amount of current the battery produces. If the electrolyte solution gets "used up" or depleted, its resistance will increase and the output voltage and current will decrease. If the electrolyte solution gets "enhance" (more active, fresh, or an increase in temperature) then its resistance will decrease and the output voltage and current will increase. The higher the voltage difference between the two metals, the greater the electric current and the potential corrosion.

A galvanic cell (aka: a "primary battery") is not a rechargeable battery (aka: a "secondary battery") in the sense that it can not be recharged by applying a voltage across it and then having a current (ie., charge, electrons) go into it so as to be stored there. The galvanic cell gets its output power (V, I) due to the new ions created at one terminal by the energy of the electrons, and those ions flowing to the other terminal through the electrolyte solution (usually water acting as a solvent) made from an acid or base, and sometimes with some salt. As the chemical energy of the cell and-or battery is becoming depleted, the voltage of that cell and-or battery will get reduced. Over time and use, the anode metal can oxidize to ions and degrade (corrode). If the used or depleted electrolyte is replaced with new or "fresh" electrolyte, the galvanic cell will continue to function again. In a **rechargeable battery**, the electro-chemical process is essentially reversed so as to effectively have new-like electrolyte, and this process is a special form of electrolysis, and it will then have the ability to be recharged and store energy again. This type of cell is also called an **electrolytic cell**. The electrolyte used is a special type that can be recharged (ie., can store energy, hence potential energy (J / c = voltage)to be used later) with energy.

As of the year 2023, Lithium-ion batteries are the popular form of rechargeable battery since they are energy dense, however the are relatively expensive, and in the future, zinc-ion batteries and sodium-ion batteries will probably be a much cheaper an alternative.

Now that Volta created the battery, it was in less than a year of time till people such as **William Nicholson** and **Anthony Carlisle,** in 1800, starting using a battery for experiments and put two metal electrodes in a container of water with an electrolyte in it, and applied a voltage to those electrodes and through the electrolyte and noticed bubbles being produced. This was the beginning of the study of **electrolysis** (to loosen and-or break apart via electricity), and of which many scientific discoveries (such a new, natural or chemical elements) were made, and practical use of. The bubbles were hydrogen gas and oxygen gas created when a molecule of water (H2O) is "decomposed" (ie., split apart by applying a force and-or energy) by nearby electricity. The hydrogen gas was produced at the cathode, and the oxygen gas as produced at the anode when a minimal voltage of 1.23v (at about 72°F water temperature) was applied. For other substances, the minimal voltage necessary to split them will be different since it takes more energy to break apart some molecules, etc, that are electrically, via electrons sharing, bonded more stronger. Electrolysis is essentially the reverse process of using a battery with chemical energy so as to create electricity, and is rather using electricity to create chemical energy and-or a chemical reaction, and of which also includes recharging a battery.

Electrolysis is the process of passing an electric current through a liquid so as to cause a chemical reaction. The word electrolysis means to separate matter by using electricity. Because it is a chemical reaction, the combined sciences and-or use of both electricity and chemistry is called **electrochemistry**.

The basic concept of electrolysis can be thought of as the reverse of a galvanic battery, and where an external voltage is rather applied to the electrolyte. The bubbles produced by the electrolysis of plain being water as the electrolyte were found to be oxygen and hydrogen gas, and this was an indication of what water was made of two gasses in a condensed state or union, and it is these things and further experiments like this that lead to both advances in chemistry, electricity and other sciences. To describe what was going on, the water was said as being "decomposed" which is another way of saying the union (later known as a molecule of water, H2O) of the two gasses that creates water was split apart, and here by using the kinetic energy of the electrons.

For some examples of what electrolysis inspired: **Geissler** applied a voltage across a gas which after many years and discoveries by others eventually lead to the vacuum tube electric signal amplifier, and the discovery of the electron, proton and neutron, the extraction of elements form ores (often an oxides or "rusted" form of the metal(s)) using a high current and the resulting temperature increase to cause the metals in ores to melt out from it.

Humphry Davy discovered several new metals using electrolysis. Davy also invented the (high voltage) **arc lamp** a few years (in about 1805) after the invention of Volta's battery which made such experiments practical, and this was a high intensity light produced by a continuous spark or "arc" in the air from one carbon electrode to the other. The carbon electrodes degraded after a few minutes and needed to be replaced, and these lights were mainly used for public settings, military, and factory lighting due to that it was not practical to be used by the average person and-or household. Most improvements in arc lamps came late in the 1870's. It is also of note that this arc lamp probably inspired the Geissler tube (much like a neon light) which was invented years later in 1857, and of which then inspired the Crookes tube in about 1869, and of which many incredible discoveries and their practical use have been made from. Michael Faraday was an assistant of Davy, and who would make many further scientific discoveries.

Rust removal by using electrolysis:

If a piece of iron or steel metal got oxidized and got rusted on its surface, much of the rust can be removed by the help of an electrolysis process. In a sense, the method is to corrode the rust so as to weaken it for removal by an abrasion process such as sandpaper and-or various brushes such as metal wire brushes to soft plastic brushes. The main steps to do this process is to attach the rusted piece of metal (here being the cathode) to the negative terminal of the power supply and place it into an electrolyte solution. The other terminal metal will be connected to the positive terminal of the power supply, and this sacrificial anode, say a piece of steel scrap, will supply electrons to the cathode and reduce the iron oxide atoms back to iron atoms, and all this movement over time will also cause the rust to be pushed away from the surface of the rusted piece of steel and onto the surface of the anode. An often used substance to make the aqueous (water) electrolyte is (inexpensive) sodium carbonate. Only a few teaspoons of it are needed. It is best to do all of this in an area with adequate ventilation. How much Power is needed to do this type of electrolysis? Only a few volts is needed, and a low amount of current, say less than 1A, and the total power (J/s) should be less than 12W. A DC power supply of several volts and up to 12v is sufficient, and if that supply has short circuit protection, then that is also helpful.

A salt and vinegar rub can be used to remove copper-oxide from copper, and this can make a copper coin or copper pipe shiny again, but it is recommended to not do this on valuable coins since coin and-or antique collectors want to see and purchase such items with the copper-oxide patina or protective coating still on them.

It is of note, that as of about the year 2020, there are some high power lasers available for purchase that can help remove rust.

Electroplating is a specific application or process of using electrolysis so as to deposit metal ions in the electrolyte solution as atoms on a metal electrode in the solution of which the voltage is applied to. Of a certain metal is to be plated onto another, there needs to be a certain electrolyte used, and it may not be practical to plate a certain metal onto another certain type of metal. If you wish to plate a metal with gold (or other element which has a low reactivity [ie., non-reactive, corrosive resistant]), you will need to have dissolved gold atoms in the electrolyte, and inorganic cyanide (a carbon-nitrogen compound, and which has a net negative electric charge), and this can be purchased from a supplier and-or made from dissolving gold pieces in a strong acid.

Some objects, such as some non-conductors (ex. plastics), can sometimes be electroplated when there is an electrolyte of (ready made) ions of the metal to be plated onto it, and a special conductive reduction agent coating is used on the work-piece so as to allow the metal atoms to "stick" (adhere to, bond, become part of the metal crystal) to its surface.

In the figure shown below, copper is to be plated onto zinc, and the electrolyte solution is copper-sulfate (a compound with molecules of copper and sulfur). For the copper atoms to stick to the zinc metal, the zinc needs to be cleaned of any debris and-or oxide, and this can be done by using chemicals made to do so and-or by using reverse electrolysis with the goal to remove just the surface layer of debris. During electroplating, the copper-sulfate will get ionized or split into copper atoms with a net positive charge, and sulfur ions with a net negative charge which will be electrostatically attracted to the anode, positive terminal or electrode plate of metal where they will be reduced to sulfur atoms. The copper ions will be electrostatically attracted to the negative (or lower in electric potential) cathode terminal or electrode plate of metal and plate (ie., cover or coat) it. During the whole process, electrons are also flow or move form the positive terminal to the negative terminal through the electrolyte, and so as to cause more ions to be created from the copper-sulfate molecules.

Michael Faraday , who is credited with discovering electromagnetism and magnetic induction, discovered that the amount of metal deposited during electroplating is directly related to the electric current through the electrolyte, the concentration of the electrolyte, and amount of time the process is used, and it then became even possible to calculate the amount of mass electroplated or deposited onto one electrode and-or how much was removed from the other electrode. Note that although electricity (ie., electrons) is being used to create the ions at the surface of one terminal, these metal ions do not travel through the external circuit, and only electrons do. When an ion is created from an atom or molecule where electricity is applied, it is called oxidation, and when the ion regains an electron, it is called reduction, and this entire process is sometimes called the **redox** (a word contraction of the words of reduction and oxidation) process and it is described here:

oxidation is a term used to describe when a element looses an electron and becomes an ion, such as iron-oxide and this term came about from when iron rusted (or "oxidized") in the presence of oxygen (ie., air and having moisture in it) and-or water (H2O), and this is called oxidation. Can iron-oxide be converted back to iron using electrolysis? Some metal oxides can , but not iron oxide because of the presence of oxygen in the water which is H2O (hydrogen and oxygen), and carbon is rather used instead. When an oxide regains its lost electron, it is said to be **reduced** back to its natural form. Many oxides of metals are brittle and-or powdery, and this is because the normal atomic bonding due to electron sharing so as to make a hard crystal arrangement of the metal has essentially been shattered by the loss of the electron(s) during oxidation.

Obviously, the longer the time the plating process continues, the thicker the plating will be, and the most costly, especially for precious metals such as gold. The larger the work-piece or object to be plated will take more plating material. Plating is generally only a few, perhaps 10 microns (1 micron = 1 micro meter = 1 millionth of a meter = 1 (10^-6) m thick, but may be thicker if the object will have much physical wear and tear that may cause scratches and-or abrasions.

Though the surface area of a cubic centimeter of a metal is only 1 cm^2, if that cube of metal is sectioned into many layers of equal thickness, the surface area available for plating will be incredibly large. The thinner or less the thickness of each layer, the more surface area will be available for plating.

For a simple example: The height of a cubic centimeter is 1 cm high or thick. If it is sectioned into square areas or plates, and with each having a thickness of 1 mm, there will be a total surface area of:

1 cm thick / 1 mm = 0.01 m / 0.001 m = n = 10 times more, : 1 cm = 0.01m , hence:
At = n (surface area) = 10 (1 cm^2) = 10 cm^2

If the thickness was 1 um (one micro-meter) = 1 (10^-6m) :

1 cm thick / 1 um = 0.01 m / 0.000001 m = n = 10000 times more, hence:
At = n (surface area) = 10000 (1 cm^2) = 10000 cm^2 = (100 cm)(100 cm) = 1 m^2

If the thickness was twice as thick at 2 um, the total area would then be only half this value of 1 m^2:
Letting n um = 2 = divisor of the area:

At = 1 m^2 / n = 1 m^2 / 2 = 0.5 m^2 : = 5000 cm^2

The density of gold is about 19.32 g / 1 cm^3 . as of September, 18, 2023, 1g of gold cost about 62.18 USD.

19.32g will cost: (grams) (price / 1 gram) = (19.32)($62.18 USD) = $1201.32 USD , hence:
$1201.32 USD / Vol. = $1201.32 USD / 1 cm^3 and $1201.32 USD / (1 m^2 1 um thick coating) =
[($1201.32 USD / (1 m^2)] / 1 um thick

Also: $1201.32 USD / 1 cm^3 = $1201.32 USD / (1 cm^2 1 cm) = $1201.32 USD / (1 cm^2 1 mm thick) =~
($120.132 USD / 1 cm^2) at 1 mm thick or ($0.12 USD / 1 cm^2) at 1 um thick

Here is a website, and if is still available, here is the current price or value of gold: https://pricegold.net/today/

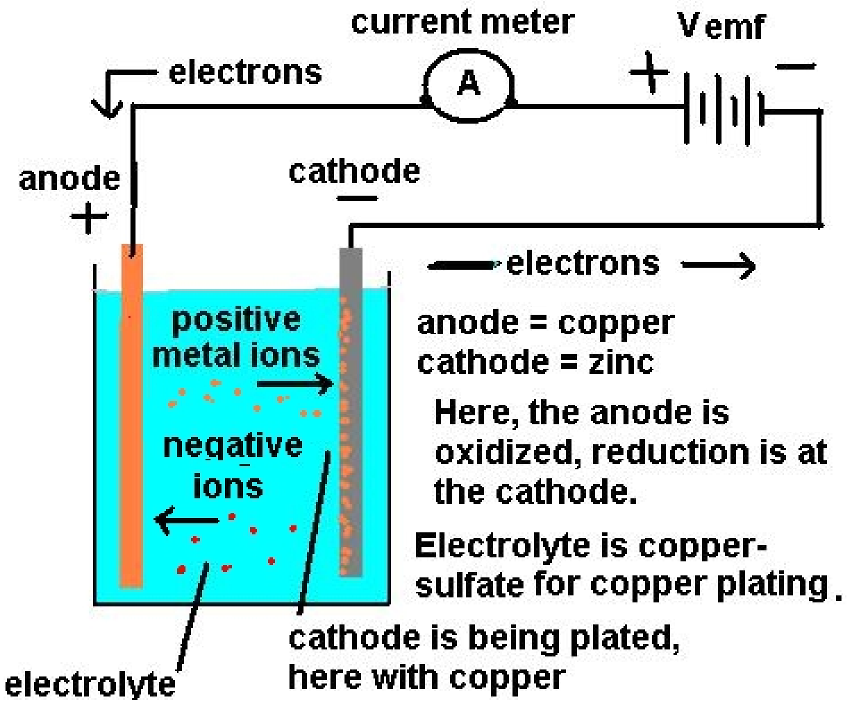
Mathematical calculations can be used to predict how much mass (grams) of metal will be plated. To check the calculation and-or to make another estimating calculation formula, the plated metal can be weighed with a fine or precision scale. An estimate formula could be based on an equal ratios if the plating is linear or proportional with respect to time:

$$\frac{\text{total grams plated}}{\text{total time to plate}} = \frac{Xg}{\text{time}}$$ when mathematically reduced to 1 time unit, and then mathematically:

Xg = (time) (total mass plated / total time to plate) : mass plated after a given time , and:

(time) = (Xg) (total time to plate / total grams plated) : time to plate an amount of mass

[FIG 310C] **An example circuit and description for electroplating.**



In the above circuit, the current is shown as conventional current which flows from the (+) or (theoretical or mathematical) higher electric potential identified as the positive (ie., higher in energy) terminal, however, it is actually electrons with kinetic energy that flow away from negative terminal by being electrostatically forced and repelled. Electrons are said to be negative in charge, and protons are said to be positive in charge, however, protons do not flow or travel in a wire due to their relatively high mass as compared to an electron.

The concept of electrolysis is filled with many basic facts and then some more complicated concepts, and uses well tested experiments and accepted methods and formulas, and all should be well if precautions are taken so as to produce the same results.

[This space for book edits.]

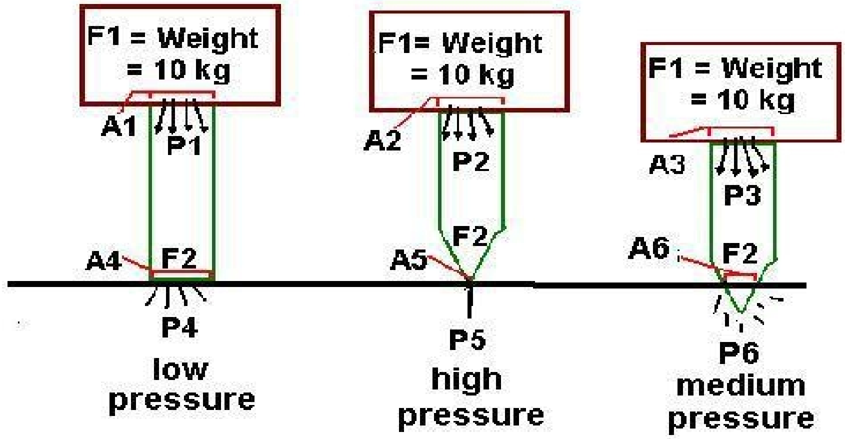
How much force can the wind apply to a surface?

How much force can the wind apply to a (perpendicular) surface?

The quick answer to how much force can the wind apply is that it depends on the windspeed and (cross-sectional, perpendicular) area of the surface that the wind energy is impacting and applying energy to it, hence the application of force upon it, and this area is therefore also equal to the cross sectional area of that wind that is impacting upon it.

Pressure = Force / Area = P = F / A , and mathematically, F = PA

Ex. If a force or weight corresponding to 10 kg is applied to a surface area of 5 m^2, the pressure upon each unit of that area is: P = F / A = 10 kg / 5 m^2 = 2 kg / m^2. Note that applying 2 kg / m^2 is equivalent to applying 10 kg / 5 m^2: Mathematically: (2 kg / m^2) (5 m^2) = 10 kg and this single weight and-or force could be achieved by placing 2 kg weights on each square meter, and the sum of each will add up to the total weight. A practical example of all this would be a several people applying force to an object so as to lift that object that once person could not lift alone. The result is that the total force applied to the object is the sum of the forces from each applying force (Fn = Pn An). If there were 4 people and each applied 10 kg of force (In this context: equivalent and proportional force due to 10 kg) or weight to the object, the total amount of force applied would be: (people) (force per person) = (total force) = 4 people (10 kg / person) = 40 kg. Here is a figure for a basic understanding of force, pressure and area. [FIG 311]



P = F / A and mathematically:
F = P A

P and A are factors of the resulting force. P and A are inversely related, but are not necessisarily reciprocals in value.

A5 < A6 < A4
P5 > P6 > P4

At each surface juntion, there is a force applied upon the area beneath it, and the average amount of force per unit of area is the pressure.

The smaller the area for a given force, the higher the pressure.

For a given system, with various forces, areas and at each junction, the product of (PA) = F is constant.

As the force and-or pressure increases upon an area, it can also cause the region on both sides of the junction to compress, and that region may get deformed.

Due to equal and opposite forces, both regions on the opposite sides of the junction will experience the same force and pressure. The amount of deformation is determined by the amount of force and-or pressure applied, and the strength of the material.

The pressure of P5 is very high due to the small area the force was applied to, and this will cause it to penetrate into and-or beneath the surface as shown at A6. It is as if the force and-or energy applied was higher, magnified or amplified, but they are effectively concentrated.

Pw = Energy / time = Joules / second = Work / s = F d / s = **F v = m a v** **:** here v = velocity

density = p = m / V , m = p V **:** here density is that of the air = (0.00124 g/cc)(1000cc) = 1.24g/L , or water = (1g/cc = 1000g/L = 1kg/L) , here V = Volume

Pw = F v = m a v = p V a v = p V (v / t) v = p V v^2 / t = p V v^2 / t = V v^2 v / d = p V v^3 / d = p A d v^3 / d =
Pw = p A v^3 : maximum before various energy losses are considered

There are several other ways, and using similar methods so as to find the same formula(s) as shown above.

The key to the above derivation and others similar to it is: Volume = V = d^3 = d^2 d^1 = A d
and: d / t = v , and: a = v2 / t 2 = v / t in general, and when t1 = 0 and v1=0 and (change in velocity) = (v2 - v1) = (v2 - 0) = v2 , and (change in time) = (t2 - t1) = (t2 - 0) = t2

From the above equations, we have:

F = ma = Pw / v = pA v^3 / v = **pA v^2** = Work / d = Energy / d ; also **F / A = pressure = pv^2**
p = density of the air , Mathematically:

For windmill blades, the area (A) for this equation is the area of the blades that the wind energy is actually applied to as "seen" by the wind. This area is analogous to the drag area of a planes leading wing surface, and not the entire surface of the plane's wing which helps determines the amount of lift force.

F / m = a = d / t^2 = vt / t^2 = v / t , v = F t / m , F = mv / t , and mathematically: momentum = p = mv = F t and F = p / t

distance = d = vt = (at) t = at^2 , v / a = t^2 / t = t , a = v / t

Comparing the energy available per area such as 1 square meter of moving air or wind, water and solar (ie., sunlight).

If the medium transferring energy and-or power was water instead of air, and since the density of water is much greater than air, it will have a larger amount of mass per unit of volume and therefore, it will have a much greater amount of energy per unit volume, and-or unit of area during an instant of time. How does solar power compare to wind or water power in these types of calculations? When the If the Sun is directly overhead at noon, and without cloud interference blocking some of its light energy, it can deliver up to 1000W of energy per square meter. A typical photo-voltaic panel can convert abut 20% (ie., conversion of energy efficiency = conversion efficiency) of that solar energy to electrical energy, hence it has a conversion efficiency of (output power / input power) = 0.20 = 20%. 20% of 1000W is 200W. A typical solar-air heater can convert about 80% of the incoming, collected or received light energy to heat energy. 80% of 1000W is 800W. This amount of power would use a large current drain from the typical batteries used in a solar electric system (SES), and will cause them to drain their charge (of current and power) fairly rapidly, and the available time of use for that charge cycle will then be shortened (ie., less time available before the battery is drained and-or ruined, and insufficient or unavailable to power the load device). The amount of power available in water is very high since it is a dense substance as compared to air, and the more matter moving, the more the total amount of kinetic energy ($KE = mv^2 / 2$, joules) it has available to make power (Pwatts = energy / time = Energy / second = joules / second).

A windmill or wind power to electric generator collects the kinetic energy in the wind and converts it to mechanical, rotational power. The maximum amount of wind these blades can collect will have an area equal to the corresponding and complete disk area of the blades. All the possible wind (kinetic) energy and-or power corresponding to that area of wind cannot be utilized for the blades to rotate because some of that wind must be permitted to pass through the blade area so as to rotate them, the axis of them, and power transmission wheels and-or gears. If the air did not pass thorough the blades, it would not create any movement and rotation of them. It is the blade angle that determines which direction the blades will spin. If the blades were rather a complete disk, all of kinetic energy of the wind would be turned into a force that will try to push that disk "straight back" in the same direction as the wind, and will result in a high amount of torque that is not perpendicular to the axis of the blades, but rather in the same direction as the axis. For there wind energy to move the blades it must strike the edge of the blade, hence there must be sections of the corresponding disk area not having blades, and therefore, not all of the total possible wind energy in that complete disk area can be transferred to the blades. Once the blades are forced to move and rotate in a direction (clockwise=cw or counter-clockwise=ccw) and gain kinetic energy, some of that wind energy will get transferred to the blades depending how efficient they are. The thicker the cross sectional area of the blade that is perpendicular to the wind will have drag (ie., air friction), and the faster the blade moves, the more rotational or movement energy lost due to drag force. In general, six triangular blades slightly angled from perpendicular to the wind will take up about 50% of the cross sectional area of the wind available, and 50% will be air gap in the complete disk of area. This means that a maximum of about 50% of that wind energy can be converted into torque (rotational) energy and-or mechanical power. If this mechanical power is then used to rotate an electric generator, then electric power can be made. If the blades are only 40% efficient at converting the wind energy upon it to mechanical energy, then they could convert: (0.60 of total energy available)(0.40) = 0.24 = 24% of the total available wind energy upon the blades to mechanical energy. This also means that (1.0 - 0.30) = 0.70 = 70% of the total available wind energy available at the total disk area of the blades was not converted to rotational energy of the blades.

If the air was rather water, and since the density of water is much greater than air, it will have a larger amount of mass per unit of volume and therefore, it will have a much greater amount of energy per unit volume and if the same velocity as the air. If velocity of the wind or water doubles or is 2 times faster, say from 5 km/s to 10 km/s, its kinetic energy ($KE = mv^2 / 2$) increases by a factor of $2^3 = 8$. Hence in a reverse manner, if the velocity of the wind is halved or is 2 times less and-or slower, its kinetic energy will decrease by a factor of $2^3 = 8$:

First, some general equations:

(change in speed) = (new speed) - (old speed) : = (difference or change in speed = Δv)

$\frac{\text{(new speed)}}{\text{(old speed)}}$ = (change in speed factor) : (new speed) = (change in speed factor) (old speed) (new speed) = (change in speed factor) (old speed) : a linear equation of the form: y = mx

Some general equations specifically for KE and velocity:

(change in kinetic energy) = (new KE) - (old KE)

$$\frac{\text{(new KE)}}{\text{(old KE)}} = \text{(change in KE factor)}$$

(new KE) = (change in KE factor) (old KE) : a linear equation of the form: y = mx

$$\frac{\text{(new speed)}}{\text{(old speed)}} = \text{(change in speed factor)}$$

(new speed) = (change in speed factor) (new speed)

(change in kinetic energy factor) = (change in speed factor)^2 , mathematically, taking the cube root of each side:

(change in speed factor) = $\sqrt[2]{\text{(change in kinetic energy factor)}}$

Here are some other mathematical derivations to consider for the above concepts:

Part 1:

KE1 = mv^2 / 2 , and if the velocity increases by a factor of (n): KE2 / KE1 = (n)

KE2 = m (nv)^2 / 2 = m n^2 v^2 / 2 : = (m v^2 / 2) n^2 = n^2 KE1

KE2 / KE1 = n^2 , hence, if the velocity changes by a factor of (n), the kinetic energy will change by a factor of (n^2) which is the square of (n).

Part 2:

(change or difference in KE) = (KE2 - KE1) = [(m v2 / 2) - (m v1 / 2] = (m / 2) (v2^2 - v1^2)
= (m / 2) (change in **[**velocity^2**]**) = m (change in velocity)^2 / 2

KE2 = KE1 + (change in KE)

If the (v old) changes by a factor of (n) = 2: v new / v old = 2 , therefore: v new = (2) v old = (n) v old

(change in v factor) = (n)

KE2 = (m / 2) (2v)^2 = (m / 2) 4v^2 = 4 mv^2 / 2 = 4 (mv^2 / 2) = 4 KE = in general: (n)^2 KE

KE2 / KE1 = n^2 KE1 / KE1 = 2^2 KE1 / KE1 = 4 KE1 / 1 KE1 = 4 = n^2 =
= (change in v factor)^2 = (change in KE factor)

(change in v factor) = $\sqrt{\text{(change in KE factor)}}$

Mathematically comparing how much more (ie., a factor, "times more") power is available in a moving mass of water than a moving mass of wind at the same given velocity, say v = 1 m/s:

$$\frac{P\ water}{P\ air} = \frac{p\,A\,v^3}{p\,A\,v^3} = \frac{(1000g\ /\ 1L)\,(1\ m^2)\,(1\ m/s)^3}{(1.24g\ /\ 1L)\,(1\ m^2)\,(1\ m/s)^3} = \frac{(1000g\ /\ 1L)}{(1.24g\ /\ 1L)} =^{\sim} 806$$

: theoretical maximum , not considering system losses

In general, the average velocity of water is much less than that of air. For example, if the air speed is 5 m/s, and the the speed of the water is 1m/s, the ratio of the power available is then much less at about: 6.5 : but is still significant

For some helpful reference and conversions of English and Metric units of distance or length:

1 mile / 1 hr = 5280 feet / 3600 s = $1.46\underline{7}$ ft / s =~ 1.5 ft / s = 18 in / s

1 kilometer / 1 hr = 1000 meters / 3600 s = $0.27\underline{8}$ m / s =~ 0.28 m / s = 28 cm / s

1 in = 2.54 cm
1 in (12) = 2.54 cm (12)
1 ft = 12 in = 30.48 cm = 0.3048m : diving both sides by 0.3048 , we have : 1 m = 3.280839895 ft

1 m/s = 3.281 ft/s =~ 3.3 ft/s and 1 ft/s = 0.3048 m/s =~ 0.3 m/s

1 ft (5280) = 30.48 cm (5280)
1 mile = 5280 ft = 160934.4 cm = 1609.344 m = 1.609344 km , dividing both sides by 1.609344 , we have:
1 km = 1000m = 0.621371192 miles , and therefore:
1 km/hr = $0.621\underline{4}$ miles/hr =~ 3281 ft / hr and 1 mile/hr = 1.61 km/hr = 1610 m / hr

1 km/hr = 1000m / 3600s = 3281ft / 3600s , dividing the num. and den. of both sides by 3600, we have:

$0.27\underline{8}$ m / 1s = $0.911\underline{4}$ ft / 1s , dividing both sides by 0.278, we have:

1m / 1s = 3.281 ft / 1s , dividing both sides by 3.278, we have:

1ft / 1s = 0.3048 m / 1s

As a reminder, pressure = force / area = P = (F / A) is like the average force per unit area, and mathematically:
Force = (pressure)(area) = F = (P)(A) is like the sum of all the individual pressures per unit area and expressed as a multiplication since repeated addition can be expressed as a multiplication.

If the (effective and-or perpendicular) area of the surface, such as for wind blades of a wind turbine are increased in size by a factor of (n), the energy collected will then be increased by that same factor of (n). **The wind pressure per unit area upon the wind blades will still be the same value as before**, however, since the area is larger, the resulting net force and-or torque will be (n) times greater:

F = (wind pressure)(area) = (n) (F / 1A) (A). : Since area is now twice as much, the force and-or torque will be (n) times more, and this amount of force can then be represented as:

(n) F

Torque = F L = (nF) L , and since the blades are longer, the effective lever arm was also increased by (n):
Torque = F L = (nF) (nL) = n^2 F L : we see that if the size of a wind turbine increases by (n), the resulting torque produced upon the generator shaft will increase by (n^2).

As shown previously in this book: **F = p A v^2** : p = density of the "fluid", here it is wind
Mathematically: **F / A = P = (fluid) Pressure = p v^2**

It must be said that 1 molecule of moving air does not provide much kinetic energy to move the wind blades, but several million air molecules striking the wind blades at the same time will effectively sum to enough combined or net energy. and the resulting combined force so as to move those wind blades.

The most common equation for the wind power that can be collected by a wind turbine is:

$$Pw = \frac{p\,A\,v^3\ Cp}{2}$$

: p = air density in kg/m^3 , A is the total circular "sweep" area of the turbine blades, hence the area of the moving air that could potentially be collected. A = (pi)(radius of the blades)^2 v is the velocity of the wind in m/s , Cp is the turbine performance efficiency at converting the available energy of the wind in the "sweep" area to rotational power. If the generator is very efficient, the electric power will be roughly equal to that of Pw value here, but less at about say 10% due to various conversion or inefficiency losses. This equation is similar to that of the **lift equation** for an airplane wings (ie., blades). Cp will be affected by the number of blades, their design and angle. For a simple example, if the total blade area is (1/4) = 0.25 = 25% of the total sweep area, then the energy collection will be <=25% of the total wind energy available. Cp is typically about 0.35 , hence about 35% of the wind power will be collected and transferred to the generator, and (100% - 35%) = 65% is essentially uncollected. If the generator efficiency is 90%, then 10% is lost as heat, and 10% of 35% is 3.5%, and this leaves (35% - 3.5%) = 31.5% of the available wind energy being converted to electricity from the generator. Notice that if the wind velocity increases by a factor of 2, that the increase in available power is then 2^3. (2v)^3 = (2^3)(v^3) = (8v). In short, when the velocity doubles (n=2), the volume of air upon the blades has likewise increased by (n^3) = (2^3) = 8. As a verification to the above (basic) formula, excluding the general energy transfer efficiency factor, consider:

Pressure = F / A = Energy / Volume = KE / V = pv^2 , mathematically: KE = pv^2 V , and:

Pw = Energy / time = KE / t = p v^2 V / t = p v^2 d^2 d^1 / t = p v^2 A (d / t) = p v^2 A v = **p A v^3** : J / s

AN EXAMPLE AND ANALYSIS OF RPM AND SPEED

A certain type of car is being designed with wheels having a radius (R) of 1 ft. How many RPM will be needed of those wheels so as the vehicle will go 20 mph?

Circumference distance of the wheel = C = 2(pi)R = 6.28 R = 6.28 (1ft) = 6.28 ft

Setting up a proportional type of equivalent fraction equation:

$$\frac{\frac{1\text{mi}}{1\text{ hr}}}{\frac{5280\text{ ft}}{1\text{ hr}}} = \frac{\frac{20\text{ mi}}{1\text{ hr}}}{\frac{X\text{ ft}}{1\text{ hr}}} \quad , \quad \text{After solving for X ft / hr :}$$

$$\frac{x\text{ ft}}{1\text{ hr}} = 105600\text{ ft / hr} = 105600\text{ ft / }3600\text{ s} = 29.33\text{ ft / }1\text{ s} = 20\text{ mi / }1\text{ hr}$$

If 1 revolution is a distance of C = 6.28 ft, then how many revolutions are needed to make 29.33 ft?

29.33 ft / **(**6.28 ft / 1 rev**)** = 4.67 revs and 4.67 revs / s = 29.33 ft / s = 20 mi / 1 hr

(4.67 revs / s) (60s / min) = 280.223 rev / min = 280.223 RPM

How Much Weight Can A Gas Filled Balloon Lift?

Various lighter than air gasses and-or mixes in a light-weight container such as a balloon can be used to lift a weight vertically, against the downward pull or force of gravity, and up into the air. Some examples of the gasses are: methane, hydrogen and helium. The example below will consider hydrogen and its specific density, but the calculations will be similar for any gases used.

The main reason it rises vertically is nearly identical to that of an air bubble rising vertically the water, and that is because of the buoyant force upon it. For an object to rise vertically in water or air, its average density (hence average weight also) must be less than that of the medium it is in; either water or air. The gasses mentioned are lighter (ie., less dense, hence less weight also) than the density of air.

The density of air at standard temperature and pressure (STP) is: $1.24 \text{ g} / \text{L} = 1240 \text{ g} / 1000 \text{ L} = 1.24 \text{ kg} / \text{m}^3$

The density of hydrogen at STP is: $0.0000838 \text{ g/cc} = 0.0838 \text{ g} / \text{L} = 83.8 \text{ g} / \text{m}^3 \approx 84 \text{g} / \text{m}^3$ = mass per cubic meter, hence often said as the "mass-weight per cubic meter"

Effective Buoyant or Lift Force = Upward or vertical buoyant Force - Downward weight of the entire balloon system

Effective Buoyant or Lift Force = Weight of the air displaced - Weight of the entire balloon system

Considering just 1 cubic meter of hydrogen gas as the most basic weight of the balloon system =
1 m^3 of hydrogen, and which displaces 1 cubic meter of air:

Effective Buoyant or Lift Force = $1.24 \text{ kg} - 84\text{g} = 1.24 \text{ kg} - 0.084\text{g} = 1.156 \text{ kg} = 1 \text{ kg} + 156 \text{ g} \approx 2.54\underline{9}$ lbs

This calculation for a hydrogen gas filled balloon can be expressed as: **1.156 kg / m^3** = $2.5\underline{5}$ lbs $\approx$ 1kg / 1m^3

To lift a mass or load of 10kg = 22.0462 lbs will require a hydrogen balloon with a minimal volume of:

$$\textbf{V m}^3 = \frac{\text{(mass of the load)}}{\dfrac{\text{(reference lift mass) per}}{\text{(reference volume)}}} = \frac{\text{(mass of the load)}}{\dfrac{(1.156 \text{ kg})}{(1 \text{ m}^3)}} = \frac{(10 \text{ kg})(1 \text{ m}^3)}{(1.156 \text{ kg})} = 8.65 \text{ m}^3$$

:This equation can be checked by rearranging it to show the equivalent proportions or fractions

The less the weight being lifted by the balloon, the greater the effective buoyant or vertical lift force will be and the faster the balloon will rise upward in the sky. The buoyant force must be greater than the load weight for a balloon to rise.

As a balloon rises into the less dense atmosphere of air, the weight of the air displaced will become less and the buoyant force becomes less. The balloon will decelerate due to the less buoyant force upon it pushing it vertically upward. The balloon having an internal gas pressure will also expand due to less external air pressure upon it in the higher atmosphere. Though this expansion will displace more air, it is less dense air, hence less weight, and less buoyant force.

The radius (r) and diameter (d) of the above balloon is:

$$\textbf{Vs} = \frac{4 (\pi) r^3}{3} = (1.333)(3.141592654)(r^3) = \mathbf{4.1887902\ r^3}$$

: **Vs = volume of a sphere**, such as a balloon and regardless of balloon shape, its the gas volume

$$\textbf{Vs} = \frac{4 (\pi) (d/2)^3}{3} = \mathbf{\frac{(\pi)\, d^3}{6}} = \mathbf{0.523598775\ d^3}$$

$$\mathbf{r} = \mathbf{\sqrt[3]{Vs / 4.188\underline{8}}} = \mathbf{0.620350\underline{5} \sqrt[3]{Vs}}$$

, and for the example and values given above; Vs = 8.65 m^3:
:**radius of a sphere = (diameter of sphere) / 2 = d / 2**

$r = 1.2734\underline{3}$ m

$$\mathbf{d} = \mathbf{2r} = \mathbf{1.2407009\underline{8} \sqrt[3]{Vs}} = 2\,(1.2734\underline{3} \text{ m}) = 2.54\underline{7} \text{ m}$$

:**diameter of a sphere**

[This space for book edits.]

A GENERALIZED LITHIUM BATTERY ANALYSIS

Lithium batteries have been mentioned in this book previously on several occasions. The main goal here is to show the amount of charge remaining in the battery via its voltage. The amount of charge left or remaining in a battery is also called the current state of charge (SOC).

Cell type considered: LiPO4 , size = 18650 , cell voltage rating = 3.2v

4 of these cells in series (S) will create a battery with a voltage rating of: (3.2v)(4) = 12.8v

The minimum voltage for each cell before it has a high internal resistance is about : 2.5v , and at this value, the
4 cell battery voltage will be: (2.5v)(4) = 10v

The maximum voltage for each cell before it can be begin to be shorted internally if made higher is about 3.65v, and at this value, the 4 cell battery voltage will be: (3.65v)(4) = 14.6v . For safety, the battery is not charged up to this voltage, but rather halfway between: 12.8v and 14.6v and this value is (12.8v + 14.6v) / 2 = 13.7v. At this voltage, the battery will be considered as having 100% of its charge still remaining in it.

Even with the above values stated, do not consider the 10v, lowest state of the battery as still in the useful rating of say for a 12.8v system. The battery still has charge and energy, but it is well below the rated values: (V , aH, Wh). For any voltage less than this rated battery voltage of 12.8v, the battery is considered drained of charge and in need of being recharged.

The aH or amp-hour rating of the battery depends on the aH capacity rating of each of the similar cells in series, and it will be the same value as each cell. If the cells are in parallel, the aH rating will be the total sum of each battery in parallel, hence if there are (n) parallel batteries in parallel, the aH rating will be (n)(aH).

The Wh or watt-hour , or "energy or oule rating" of the battery will be:
From: P = energy / time , energy = (power)(time) = energy = (VI)(time) =
energy = (rated Voltage of the battery) (aH rating)(time) : = total energy available in joules

As the voltage level of the battery decreases, the amount of current and power it can then deliver is less. The aH and Wh ratings are rather for the average value between 12.8v and 14.6v. This average voltage is: (14.6v + 12.8v) / 2 = 13.7v. To have a steady or constant amount of current will then require a voltage regulator or constant current regulator.

When this battery has between 20% and 90% of charge left in it, the battery voltage will decrease at a relatively slow rate with respect to time and-or usage under load, and this is an amazing thing with a battery such as a **LiFePO4** (Lithium-Iron-Phosphate) battery. The current available will be near the battery's aH rating, and the power available from it will be near the Wh rating of that battery. As of the year 2024, tt is unclear if there wiill be batteries superior to the LiFePO4 in terms of energy density (joules / weight or volume) and price which is about $2USD per aH for a 100 aH battery as of 2024.

If a battery is rated as 12.8v, then any value less than this, the battery cannot supply its rated values, and hence when this battery voltage is at 12.8v or less, it is considered as drained of (necessary) charge, and in particular, it cannot supply its aH and Wh rating.

Here is a chart that considering the LiFePO4 battery being discussed above as it is drained of charged (ie., current):

Battery Voltage	A typical % of the battery's rated charge remaining	
13.7	100	: sometimes the battery voltage might be charged to a slightly higher value. 3.7v is a typical value
13.63	90	
13.56	80	
13.5	70	
13.42	60	
13.36	50	
13.29	60	
13.22	50	
13.16	40	
13.09	30	
13.0	20	
12.85	10	
12.8	0%	: at this voltage, the aH and Wh rating cannot be sustained for lower voltages.

Essentially, each 10% difference in voltage represents 10% of the aH and-or Wh rating of the battery. If the total aH rating of the battery is 50aH, then each 10% change lesser in voltage essentially represents that: (50ah)(0.10) = 5aH of the total energy and-or aH in that battery has been used or "drained" and is no longer available for use.

Note that (13.7v - 12.8v) = 0.9v , and this is only about a 1v range between fully charged and what is considered a drained battery of its sustainable rated aH rating. (1v drain / 4 cells) = 0.25 v drain per 1 cell. This is also the voltage increase of each cell above its rated voltage of 3.2v. Each cell when the battery is charged to 13.7v will have a voltage of about: (3.2v + 0.25v) = 3.45v.

The above percent (%) values can also be considered as the percent of the aH rating left. The watt-hours remaining is the voltage remaining times the current at that voltage:

Wh remaining = (V remaining) (aH remaining) =
= (Power drawn)(hours of useage)

Mathematically: (hours of usage) = (Wh remaining) / (Power drawn)

Why not just simply charge the 12v rated battery to 12v?

The simple answer is that if the battery was charged to only 12.0v, the battery voltage would soon go less than this value which is its rated value, and then it may not be able to sufficiently power devices rated for a 12v input supply..

An Analysis of an Example For Consideration:

Mathematically, when the voltage and-or battery's energy is reduced by a certain percentage, the current available through the same load or resistance will reduce by that same percentage.

Ex. A 12v battery across a 10 ohm resistor.

Ir = Vr / r = 12v / 10 ohm = 1.2 A

Pw = Vv Ia = (12v)(1.2A) = 14.4 W

If the battery voltage got reduced from drawing power from it and if its voltage is now 11.8v, the voltage has decreased by: (12v - 11.8v) = 0.2v and the new battery voltage is: (11.8v / 12v) = 0.9833 or= 98.33% of 12v. In terms of the percent reduction in voltage, this is: (100% - 98.33%) = 1.67% . The voltage has decreased by 1.67%. Then:

Ir = Vr / r = 11.8 / 10 ohm = 1.18 A , a decrease of (1.2A - 1.18A) = 0.02A

(1.18 A / 1.2 A) = 0.9833 : A current reduction of: (100% - 98.33%) = 1.67%

Pw = Vv Ia = (11.8v)(1.18A) = 13.924 W

A power reduction of: (14.4W - 13.924W) = 0.476 W less , and as a ratio:
13.92 / 14.4 = 0.9667 , And this is a reduction of : (100% - 096.67%) = 0.0333% and (1 - 0.9667) = 0.0333

0.476W / 14.4W = 0.03306 = 3.306% when the voltage and current were reduced by 1.67%, hence the power reduction is twice that of the voltage and-or current reduction: 2 (1.67%) =~ 3.33%

When the voltage decreased to 98.33%, current decreased to 98.33% of its previous value. The product of these two relative values is: (0.9833)^2 = 0.96694 =~ 96.7% = 13.924W / 14.4W which is the ratio of the new voltage to the previous voltage before the voltage drop.

In short, when the voltage decreases by a certain percentage, the current (I = V / R) , will decrease by that same percentage since they are directly related and proportional in value. The total reduction in power here is equal to the square of the percentage of the voltage and-or current reduction, hence the available power and-or energy density is **rapidly decreasing** for each decrease in voltage and-or current. Fortunately, the internal structure and chemistry of a lithium type of battery allows it to maintain its rated (or slightly higher) voltage for a longer time of use as compared to that of a lead-acid battery of which must then be charged more often so as to maintain its rated voltage and-or energy (Wh). In short, the internal resistance of the lithium battery has a region where it does not change too much, and therefore, the battery can maintain its rated voltage and current for a longer period of time.

It is of note that when a battery voltage is less than its rated voltage, it is not safe to still use that battery to power a device rated to be supplied with that rated voltage. Some devices may work to say as low as 80% of that rated voltage. Much energy (ie., charge, electrons) is still within the battery when it is less than its rated voltage, and it is possible to uses it to power lower voltage devices if a voltage regulator is between it and the battery. **Using a battery below its rated voltage is not recommended, for it can damage the internal composition and capabilities of the battery to store charge again.**

Checking the battery voltage:

For any battery, when a (current, power) load (especially a low resistance) device is connected to it to be powered by it, the internal resistance of that battery will develop a voltage drop across it, hence the voltage to the load will be less than measured by a high resistance voltmeter:

Vload = (Vbattery unloaded - V loss due to the internal resistance of the battery when powering the load.)

You can also easily measure Vload using a voltmeter across that load when it is being powered.
Possibly, a power resistor to simulate a certain expected load or device can be used as a substitute load so as to measure Vload.

Power loss in the battery:

Because there is a voltage drop internally in the battery, there will also be a power loss within the battery, and it will not then be available to the circuit and-or load device. Pload = (V load)(I load). When the charge in a battery is depleted, its internal chemistry will temporarily change until the next recharge. The more the battery is depleted, the greater the internal resistance, voltage drop (ie., loss) and power loss. The battery's ability to sustain the current for a long time (ex. 1 hour) will be less unless if it is a battery of great size and charge storage capacity to initially begin with.

[This space for book edits.]

A POWER INVERTER STUDY AND EXAMPLE

A power inverter has been discussed in a few places previously in this book, but here is some additional information which may help some people have more of an understanding.

A power inverter is much like the concept of a voltage transformer, usually to increase the output voltage. For example a 12Vdc can be converted to 120 Vac, hence the voltage gets multiplied by a certain factor, here 10, however this also divides the available current by 10 since in general: power in = power out.

A power inverter that we are interested in for this example has a 12Vdc power supply, such as a battery, as its input power.

The battery can be a car battery if the engine is running and charging that battery while current is being drawn from it. The battery can be a "deep cycle" battery or a type of rechargeable battery such as a lithium battery (ex. LiPO4 = lithium iron phosphate).

It is best to use an inverter with a pure sine wave output ,however some devices such as heaters may work reasonably well with the square wave type of output. The AC output of the power inverter should be 120 Vac.

Ex. To power a 600W AC electrical device using a 12V battery.

If the voltage is increased to 120V ac, that is (120v / 12v) = 10 times higher.

P = V I
600W = (120V)(I) : (volt)(amps) = watts = joules / second mathematically:
I = P / V = 600W / 120v = 5 amps

Now consider 5 amps being drawn from the battery:

P = V I = (12v) (5A) = 60 watts, and this is not enough power to power a 600W device. Surely then, more current is needed to obtain the needed 600 watt device.

I = P / v = 600W / 12v = 50 amps from the battery.

Now compare: The voltage gets increased by 10 , from 12v to 120v. The current needed, here 5A through the load, increases by a factor of (50A / 5A) = 10 from 5A to 50A at the battery. The 50 amps drawn from the battery will get decreased by inverter to just 5A. Still:

Pin = Pout

Ex. If an inverter is rated at 2000W maximum rated output ?

The maximum current from the inverter is then: P = V I , I = P / V = 2000W / 120v = 16.67A

For the battery: P = V I , I = P / V = 2000W / 12v = 166.67A hence 10 times more, and this is due to the voltage step-up transformer, and of which the current is reduced 10 times, and therefore the battery must supply 10 times more current so as to have the same amount of power.

Note that an inverter is often only about 85% to maybe 95% efficient at the power conversion, and with an average of bing 90% efficient, and there is about 10% of the input power lost as heat, and it will then not be available at the output. Since an inverter is generally guaranteed to be 110Vac to 120Vac, the power lost is generally of the current available, and also due to that the battery voltage is generally a fixed value of about 12v. For the above example:

Total Current Needed Due To Likely Inverter Power Losses = Basic Current + 10% Basic Current =

166.67A + 16.67A = 183.4A

The battery must be able to allow this much current from being drawn or taken out from it. If the battery Ah is insufficient, you will then need to consider parallel batteries to increase the total Ah available. The wire or cable used from the battery to the inverter is generally short, and must be able to handle this maximum amount of current through it. Using a fuse will help protect the battery and-or inverter from short circuits. It is best to use a DC fuse before the inverter, and an AC fuse after the inverter. Electro-Magnetic circuit breakers can also be used, and some inverters may have this included in the design. While fuses (an inexpensive type of circuit breaker) need replacing, (electro-magnetic) circuit breakers can be easily reset manually if the circuit problem no longer exists.

To reduce current drawn from a battery by half, consider using a 24 volt battery and inverter system. This battery can be purchased or created from two 12v dc batteries connected in series. Positive (+) to negative (-), and-or negative (-) to positive (+).

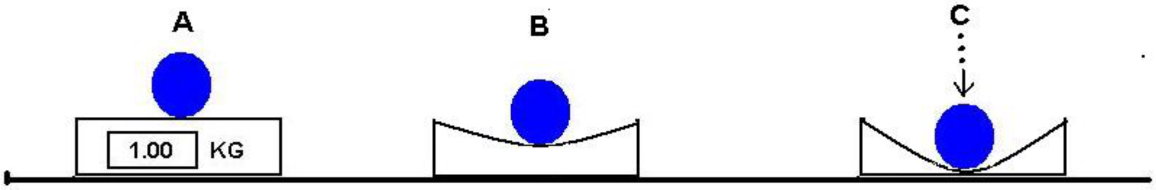
To further reduce the current (ie., which comes from the saved charged over time) needed and drawn, you can also consider a 36V or 48V system. Considering the above 2000W load example with having a 48v rated battery and a 48v rated inverter:

I = P / V = 2000W / 48V = 41.67A : this is 4 times lower in current, and the wire from the battery does not then need to be so thick, but it must be capable of safely passing 41.67A, and its current rating must then be a bit more, and giving a 10% safety margin: 41.67A + 4.167A = 45.85A The fuse used between the battery and inverter should then be based on this value of current, and the fuse's current rating should be of just a slight amount of amps higher at say 46A to 50A..

Typically, a 48v battery is essentially composed of four 12v batteries connected in series so as to increase the available voltage. The aH rating of a 48v battery is typically 4 times more than that of a 12v battery. Drawing less current from a battery means it will also charge up faster, and-or have more time to power a device(s) since the aH and Wh ratings are higher for a charged 48v battery.

AN IMPACT STUDY

Impact has been previously mentioned in this book, and so here is some extra data and equations about it that you may consider and occasionally encounter. Here is a simple illustration to consider before discussing the concept of impact further. [FIG 312]



A weight to mass scale

Has a rigid metal surface which does not visibly bend unless the weight is very high in value.

Since gravity is still acting upon the ball, the weight will always be shown. Since the surface is rigid, the ball cannot change in velocity and position.

The downward force or weight of the ball is constantly and effectively cancelled by the surface tension and its force in the opposite direction.

Here, the surface is not as rigid and can bend more easilly, and this helps us visualize the constant weight = force. For example, a thin metal, plastic or rubber surface like a balloon, and which can stretch . If the ball is removed, the surface will be restored to its original flat shape if the weight and-or impact was a low value and the surface was not permanently deformed.

Here, the ball and surface is shown after it was dropped from a height. The impact force is greater than the weight of the ball, and the curve is deeper, but since the weight is the same, and the surface was not permanently deformed, the curve will then become as shown previously at B. This is due to the elastic tension force in the stretched rubber surface which will raise the ball upward slightly after its gained motional energy is converted to and dissipated as heat energy.

For the difference between the words "impact" and "impulse", these two words are sometimes used interchangeably for a "collision". but there is a more strict definition. In brief, the word "impact" is another word for "collision" or "contact" of two objects, and the word "impulse" is used to describe the temporary application of the force during the impact.

Because of equal and opposite forces, when object A impacts object B and places a force upon object B, object B will place an equal and opposite force upon object A.

If object B has a great mass, it will have a great inertia and it will not move much due to an impact, and it will rather move more easily when more energy has been applied by a force.

An object or mass in motion or velocity is said to have momentum. Momentum ($p = mv$) is a general measure of that objects ability to keep moving. Momentum is like the opposite in meaning of inertia which is an objects ability to initially resist motion and-or the applied force meant to cause motion. If a force is applied in the opposite direction to its motion, that object will then reduce in speed in the direction it was going during the time that the force is applied. If a small force is applied for a long enough duration in the opposite direction to an objects motion, the momentum of that object will eventually be reduced to 0. What is happening is that the object will constantly loose some kinetic energy ($KE = mv^2 / 2$) when that force is applied.

If object B has a velocity during an impact in the opposite direction to that of object A, object B has momentum also, and the force of impact will be greater.

If the mass is doubled in the above figure, the scale will show twice the mass and-or weight. This indicates that the force upon the scale is twice or 2 times more. If the mass is more, the bend in the supporting surface will be greater, and for a generalized approximation, the bend will be twice as deep if the mass and-or weight is twice as more. Extra: In essence, the bend amount can be used as a mass and-or weight scale itself, much like a spring scale of which the calibrated length of the spring indicates the weight applied to it.

If the mass is not 2 times more, the force and-or weight can be 2 times more if it had kinetic energy (ie. motional energy) that resulted in the apparent weight (ie., a force) of the object being two times more.

When an object is lifted a height, it is effectively gaining and storing gravitational potential energy (GPE) due to its position. At rest at this height, it will appear to have gained no energy, and in fact having no kinetic energy (KE), but once it is allowed to fall in the presence of the constant force of gravity, it will constantly increase (ie., accelerate, and change) in velocity and gain kinetic energy. $KE = mv^2 / 2$.

Now to find the relationship between force (the application of energy) due to an object with KE.

$F = ma$, $m = F / a$, $F = ma = m \ (\text{ch } v) / (\text{ch } t) = m v / t$, and if the changes were from $v=0$, and $t=0$

Note that if the force applied is constant, the acceleration is then a constant and not an average value: $a = F / m$, and then what would then be increasing is the velocity, momentum and kinetic energy of the object.

$KE = m v^2 / 2$ and mathematically: $m = 2 (KE) / v^2$ and $v = \text{sqrt} [2 (KE) / m]$.
Note that: $(2 / m)$ and-or $(m / 2)$ is a constant value.

Mathematically: Since $F = ma$, $m = F / a$ and:

$KE = mv^2 / 2 = F v^2 / 2a$ and since: Energy = Work = $F d$, $F = \text{Work} / d = KE / d = KE / v t$,
$(KE - GPE)$ = Total Energy = $F d$

In gravity, $a = g$: , if the acceleration is actually deceleration: $a = -g$, and $F = ma = mg$, $F = m -g = - mg$

Some extra formulas to consider:

$F d = W$ joules = Energy = F (height) joules = (Weight)(height) joules = $mgh = KE = GPE$, mathematically:

$F = KE / h = GPE / h = ma = m v / t = (m d/t) / t = m d / t^2 = m h / t^2$: if $a=g$ is constant , and

$F = m h / t^2 = m h / (d/v)^2 = m h / (h^2 / v^2) = m v^2 / h$

$F = m a = m (d^2 / t^2) / h = m (h^2 / t^2) / h = m h / t^2$: This shows that F is directly related to height

$F = m h / t^2 = md / t^2 = m d / t t = m (d/t) / t = m v / t$: This shows that F is directly related to velocity

$F = m h / t^2 = mv^2 / h = m v / t$: $h = d$ = distance lifted vertically. Note that when the height is higher, the time needed until impact will be more.

$F = m a = m v / t = m v^2 / d$, hence these factors are equal: $v / t = v^2 / d$ mathematically:
$d / t = v$: checks

The force and-or weight on the scale is equal to the weight of the object + the temporary force due to any gained kinetic energy of the mass being applied to the scale also. This KE came from, and is equal to the GPE it gained initially:

Energy in = Energy out , $KE = GPE$, $KE - GPE = 0$ Joules

Gravitational Potential Energy gained from the reference position or height = $GPE = Fn\ dm$ = work in joule units = (F in newtons) (height in meters) above the reference ground or 0 energy state.

$F = m a = m v / t = m (d / t) / t = m d / t^2$.

$d = a t^2 = g t^2$, after multiplying each side by F, we have:

$F d = F a t^2 = F g t^2$ = work = energy = $KE = GPE$ mathematically:

$F = GPE / g t^2 = GPE / d = GPE / v t = GPE / (at) t = GPE / a t^2 = KE / d = KE / v t = KE / at^2$
Showing that F is directly related to Energy in general.

$Fd = mad$ = energy and F = energy / d

If d is low, much like the contact or impact distance, a high F will be applied will be in a short amount of time and distance, however the total KE can not change and is the same.

force / area = Pressure (ie., the effective force per unit of area) can be effectively increased if the area is smaller and the energy is then concentrated and-or distributed in a smaller amount of area. If all the energy is released quickly in a short amount of time, then (d) will be lower in: $F = KE / d$, and the impact force (application and-or transfer of energy) will then be greater.

$F = KE / d = E / d$: if the energy is spread out over a long distance, the energy per unit distance will be lower, and the Force per unit distance will then be lower. In general, a longer distance will take a longer time given the same or lower velocity. A lower velocity then implies a deceleration due to a force such as the equal and opposite force of the impact.

$F t = m v = p$ = momentum = a joint measure of the motion of a mass and its velocity.
$F t = m a t = m v$

$F = m a = m v / t = m v^2 / d$, $v / t = v^2 / d$: note: $v^2 / v = v = d / t$
and: $a = v / t = v^2 / d = d / t^2$, and: $v^2 = d a$

$W = KE = F d = ma\ d = ma\ a t^2 = mg\ g t^2 = m\ g^2\ t^2$: $d = v t = (at) t = a t^2$
$W = KE = F d = ma\ d = m a$ (height) $= mgh = GPE = mv^2 / 2$, mathematically:

$W = KE = GPE = mg^2 t^2 = mv^2 / 2$: of which many single variables (m, g, t, v) can be solved for
Also: $(d/v)=t$, $t^2 = (d/v)^2 = d^2 / v^2$, $d^2 = v^2\ t^2$
Since F=ma, $m = F / a$, and substitution this, we have:

$W = KE = GPE = F d = F a t^2 = F v^2 / 2a$

$F = ma = mg = GPE / d = KE / d$: If $KE = GPE$ doubles, then F will double , they are directly related
If F doubles , KE doubles since Fd = work = energy = KE joules

F = m a = m d / t^2 = m d / t^2 = m d / (d^2 / v^2) = m v^2 / d = m (d/t)^2 / d = m d^2 / t^2 d = m d / t^2

The higher the object is in distance (h = d), the more GPE it will have at its maximum height, and then when the object is allowed to fall, the more KE (which includes an increasing velocity due to the constant force of gravity applied to it and applying energy to it) it will have just before impact.

Energy = Work = F d = ma d = ma h = P A d = P A h = P d^2 d = P d^3 = P V : From: P = F / A , F = P A
Note in PAh , for a given energy and P, if A is small, h is then large due to an inverse relationship
GPE = KE = Work = Fd = mad = mah = P V , therefore: P = F / A = GPE / V and V = GPE / P
F = GPE A / V = GPE d^2 / d^3 = GPE / d
P = F / A = (GPE / d) / d^2 = GPE / d^3 = GPE / V
GPE = P V , V = GPE / P

Impulse Force = the force created during an impact = change in momentum / change in time =
= (mv2 - mv1) / t , if the impact time is quick, then the force is very high, and the energy is exchanged quickly. When the change in momentum is high and happens in a short amount of time, all the available energy is transferred during that short amount of time, and the application of that energy (ie., Force) will be high.

F impulse has units of Newtons = m a = (mass kg) (meters / s^2)

F = m a = m (chv / cht) , from this: chv = F t / m : the larger the mass, the more inertia it has, and the less the change in velocity will be for a given amount of Force and time it is applied.

chv = Ft / m = change in momentum / m , therefore: change in momentum = m chv
units of momentum are those of mass and velocity , hence ,
mv = (kg)(m/s) = kg-m / s

P = F / A : if the impact area , or force application area, is smaller, the pressure applied to it is then higher, as if the impact force was greater at that region, and the damage in that area or region will most likely be greater as more (KE) energy is transferred to that smaller area. It is essentially concentrating the (constant) energy available and applying it to a smaller area and it will affect then that area more. Constant in mentioned since regardless of the area, the total energy is usually constant and-or just before impact. For the impact force to increase, the available energy must first increase before impact where pressure will be applied to the area. As an extra note, if the area is simply 1 unit of area, then the pressure value will have the same numeric value as the force.

P = F / A = m a / d^2 = m a / (v t)^2 = ma / v^2 t^2 : d = v t , d^2 = (vt)^2 = v^2 t^2 , ,
a = ch v / ch t = v / t from t=0

Given a weight = force = ma , if a (lifting, raising) force is applied in the opposite direction, it can lift that object to a height, and the larger the upward force being greater than the (downward) weight force, the less time it will take. **

h = d = v t , F d = work = energy = KE = GPE = F v t , F = energy / v t = energy / d , v = energy / F t
F = weight = ma = mg = energy / d = energy / h

If the energy was transferred in a short or low distance value, then the F will be high. Since energy = F d , the longer the distance, the more energy needed . Note that d = vt , and that if it is a constant , if one variable is increased by (n) the other is decreased by (n), and then Fd = work = energy will remain constant , for example given a limited or constant value of: GPE = KE = energy = work

h = d = GPE / F = KE / F = Work / F
d = v t = GPE / F , GPE = F v t = F d

** t = GPE / Fv , v = GPE / Ft , GPE = F t v = F d

No matter how fast or slow an object is raised, the GPE it stores will be the same value for a given height, and the KE needed to put it there is always be the same.

If a force of 1N is applied for 1s to an object, the impulse (I) is:

I = (change in momentum of the object) = F (change in time) = (1N)(1s) = 1N-s

If this force was applied in the direction that the object was already traveling or moving, this would add to the objects momentum and kinetic energy. If the mass remains the same, only velocity will increase.

F = m a = m (change in velocity) / (change in time) , mathematically:
F (change in time) = m (change in velocity) = (change in momentum) = impulse =
= impulse = Δ p = Δ N-s = m (change in velocity)

(change in velocity) = (change in momentum) / m = (impulse) / m : m = mass

Due to the inverse mathematical relationship shown in the above equation, he larger the mass for a given impulse upon it, the smaller the change in its velocity, and this is due to the inertia of that mass, and that it simply takes more applied energy (ie., force) to move a larger mass.

From: F = ma , a = m / F , the larger the mass for a given force the less it will accelerate and the less change in velocity it will have. To have the velocity change by a factor of (n) for a given mass, the change in momentum = F t must then change by that same factor of (n).

(change in momentum) = m (change in velocity)

m = (change in momentum) / (change in velocity). : for a given mass, m, to maintain the equivalent fraction, if one factor increases by (n), the other factor will decrease by that same value of (n).

m = Fn / a = (change in momentum) / (change in v)

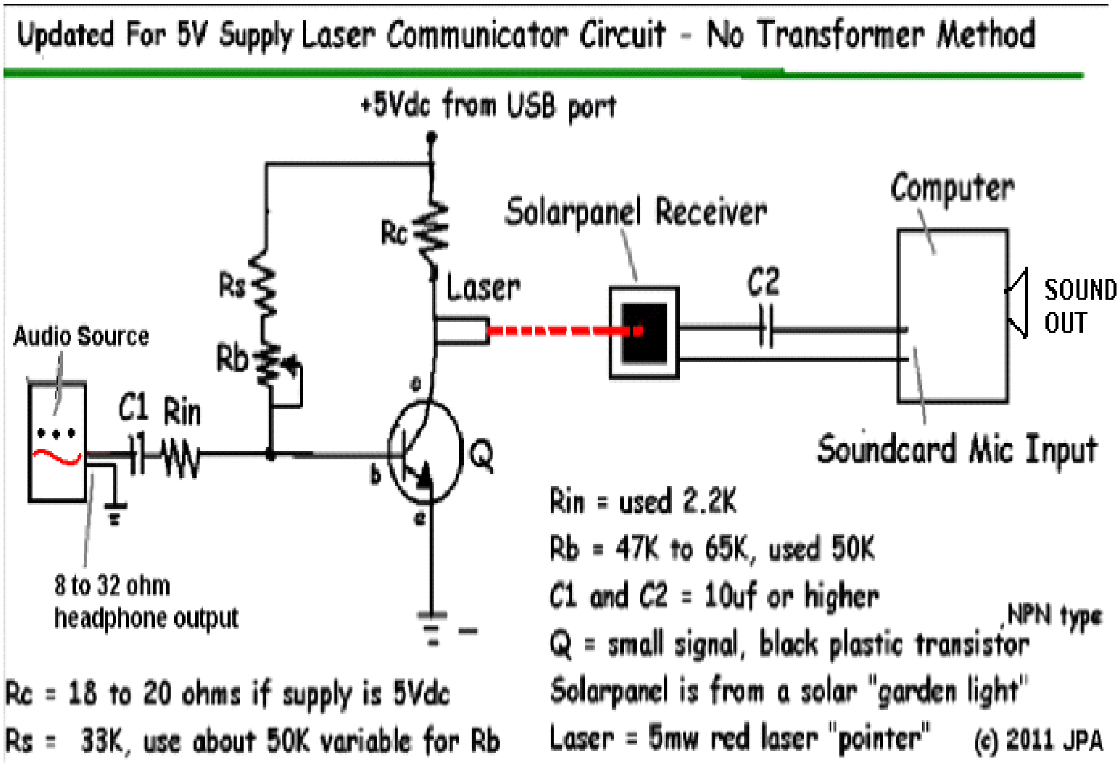
In an "**elastic collision**", the amount of energy lost during a collision is a very low value, and if 0 joules is lost, it is a theoretical, "pure elastic collision". A simple example would be a ("super") rubber ball that when dropped form a height, it will nearly bounce or rebound back up to its original height.

In the first studies of impact and force, dropping a mass from a height and observing the dent in the soil, would make a person naturally believe that the force of the impact is directly related to the mass and its velocity. $F = mv$, but Newton realized that if the object strikes a moving object then the applied force is not as much when it is applied in the same direction, and the equation was rather modified to include acceleration or deceleration which is a variable which does include velocity(s): $F = ma$.. All of the Kinetic Energy of the object colliding with the other may not be transferred to the other object, but only some will , and this will increase its Kinetic Energy. If the velocity of an object has been reduced to a value of 0, then all of its kinetic energy has been transferred elsewhere, and most likely to the object it collided with.

[This space for edits.]

A CIRCUIT TO TRANSMIT A SOUND SIGNAL USING A LOW POWER LASER

This circuit will transmit (ie., send) an electronic audio signal using a few inexpensive electronic parts. **Please use proper eye protection for lasers, and be responsible with lasers so as not to do any harm to people, animals, plants, objects and-or cause a public disturbance**. Lasers can also transmit digital or computer data in the form of quick high power pulses. This data will then need to be decoded by a microprocessor (ie., a computer) and computer program so as to do so.
[FIG 313]



The input (electric form representation of an audio signal) signal will be used to modulate (ie., vary, control, adjust) the amplitude (ie., energy or signal intensity) of the signal output from the laser. The solar panel will convert the light intensity of the laser light received to a corresponding intensity of a electric signal.

As indicated, the solar panel is from a garden light, and that all may not work too well for this circuit and laser light, and it may take some experimentation. The area of this small solar panel was about 1 square inch.

The laser used was an inexpensive, $1USD, low power, legal, consumer, 5 milli-watt (ie., 0.005W), LED (with red colored light) laser pointer, however, premade laser diode "modules" and-or circuits are available for experimenters and-or for replacements. You will need to determine the voltage polarity of the input power supply pins of the laser and-so as to prevent the laser from being damaged. Do not look directly at the laser beam, and-or for too long at it striking and-or reflecting from a nearby surface and still having a high intensity. The light or photon output of a laser diode has a single (rf, electro-magnetic) frequency based on its construction, and is therefore called a monochromatic light or a light of a single color. The laser used for this circuit emitted a red light of about 650nm (nano-meters) in wavelength. A green laser light would have about a 525nm wavelength, and violet laser light would have about a 425nm wavelength.

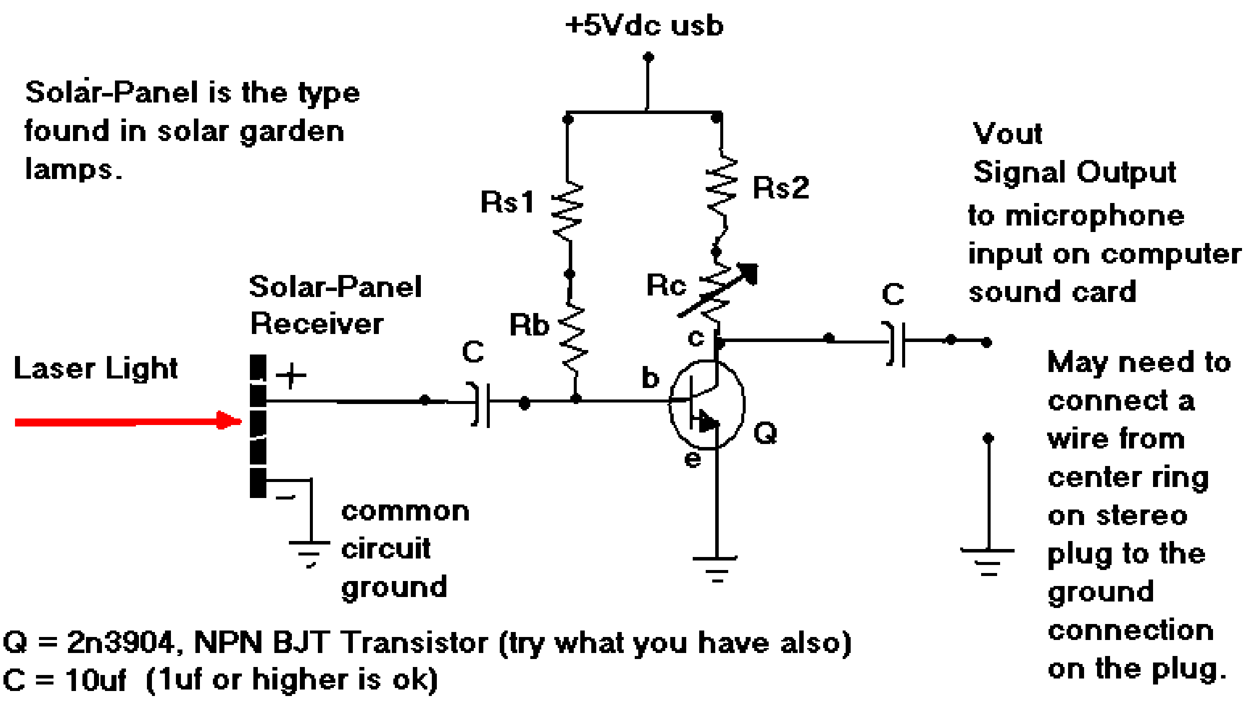
(Q) is a small black plastic NPN type. You can purchase a new quantity of these and other parts (ie., components) relatively cheap from websites such as Ebay.com It is also good to get a dozen or two of "spring clip hookup or connection leads" to easily connect components together for testing circuits, and without the need to solder them just to test them.

Rs is basically a "safety resistor" so that if you turn Rb all the way to a low value, excessive base (and-or collector) current will usually damage the transistor. Rc is included to prevent the voltage across the laser from going over 4.5Vdc which would either prematurely age the laser and reduce its light output, and-or cause it to be burn out and be of no use.

To increase range, various light concentrators can be experimented with. The simplest is a funnel or cone shape having an inner surface made of a reflective material. Another simple method is to uses a magnifier so as to focus and concentrate the received light energy onto the solar panel. Mirrors can be used to direct a laser beam to a certain direction.

The circuit shown below in the next figure is essentially a preamp circuit to help amplify or "boost" the signal output from the solar panel before it is sent to the computer microphone input so as to be amplified. There are many things to experiment with these laser circuits, so be patient and keep notes of what works and what doesn't. There are also free oscilloscope programs available that work well with most audio signals, such as for setting the maximum level before "clipping" or signal distortion happens due to too much amplification. These programs use either the microphone and-or line input of the sound card for the input signal to be displayed on the screen. The laser circuit above generally works well without the need for the preamp shown below. [FIG 314]

Solar Panel Receiver Amplifier Circuit For Laser Communicator



Q = 2n3904, NPN BJT Transistor (try what you have also)
C = 10uf (1uf or higher is ok)
Rs1 = 1K safety resistor, Rb = 1M (fixed or variable)
Rs2 = 100 ohm safety resistor, Rc = 5k Variable resistor
Adjust Rc for best output

(c) JPA 2017

Some solar garden panels from solar lights will work better than others. They type I used often had several smaller solar cells in it. If the circuit oscillates and produces noise or a tone, try putting about a 100pf capacitor across the transistors collector and emitter leads, or across Rc. The laser and-or preamp circuit is sometimes sensitive to the light frequency radiation or 50hz or 60hz noise from household lamps and some flashlights that boost their internal power supply voltage and frequency using some type of "voltage step-up" circuit. An **op-amp (operational amplifier, or opamp)** on a IC chip is a small, very high gain amplifier circuit option to experiment with instead of using regular transistors, however for powerful pulses (brief, short duration transmission) of advanced laser communication, the output circuit often uses a high gain power transistor or MOSFET (metallic oxide field effect transistor). A high impedance (usually desired to be resistive only, with minimal capacitance and inductance of which can limit input frequencies and-or short some signal to ground) op-amp is ideal at the first amplification stage for low power RF signals such as for a crystal radio receiver. To amplify weak signals with a small voltage, it greatly helps to have an amplifier with a high input impedance (usually desired to be just an ideal, infinite resistance or resistor, hence with no capacitance or inductance involved, and with their reactances, and which can also cause some AC signal loss to the ground and wasted rather than amplified) so as to apply the full received signal voltage to it rather than share it with another resistor in a voltage divider and then waste part of that signal. With a high input impedance, there will surely be not much of any current flowing into the op-amp. The op amp is much like a FET that is designed to function by and-or amplify voltages rather than current like a typical BJT transistor amplifier would which requires some input current to function. an FET is said as being voltage operated, and a BJT is said as being current operated. For some more about op-amps, please read the next note further below.

The author has used this basic laser system to transfer a text file, and then a small image file over a short dance of several feet, and the process is somewhat similar to the **Slow Scan TV (SSTV)** concepts developed later which are used to transfer small images or text files via an audio signal transmitted via a radio wave signal. Used was a program to convert audio signals such as from a common .wav file used to store audio data as a computers digital or digitized data form. The program was based on the **Kansas City Standard (KCS)** = **BYTE Standard**. that is used to convert digital byte data to a coded audio data, and for an older computer system, it was then stored by using a modified (audio) tape cassette. The tape cassette is not needed in this situation since the computer itself can be used to directly send or store the data, and then convert it back into digital computer data such as for an image, audio, or text file. The coded .wav files are relatively large and-or time lengthy to send and receive, however they can be highly compressed (do not use any mp3 format since it is actually a "lossy" format since some data considered as unnecessary or is omitted) for storage until needed. A free KCS program can be found on the internet, and search for something like: **Ed's DX-Forth And Utilities Page**, if still available, and-or KCS standard and-or programs.

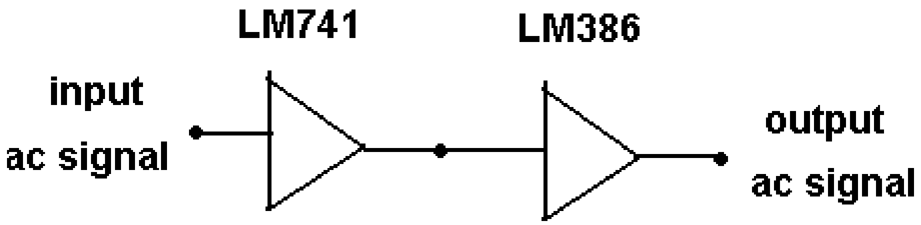
A note about operational amps and their use in terms of amplification:

Many operational (op-amps or opamps) are designed to amplify the **difference** between the two voltage applied to its to input pins. This (signal, input) voltage can be either AC or DC. This output difference signal or voltage may have also been amplified by the opamp. The gain or amplification of many op-amps can often be set and-or is variable by using a stated resistor and-or capacitor value. If one input pin is grounded to 0v, the output difference will simply be that of the voltage applied to the other pin or input. An opamp is often called and-or functions as a difference amplifier. One common example of a difference amplifier is found in temperature control circuitry. For example, if the temperature (voltage) signal from a temperature sensor is higher than a preset value by the circuit, then perhaps the heat source can be turned off, or a fan can be turned on.

An operational amp or "op amp" was mentioned above, and a popular, general purpose, low-cost op-amp is the **LM741** IC. It has a fairly high input impedance of about 1 to 2 Mohms. This op-amp is ideal as an input or "front end (radio section)" pre-amplifier to amplify a weak radio signal, such as that after the diode that helps to isolates the audio signal form the RF signal. **The LM741 has a maximum input frequency of about 1MHZ before the gain is reduced to 0**. The gain or amplification of this IC can be adjusted so as to be very high if needed, perhaps several thousand if the input signal is small so as to prevent "clipping" or audio distortion due to the maximum output signal's amplitude due to the voltage supply, say 9V to 12V. The output impedance of this specific op-amp IC is rated at about 75 ohms, and this is very practical for the microphone input on many modern computers of which can then amplify it further with its sound card and-or amplified speakers connected to the sound card outputs.

The output of the LM741 op-amp can optionally be sent to any amplifier, but those typically have a much higher input impedance and you will have to test the results. For a small amplifier system, the output of the LM741 used as a pre-amp can be used as the input to the low-cost, low-power audio (frequency, range) amplifier such as the **LM386** IC which has a settable and-or adjustable gain of about 20 to 200 and higher current to "drive" or power a speaker. It's input impedance is about 50K ohms. You can even then send the output of the LM386 to a higher power "push-pull" (power) transistor amplifier circuit that uses both a NPN and a PNP "complementary pair" of transistors which have similar electrical characteristics (ie., a "close, matched pair"). The output impedance of the LM386 is low and is ideal for an 8ohm audio speaker, but it can generally handle impedance of various speakers rated from 4ohm to the 16ohm impedance types. It is of technical note that these specific IC's mentioned have a cutoff or maximum frequency of about 1Mhz, and will therefore work well with audio frequencies which are much lower. It is possible to supply power to both of these IC's from a single 9v battery, and this would be ideal for a homemade radio or a small "amplified speaker" for a guitar, headphones, or a computer.

Here is a block diagram of the above discussion: [FIG 315]



The common electric symbol for an amplifier is a triangle as shown above. An op-amp also may be shown as having two inputs, one is for the non-inverting input, and the other is for the inverting input. The inverting input will have its output being "phase shifted" (ie., effectively time shifted or difference, leading or lagging in time) by 180° with respect to the input waveform. Because of this, an op-amp can also function as a (input signals) difference amplifier if there are two inputs. That is, only the difference between the two signals (ie., frequency, voltage) is amplified. A summing amplifier will (mathematically) combine both input signals amplitudes and produce a single amplitude signal for the output.

A HELPFUL LIST OF SOME POPULAR RADIO TYPES, CHANNELS AND THEIR FREQUENCIES

USA area region , CB Radio Frequencies

A list of the USA, 40 CB radio channels and their corresponding radio frequencies (in Mhz) is shown below, this is helpful if you have a radio that does not have the CB, etc, channel numbers, but rather requires a radio frequency value to enter so as to tune that radio to it, and so as to receive and-or transmit with that specific frequency. The frequencies that CB is allocated is in the HF = High Frequency band of frequencies, and it is often called the 11 meter band due to its wavelength. Also indicated in this list is the common use for a specific channel.

Note for example that: 26.965 Mhz = 26 Mhz + 965 Khz = 27965000 hz

In brief, wavelength (Lw = Wl) in meters = distance or length the wave would appear if it could be seen, and this is the distance per 1 cycle (c) or hertz (hz) of it. Lw = d / c =~ (300 Mc / s) / (f hz) . For example, a 100 Mhz radio wave signal has a wave length of about: (300 Mm / s) / (100 Mc / s) =~ 3m =~ (3m)(3.28 ft/m) = 9.84 ft

CB Channel #	**Frequency**	
1	26.965	: Lw =~ 11.13 m =~ 36.5 ft
2	26.975	
3	26.985	
4	27.005	: TRAILS , HIKING
5	27.015	
6	27.025	: GENERAL TALK FOR ALL IN RANGE
7	27.035	
8	27.055	
9	27.065	: ● EMERGENCY ONLY , MONITOR
10	27.075	: LOCAL TRUCKS
11	27.085	
12	27.105	
13	27.115	: RV's and BOATING
14	27.125	: WALKIE-TALKIES (very low power)
15	27.135	
16	27.155	: TRAILS , HIKING , SSB OK
17	27.165	: N & S HIGHWAY TRUCKS
18	27.175	
19	27.185	: E & W HIGHWAY TRUCKS
20	27.205	: Lw =~ **11.0 m** =~ **36.2 ft** , "CB" typ. Fhz
21	27.215	: LOCAL TRUCKS
22	27.225	
23	27.255	
24	27.235	
25	27.245	
26	27.265	
27	27.275	: FM MODE IS "SUGGESTED" FOR THESE
28	27.285	: FM MODE
29	27.295	: FM ,TRUCKS
30	27.305	: FM , REQUEST (CALLING)
31	27.315	: FM MODE
32	27.325	
33	27.335	
34	27.345	
35	27.355	
36	27.365	: ● SSB , AM, SSB , USB, REQUEST MONITOR
37	27.375	: SSB
38	27.385	: SSB : USUALLY FOR LSB
39	27.395	: SSB
40	27.405	: SSB : Lw =~ 10.95 m =~ 35.9 ft =~ 36 ft

Frequency range from Ch1=26.965 Mhz to CH40=27.405 Mhz is a total of: (27.410 - 26.960 Mhz) = 450 Khz and this includes an extra 5kz to allow the full (usb and lsb) 10 Khz audio bandwidth on the lowest and highest CB frequencies.

As of 2024, any channel can technically utilize either an AM (Amplitude Modulation of the carrier frequency radio wave), FM (Frequency Modulation of the carrier frequency radio wave) or SSB (Single Side Band, AM) mode. For audio clarity, both the transmitter and receiver must be set to the same radio mode. SSB offers a longer transmission range and it might be used by someone on CH 36 (preferred) or possibly CH 9 who is in need of assistance. FM mode is generally for short ranges less than a mile, and offers clearer communication with less noise interference. Each CB channel is allocated a 10Khz bandwidth (range of frequencies). For the FM mode, it is sometimes expressed as Narrow Band FM (as compared to standard, public FM radio with a huge bandwidth). **For the SSB channels, it can only have one conversation, and on either the USB (Upper Side Band) or LSB (Lower Side Band) mode, and this is due to that the SSB signal is converted back to the entire CB channel bandwidth of 10Khz at the receiver.** A **"clarifier"** circuit and-or knob can help tune a SSB signal frequency slightly for best audio quality. Many CB's do not have a frequency display, however as of the year 2024 there are several inexpensive, premade circuits or modules available that are available for purchase which can be placed in the radio, and-or near the transmission antenna.

In general, for any transmitter radio, do not try to transmit without a proper antenna connected to it, and since it may damage the internal circuit of the radio when the SWR is high and the power is not being transmitted. It is possible to use a length of common wire, perhaps about (300m / 27mhz)(3.28 ft) = 36 feet long, or a half length at about 18 feet, or a quarter of that wavelength length at about 9 feet = 108 in. long, etc, but it might not be tuned properly in length for the desired frequency of use and-or for a low SWR reading for transmission efficiency, but it probably will work reasonably in an emergency. A **telescoping antenna** is an adjustable length antenna, and is therefore suited for a greater band or range of frequencies. An alternate to a telescoping antenna, especially for long wire antennas is what is called **antenna links**. These are small pieces of metal that can easily join antenna sections and then easily allow a (more distant) antenna section to be easily removed from the antenna, hence the antenna length can then be made shorter so as to tune it to another frequency and-or wavelength. Try to insulate the antenna wire from the metal parts of the radio for it will most likely cause a short circuit of the signal and damage the radio due to high current. If the transmitter is not a portable transmitter, the antenna should also have a ground connection, and of which to what is called a "**ground plane**". This (horizontal) ground plane for a vertical antenna can be a piece of flat-like metal, such as aluminum foil, sheet-metal and-or a metal window screen of at least 1 foot in area or greater if possible, say having a side length of (1/4) the signal wavelength, and this will then be connected at the ground terminal of the antenna itself and not the radio itself due to the usual cable in between the radio and the antenna. Some use wires for the ground plane, and these are called "**radials**". These can be above and-or in the ground, and help the antenna perform better. It is possible to use a CB radio as a receiver only with using a 8 foot wire or aluminum foil folded, twisted and pressed into the female PL239 antenna connector found on many CB transceivers, and with the RF gain set high if it is available, otherwise a RF amplifier can be used between the antenna and the CB. A "**counter poise**" is much like the concept of a ground plane and-or radials, however a counterpoise is rather used to match impedance's by adding some (wire, metal) capacitance (here, for energy storage and release) to the antenna system.

Maximum antenna height for a CB radio system is 60 feet from the local ground surface or 20 feet above a tree top or local man made structure such as a building or house. In an emergency situation, the strict rules for the public masses might be overlooked so as to provide beneficial communication on a limited basis only. For any radio system, please research all the laws (local and-or national) and-or requirements. **Note that a tall and-or high antenna system in a weather storm can act like a lightning rod that attracts lightning which can injure and-or cause damage to the radio and other nearby structures. Before an incomming weather storm, the antenna can be lowered to the ground and-or disconnected at its base. Special "lightning arrestor" circuits are also available, and it is beyond the scope of this book.**

CB CH1 has the lowest CB band frequency and the longest wavelength: f = 26.965 Mhz , : Lw =~ 11.13 m =~ 36.5 ft
The half-wavelength of this is: 5.565 m =~ 18.25 ft
The quarter-wavelength is: 2.7825 m =~ 9.125 ft = 9 ft + 1.5 in

Though this book covers some of these topics that can match impedance, filter, and improve reception and transmission, you can further research: **balun**, **unun** , and **trap** which is much like a LC tuned circuit so as to select a desired frequency and reject and-or reduce all the other unwanted frequencies. These devices usually require a ferrite torroid shape of a certain size or diameter, and you can purchase these devices or make your own from a purchased "kit" (ie., circuit) to assemble.

There are "CB Shops" that sell many things related to CB radios, and they can even repair and "**peak tune**" a radio so as it is more stable on frequency and-or produce the maximum allowed and rated power on AM, FM and SSB modes. They can also do other radio modifications, and of which any may or may not void the warranty of the radio.

If there is a "grid down" situation where mobile phones wont work, a CB is good option, however, for the local area only so as to share the frequency bandwidth with distant transmitters. Please allow others in the local area to state and-or transmit or relay an important distant message (perhaps vetted military) so as to be beneficial to others.

USA , FRS Radio (Family Radio Service)

The 22 **FRS** channels are separated by a 12.5 Khz bandwidth. The transmission and reception mode is FM, and with a (+, -) 2.5 Khz deviation from the center carrier frequency. This bandwith allows a "narrow band FM" communication.

GMRS (General Mobile Radio Service) also uses the same initial 22 channels and frequencies as FRS. With a 2W maximum output as of the year 2017, a FRS radio can transmit up to about a 1 mile radius about it. Low power signals limit the range, however it also reduces the chances of interference from many other, more distant people who are using the same channels. Some FRS and GMRS channels (indicated below as: *) only allow up to 500 mW = (1/2 of a (ie., 1) Watt), and the range on these 8 channels is about 1/2 a mile. A future suggestion would be to allow a standardized FRS "emergency channel" and-or special use, "emergency setting" so as to have say 4W or more of transmission power.

The FRS and GMRS frequencies indicated below are in Mhz. FRS and GMRS use part of the UHF frequency band. The allocated bandwidth for each GMRS channel is 25Khz.

1	462.5625	: Lw =~ $0.64\underline{9}$ m =~ 2.13 ft
2	462.5875	
3	462.6125	
4	462.6375	
5	462.6625	
6	462.6875	
7	462.7125	
8	467.5625	*
9	467.5875	*
10	467.6125	*
11	467.6375	* : Lw =~ $0.64\underline{2}$ m =~ 2.1064 ft
12	467.6625	*
13	467.6875	*
14	467.7125	*
15	462.5500	
16	462.5750	
17	462.6000	: Lw =~ $0.64\underline{9}$ m =~ 2.13 ft = 2 ft + 1.551 in =~ 25.5 in
18	462.6250	
19	462.6500	
20	462.6750	
21	462.7000	
22	462.7250	

GMRS allows up to 5W on CH 1 - 7 , and up to 50W on CH 15 - 22. Some GMRS radios have a detachable antenna. CB and FRS are free to use without a license, however GMRS requires a license to use, and the permitted "call sign" for communication identification. Once a 10 year license is obtained, all members of the immediate family can then use the GMRS radios so as to communicate as a family. If you just have a radio receiver, rather than a transceiver (transmit and receiver) you can still be helpful to the community by monitoring communications and relaying (ie., sharing, giving) messages to your neighbors, civil services, etc.

GMRS also has 8 more channels than FRS has, and for a total of 30 channels. These extra channels are generally used for accessing (here , calling to request and acquire) communication repeaters (ie., receivers with a high power retransmitter ability) located on towers, buildings or mountains, and when able, they will then transmit the radio signal at a high power and at a frequency of 5 Mhz less than your input radio communication frequency. GMRS channels usually have a total bandwidth of 25Khz on all channels except for CH 8 - 14 which have a 12.5 Khz bandwidth and an output of 0.5W. CH 8 - 14 are then similar to the same FRS channels allowed usage. The deviation from the carrier frequency for GMRS is (+ , -) 5Khz , hence allowing a more clearer audio than FRS. Even though GMRS channels are separated by 25 Khz, only the center 20 Khz about the carrier frequency can be modulated by the audio source or input.

23	467.5500	: Lw =~ 0.642 m =~ 2.1 ft
24	467.5750	
25	467.6000	
26	467.6250	
27	467.6500	
28	467.6750	
29	467.7000	
30	467.7260	

USA , MURS Radio (Multi-Use Radio Service)

MURS has 5 channels as of the year 2024

1 151.82 Mhz : this is in the VHF band , this is about 50 Mhz higher than the common VHF, FM broadcasting band
2 151.88
3 151.94 : Lw = wavelength =~ 1.96 m =~ $6.4\underline{8}$ ft
4 154.57
5 154.60

MURS CH 1 - 3 are for narrow band FM, and CH 4 - 5 can use wide band FM. MURS can also use an AM mode, but its bandwidth allowed per channel is then just 8Khz wide. The maximum transmission power of a MURS radio is 2W. Maximum antenna height for a MURS radio system is 60 feet from the local ground surface or 20 feet above a tree top or local man made structure such as a building or house.

Some allocated and-or standardized USA Civil Service and-or Local Radio Frequencies. If you live in a different country, please check for the frequency and-or bandwidth allocations there, and legalities of radios, transmitting and-or reception.

National Guard, emergency radio = 34.90 Mhz
State Police, state emergency radio = 39.46 Mhz
Red Cross, national Emergency radio = 47.42 Mhz
FEMA (Federal Emergency Management Association) radio = 138.225 Mhz
Fire Department, local emergency radio = 154.28 Mhz
State search and rescue radio = 155.160 Mhz
Federal Government radio = 27.54 Mhz - 28.00 Mhz
Civilian Government radio = 27.575 Mhz and 27.585 Mhz
Coast Guard Auxiliary radio = 27.98 Mhz
Civil Air Patrol radio = 26.62 Mhz
U.S. Gov. = 26.48 Mhz - 26.96 Mhz :This band is just "below" (lower in frequencies) the U.S. CB band
U.S. Gov. = 27.575 Mhz - 27.585 :This band is just "above" (higher in frequencies) the U.S. CB band

In brief, and there are many allocations and rules for a given frequency band (ie., bandwidth - frequency range), and depending on the country. If unsure what a channel is allocated for, it is best to not transmit or broadcast on it, unless there is an emergency or fair permitted reason to do so. These allocations and permissions ensure a sharing of the radio frequency spectrum. If there is an emergency, a channel that is already active with a conversation may sometimes be a permitted and good option so as to reach help quicker.

USA , 12 Meter band = 24.89- Mhz to 24.990 Mhz : AM mode

USA , 11 Meter band = 25 Mhz to 28 Mhz : various transmission modes, AM, FM, SSB (USB, LSB)

26.965 Mhz to 27.405 Mhz : **USA CB band** , 40 Channels, AM and FM = 4W max , SSB=12W

Canadian GRS band (**G**eneral **R**adio **S**ervice) has the same channels as the **USA CB** band.

UK CB band: 27.60125 Mhz to 27.99125 Mhz these 40, 4W, **FM** channels have a strict step of 10 kHz. Allowed: AM 4W , DSB and SSB = 12W PEP (peak to peak signal)
CH 9 = Emergency , CH 14 = calling (request) frequency.

CEPT (**UK and European, EU**) channels use the same frequencies as the USA CB frequencies: Ch1 = 26.965 Mhz, RF transmission modes allowed: FM, AM and SSB. CEPT is the **C**onference of **P**ostal and **T**elecommunications for **E**urope.

Fair Warning: Foreigners must tell customs (ie., border control, etc), and obtain the **permit** from a consulate or government tourist office in **Mexico** to use a CB radio. Mexico CB's are also 40 channels, and are similar to, but not identical to those in the USA. Mexico has 5W max, for CB, but only permits CH 9, 10, 11 for general public radio communications. A "**Roger Beep**" (RB) signal is also required in Mexico so as to signal to the end of transmission to the recipient that the microphone push to talk is no longer being pressed, and a possible response can then be transmitted. Echo and repeat modules are required to be part of the CB system. These can help make the received audio more reliable when used in moderation. **FRS** frequencies are also used in Mexico.

Australia CB band is in the UHF frequency band from 476.4250 Mhz to 477.4125 Mhz. There are 45 channels commonly available to the public and with an extra 32 channels assigned to be used for radio repeaters that extend the range of the signal, and another 3 channels reserved for any future use. **Ch5 and Ch35 are for emergency.** Ch11 is the "(temporary use) calling channel" to request a conversation. The bandwidth of each of these FM channels is 12.5 khz. UHF radio is said as being less affected by the atmospheric conditions.

COMMUNICATION SECURITY:

Because CB and most other common forms of radio is an unsecured method of communication, care must be taken for **personal privacy** and-or the privacy of others when communicating, and so transmitting personal information, location, etc. should be avoided unless there is an emergency, and it may be better to use an available telephone. Rather than use your personal name, particularly your last name, use an identifying "**handle**" (ie.,an identifying "nickname") which is permitted to be used. The benefit of CB, or say FM radio for the masses with FM radio receivers, is vital mass communication when needed. Relatively nexpensive (public) FM transmitters are available for purchase, and can help your local area of a range or radius depending on the power output of it. Perhaps news, etc, can be broadcast to help people. People without FM, or possibly AM radios, can be informed via spoken and-or written word.

USA , 10 Meter band = 28 Mhz to 29.7 Mhz : 29.6 Mhz, FM, simplex, calling (request, establish) frequency 28.3 Mhz to 29.7 Mhz is only permitted for the general, advanced and extra class license, and the SSB is typically used globally. 28.5 Mhz to 29.7 Mhz is for all classes, and is permitted for use for the novice or technician class license. 10m radios are usually manufactured so as have a higher radio wave energy power output than that of CB radios where low power is used to help share the same frequencies and prevent overcrowding that distance stations might cause. 10M radios are rather used for licensed amateur radio communications for long range communications, often to locations over the local horizon,and relying on "skip" or reflection from the atmosphere to help transmit their messages.

In general, in the USA, and without a license, you are allowed to listen to any radio frequency being broadcast if you are legally permitted to have the radio receiver and-or transceiver made for those frequencies, however, you will usually need a license (Technician, General, Extra) to broadcast (ie., transmit) on those not authorized for public use frequencies, except as mentioned such as the unlicensed, available for public use CB band in the USA and some other countries. **Non-permitted, illegal broadcasting is prohibited**, and it can also cause radio interference on vital communications and-or machines, and can also be an annoyance and-or problem for sensitive electrical devices in the local area. When found, these illegal transmitters are confiscated by the authorities, and the operator is jailed and-or fined. There are easy to use, low cost, low power radio transmitters approved for home and-or automobile use, such as to transmit audio to a nearby FM radio.

There are many relatively inexpensive radios available that can receive the HF (High Frequency, about 3 Mhz to 30 Mhz) bandwidth so as you can listen to them. Many radio receivers can also receiver higher frequencies. In general, it is also legal to purchase a radio transceiver (both receives and transmits) in many countries without a license, such as for listening and-or monitoring for calls for help and other issues, and then having it available for a (then **generally permitted**, tolerated, encouraged) **emergency transmission** if you or someone nearby knows how to use the available communication system properly. Having some minimal instruction and-or documentation (ie., a written or typed note) of a communication system(s) at hand would help someone make an emergency transmission. Some transceivers can transmit a good amount of power, say 100W so as to transmit a great distance, say 100 miles for example, but many others do not at say 5W, and those will then need a RF amplifier between the transceiver and the transmitting antenna if there is an emergency, otherwise, these amplifiers are generally illegal for general usage, particularly for CB radios where the legal maximum power is 4W AM and FM, and 12W SSB. This limit allows the local area to more effectively share the relatively limited number of CB frequencies or channels, and the relatively high number of CB radios in the population, albeit only a fraction of them are in use at any one instant. As for any radio, make sure it is legal to even have in your local area and-or country, and what laws or rules apply to its use.

Whether you hear a particular radio station's transmitted signal (wavelength, frequency, power, information) depends on that stations distance from you, its power output and the actual amount of power your antenna will receive, obstacles between you and the stations antenna, helpful sky reflection. your radio receiver's antenna length, antenna direction if not a vertical antenna, design and-or tuning so as it will have an impedance of the standardized 50 ohms, the radio wave's wavelength and of which the antenna should be tuned (ie., resonant, having a maximum amount of power transfer to it) to via the length of it, and the sensitivity (ie., the minimal voltage and-or power it can utilize and rectify to an audio signal) of your radio. Inside many AM radios, there is a coil wrapped around a ferrite bar, perhaps 1 to 4 inches long, and so as to help improve the reception of weak radio signals, and it is also directional, meaning if you turn the radio to a certain angle and-or direction, you can improve the received signal power, and help reject unwanted signal that are close in frequency.

Weak signals can be increased by tuning your antenna length to be a particular fraction (1 , 1/2 , 1/4 , etc) of the wavelength of the main carrier frequency that you are trying to receive. It is of note that reducing the length of a simple wire or metal antenna will reduce its impedance, and a radio **antenna tuner** will be needed to set it to the expected standard of 50 ohms of impedance. An SWR meter connected to the antenna system can be used to determine if is tuned properly (ie., to typically having a 50 ohm impedance). Some radios have a built in SWR meter which can be used to help to an antenna to a desired resonance (ie., frequency, wavelength). In general, external antenna tuners can be automatic and will require some power (usually an internal rechargeable battery) to do so, and there are also passive antenna tuners available which do not require a power supply. Weak signals from the receiving antenna can be slightly increased by using a relatively low power RF (rf, radio frequency) amplifier placed between the antenna and radio, and these amplifiers and-or radios may also have some RF and audio (LF) noise filtering (ie., reducing, removing) abilities for a certain radio frequency and-or range of frequencies. A (RF rated) choke can help prevent antenna current from flowing back into the transmitter and-or filter unwanted higher frequencies received.

The most reliable long distance communication band throughout the day and year when the atmosphere and solar conditions are favorable is often noted as being the 40m band with an allocated frequency range from 7 Mhz to 7.3 Mhz. An amateur ("technician") or greater ("general" and "extra") radio license is required to transmit on this band. Each state usually has several educational resources and testing centers.

The letters **DX** are often used to indicate long distance transmission and-or communication. **QRP** is often used to indicate, question or request a low or "quiet" power transmission (<= 5W AM and-or <= 10W SSB typically), often to experiment and see how much range and-or contacts (successful receptions of the transmission) that a low power radio system and-or the set transmission power can make.

Transmitting the words "73" or "Seventy-Three" is an often used transmission to signal the end of a conversation and means "thank-you, "best regards (ie., to be well)". These useful and special codes for some communications originally helped reduce the length of some telegraph and-or telegram transmissions.

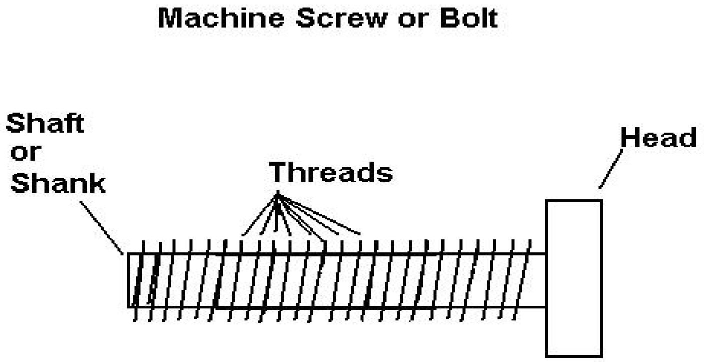
Software Defined Radio (SDR)

There are now many SDR receivers and (low power) transceivers available. These are relatively low cost, small, and can connect to your computer via a USB cable, or be carried. These devices allow you to adjust the available settings by using your computer running the SDR program, and-or adjustment knobs on some devices. These SDR devices still require an antenna tuned to the desired frequency that you want to hear and-or transmit on. A computer can also display a portion of the frequency bandwidth you are currently using, and some SDR radios also include this "waterfall" display on the radio itself. An electronic **waterfall display** of a radio receiver or on a separate module or device allows you to easily visualize if a frequency(s) is currently being received and-or used by a radio transmitter, and you can then monitor a selected transmission and-or frequency if need be, and this helps reduce the time and effort to scan many frequencies.

BOLT NOMENCLATURE OR SIZE DESCRIPTION

This description is mainly about the nomencaluature or size description for machine screws where the bolt and nut combination is used to clamp together either one or two pieces of metal to a surface and-or themselves. The nomenclature of wood screws is similar.

[Fig 316]



The head is often a hexagonal shape so as a wrench tool of a specific size can be used to tighten or loosen the bolt. It is also possible a bolt is to be tightened or loosened vai a hexagon tool or via a slot for a screwdriver. A corresponding nut and-or washer size must also be used so as to fit firmly on the shaft of the bolt, and for adjusting position along the entire shaft length . The **threads** are not individual circular rings, but are rather composed of one continuous lengthwise spiral about the bolt shaft. Threads can be moulded, but are usually cut on a lathe machine. The nut has corresponding threads on its central, inner surface ring.

Minor Diameter - diameter of the shaft without any threads.
Pitch Diameter - diameter of the shaft at half the thread height. The smaller the pitch which is the distance between each thread, the larger the thread count for a given distance.
Major Diameter - diameter of the shaft which does already include the thread height.

Pitch - the distance between each thread crest or edge
Thread Depth - the distance between the Major and Minor Diameters
Thread Angle - the angle created at the vertex of two adjacient threads

M(diameter)-(pitch)x(length) : **Bolt Nomenclature** , Ex. M5-1x30 = Metric, 5mm bolt, 1mm thread, 30mm long M , if used, means metric, and distances are in mm , otherwise if M is not used, distances will be in inches.

A bolt might not have threads on a segment(s) of it, and this area is technically called the shank part of the bolt. Some bolts must also be tightened to a certain value of tightening or clamping force , and they will require a torque wrench with a calibrated scale so as to properly do this.

Colors Created From RGB Emitted Light Combinations

RGB = Red, Blue, Green light and-or colors seen : primary colors of white light

The primary colors of white light cannot be created by combining or mixing two other colors of light.

After mixing or combining equal amounts, intensity and-or energy of each two primary colors of light, we can create a third and new secondary color that is the combination and result of those two colors:

red + green = yellow
green + blue = teal (turquoise, aqua-marine)
blue + red = magenta (light purple)

If you have light sources that emit these colors, you can shine them all onto the same location on a white surface and then see how they can be combined together so as to create various other colors. There are computer programs so as to mix RGB colors of light or paint, and will express the corresponding RGB values used between (0d and 255d) so as to recreate this color elsewhere such as on another computer screen, etc., if those are calibrated to display the same colors as initially seen. An untarnished piece of copper, silver and gold, etc. can help adjust and-or calibrate a computer screen so as to display colors correctly and-or as standardized.

Yellow, teal, and magenta are secondary colors of two of the primary colors of RGB or white light.

By varying the intensity or level of each of the two primary colors, different "shades" of yellow, magenta, and teal can be created. The less intense one primary color is, the greater the resulting color being that of the other primary color.

Since RGB colors of light are additive in nature, it means that the resulting secondary color will be apparently closer to that of white light, and-or appear as somewhat brighter. When the three primary colors of light are combined together, and having the same intensity each, the result will appear to be white light.

If the range of each color is say is 0 to 255 in decimal, and which equals FF in hexadecimal: 255d = FFh
we can convert a given value (N) to a percentage from (0% to 100%) by using a proportional type of equation and-or
an equivalent fraction. To make a liter shade of a color of paint, simply mix an amount of white color paint into it.

Black and White are not true colors as we know, but are often called as colors. When black and white are mixed at various percentages, various shades of grey can be created, and they could be considered as shades of either white and-or black. Common grey can be considered as a mixture of 50% black and 50% white.

A colors intensity on a (0 to 255) scale of values. This range is also the numeric of 1 byte which has 8 bits (0 or 1) of data.

If we let a value of 255 = 100% or the maximum setting:

255 is to 100% , as is, or equals N is to x%

For example:

If the intensity (0 to 255) of red was set at a level of 75d:

If red = 75d: $$\frac{255}{100\%} = \frac{75}{x\%}$$

$$\frac{255}{1} = \frac{75}{x}$$

Extra, if needed:
75d = 75 / 16 = 4.675
(16 x 4) = 64 = 4h , (75 - 64) = 11 = Bh
75d = 4Bh = 48 hexadecimal
And:
4Bh = (4 x 16)d + (B=11)d = 64d + 11d = 75d

$$x = \frac{75}{255} =^{\sim} 0.29\underline{4} = 29.4\% =^{\sim} 30\%$$, mathematically:

If red was set at a level of = 29.4% of 255 , $d = (29.4\%)(255) = (0.294)(255) = 75$

Though red was set at a level of 29.4% = 75d on a (0 to 255d) scale, this does not mean that the volume of that red shade of paint in a mix is that same 29.4% value. For example, the volume of a certain color in a paint mixture, does not equate to the shade level of that color used. Still, the volume of a certain color of paint will help determine the color of the resulting paint in the total volume. Consider that if only a few drops of a shade of red, even if at 255d = 100% of its total possible value, if then mixed in to a large volume (ex., a gallon or liter) of blue and-or green paint, then that low amount (a few drops of volume) of red will not make much of difference in the resulting color produced, and because it was a very low percentage of the total volume. Note however, that if the weight of a certain object such as some paint increases by a factor of (n), then the volume of it will also increase by that same factor of (n). Also note that the volume of red used may double (2), but the volume of the final paint mix does not generally or necessarily double, and particularly when red volume was low to begin with as compared to the total volume of the resulting mixture. If red, green and blue were of the resulting mixture, its total volume will be the sum of each volume of red, green, and blue used, fraction of the total volume and-or % of total volume of each color can be calculated as:

$$\frac{\text{volume of a color used in mixture}}{\text{total volume of the mixture}} = \text{fraction and-or percent of that color used in the total mixture volume composed of various colors}$$

Note that if a color is mixed with a certain amount of white so as to make a lighter shade of it, then that amount of white becomes not only a percentage of the color it was mixed with initially, but it also becomes a certain percentage of the total mixture volume of colors.

COMMON COLORS CHART

[FIG 317]

The **primary colors of light** are Red, Green, and Blue - (RGB). Primary colors cannot be made from the mixing of other colors. Mixing some primary colors together will create **secondary colors** such as yellow, cyan and magenta.

Some colors not mentioned or shown are much like a mix of two other colors. For example, Maroon is like a mix or "shade" of Burgundy (a Purple and Brown mix) and Brown. A Tiger Lilly is orange in color. Sea-Foam Green is a very light colored green, somewhat like turquoise, but without any hint of blue in its mix. Cocoa powder a brown. Lilac is like a very light shade of Lavender. Cyan is a mix of green and blue. Magenta is a mix of red and blue. Cobalt Blue is a mix of 40% green, and 60% blue. Tan can be thought of as a light brown color. People may sometimes see and-or understand a slightly different color and-or shade than another person, and this concept is said as being "subjective" or personalized with respect to a certain viewer or person. The colors shown and seen in the above figure could be called as typical. A RGB mix and their corresponding numeric values (0d to 255d) and-or color standardization can help with this issue.

It is understandable that nature is often the foundation of color standardization, such as green leaves, shiny or oxidized (rusted) copper metal, gray-like silver and steel metal. A common ant with a brown color. A red tomato. A yellow colored Bee, mustard and dandelion flower. A lite to medium blue sky. A green leaf and grass. A turquoise colored ornamental stone. Gold colored gold metal, etc.

Given any of the colors shown above, and including black, it is very possible to make it brighter by mixing it with some white color, or darker by mixing it with some black color. The resulting color can be called a "**shade**" of the original color if black was mixed in, or a "**tint**" of the original color if white was mixed in. As a simple and common example of mixing colors or shades is that Grey can be considered as a mixture of 50% black and 50% white. Mixing a specific shade of gray with a color is called a "**tone**" of that original color.

A **hue** is the basic color before any shade or tint of it is added. The intensity of a color is often called the saturation of that color, and can range from low saturation where the color is mixed with a high level of gray or white, and high saturation where there is no gray or white mixed in. The **luminance** of a color is its perceived brightness or its apparent energy level in relation to another color or colors. For example, common yellow is more luminant than common green or blue. Color **contrast** is a concept to see and-or use different colors so as to help distinguish something. A common example where contrast is used is with a dark ink on white paper, or perhaps some text being colored as yellow letters on a green or blue background, rather than green colored letters on a green background and therefore making it difficult and-or impossible to read.

In the above figure, silver gray is approximately a 1% to 15% black and a 90% white mixture. Light gray or lite gray is approximately 25% black and a 80% white. Gray is 50% black and a 50% white. Dark gray is approximately 75% black and a 25% white mixture.

When white light passes through a **glass prism**, a continuous "**rainbow**" of colors is created from infrared to ultraviolet, or in simple terms from visible red to violet. In terms of frequencies, this is about: (400 THz to 800 THz.) The most common colors are red, green, and blue: RGB. ROYGBIV stands for red, orange, yellow, green, blue, indigo and violet. The color between each two of these successively higher in frequency colors could be considered as a mixture of the nearby higher frequency color and the nearby lower frequency color. Mixtures of colors that are not successive in frequency are not a visible part of the rainbow spectrum of colors, and for example: teal, pink, cyan, magenta, peach, etc. Animals may see colors differently than we humans do, such as perhaps a limited high frequency range but yet have an extended lower frequency range giving them a better night vision, such as that of a deer and cats. Some animals can see ultraviolet better, such as bees and butterflies. Colors having a single wavelength are called monochromatic, pure, or spectral (spectrum) colors. Passing a monochromatic light through a prism will not separate that beam into other colors. A prism can be used to extract or filter out all other colors (or their frequencies) of light, such as white light which is a combination of all the other frequencies and-or colors, and so as to have just one frequency and-or color available.

COLOR , **FREQUENCY** THz (Tera-Hertz or trillions of hertz) , **WAVELENGTH** in nm (nanometers) . **typical values:**

red	440 thz	680 nm	
green	540 thz	555 nm	
blue	640 thz	470 nm	
orange	495 thz	605 nm	
yellow	520 thz	575 nm	
violet	730 thz	410 nm	(a relatively short wavelength in the visible spectrum)

A simplified calculation for wavelength can be 300 / Fthz = 300/440 = 0.680 and then multiplying by 1000 since 300 (10^6) m/s is associated with the speed of light.

wavelength = length = distance = (speed)(time) = c t = c / f
680 nm = 680 (10^-9) m , hertz = cycles per second = c/s
300 (10^6) m/s / 440 (10^15) c/s = (300/400) (10^-9) m/c =
m/c = meters per 1 cycle = meters per 1 hertz
= 680 (10^-9) m = 680 billionths of a meter = 680 nm

Higher frequency light and-or radio energy having the same amplitude or intensity, has more total energy per unit of time, hence having a higher amount of power.

One common standard for color selection and-or matching in the manufacturing and-or printing sector is called the **Pantone** (R) system of colors or color standard, and where each is assigned a unique number (usually 3 digits, but could have a 4th digit) next to each visual sample of color. This system is also known as the the Pantone Color Matching System (PCMS or PMS). While most people can recognize a basic color such as red, green and blue, it is the numerous subtle shades or tints of a color and-or color mixing that can become subjective to each person, and so this coloring numbering system was then developed as a standard that all can utilize.

There are computer programs and-or phone apps that can convert between RGB values and the Pantone system values. Currently (June 2025), Google.com has a free to use online color picker app. Search for "Google Color Picker". There is also some other online apps available. The Windows Paint (R) program can display RGB values in its color editor.

CONCLUSION

Many new math concepts and ideas take some time for the mind to "adjust" or comprehend to where those ideas seem simpler, practical and available for more immediate and-or further use. Nobody is born knowing much about any subject, and everyone can learn it on their own time and abilities, hence no one born should feel that they are behind or lacking. Some educated, math-minded people may only have a general or basic knowledge of much of math, and yet only are comfortable, focused with and specialize in one main or certain subject of it, say statistics for example, and may not even know much about any other math subject. There is also a great need for what can be called as "math computer programmers" so as to make mathematical or computational computer programs such as for a factory, business or anyone in need of a helpful computer program. Computer programming is not all about text strings, games, images and data, but it is also about some math to do some necessary calculations - even if just addition and subtraction.

Hopefully. this book has inspired the reader's interest and understanding of math and science. Learning new things could be interesting and fun, but it can also be stressful, often due to an overload of unprocessed information and the ability to retain memory (note: that repetitive practice helps, and it could take years sometimes), so try to learn at a comfortable pace and-or manner, and put the books aside and let your mind digest, processes and clarify new knowledge. There is sometimes a fear and apathy to math, and it may be because it is perceived as being so vast and then can only be unattainable and not worth trying to even start if you cant finish so to speak. Take into consideration that this book includes many of the common and simple basics of math that even advanced mathematicians always use and rely upon. Every book will eventually be set on the shelf, either before, during or after they are needed and read, still, just having the availability, quick access and some time to put useful knowledge within a mind is very important to you and others so that it can be quickly applied in some useful or practical way when needed.

The field of science and or math is so vast, and it is still being developed and-or "expanded", that it has now become impractical to be very knowledgeable and proficient in all of it, and it is much better for a person to focus on just one certain field of science and-or math, and even then, to perhaps focus on just a select amount of equations and-or some aspect of a process and teamwork, and so as to create and apply the results and be useful for others. Let education be a step to reach goals, and not be the endless goal in itself. Knowledge without works is not helpful, but wasteful to you and society which we rely upon.

Each book also seems to lack in some way and yet excels in other ways. Some math conscience, ability or minimal requirement, even if just adding and subtracting, seems to be almost everywhere because of its usefulness at providing solutions. Knowing some math will provide you with extra confidence, knowledge and professionalism in any work or field of study.

After writing this book, I began to realize a word such as "mathization" could be a generic-like word for all science things and books of math(s), and which is sometimes collectively called as "polymath" or "maths". I can not possibly write about all of these topics, and out of respect for all others, maybe I should change the book title to something like: "The Joys Of Math" or perhaps: "A Math Cornucopia". With this understanding of some math and science within this book, it is hoped that you can now more easily understand, explore and-or apply such things. Vast knowledge belongs in a library, but practical, useful and immediate knowledge belongs within you and a book like this.

Edition as of July 7, 2025
