A MATH SUPPLEMENT FOR ANY HOME-STUDY, HOBBY, WORK OR COURSE

Includes Many C Language Source Programs

FORWARD

This ebook is about learning some basic and essential mathematics from the author's perspective and considerations. Mathematics is the study of measurements, numerical relationships, quantifying, solving, and where arithmetic is the general study of counting, which can be called basic or fundamental mathematics. I have considered this book to be practical for the average person who just needs some basic knowledge on a particular subject and-or concept and then goes and does something useful with it. Each other math book is usually a trade-off between the maximum number of topics and an extensive and-or complicated view of a few topics. This book may be just right for those seeking a way to finally learn math, especially for its unique overview of topics and an informal approach, rather than leaving the casual reader wondering if they should have taken some kind of advanced calculus and-or perhaps being born with exceptional mathematical abilities and thought processes. There is already many other math books available, and for me to write something new would mean writing something that is hopefully different in some ways. This book will hopefully make you feel comfortable about mathematics to the point where you actually want to keep reading this and other learning material and applying what you know when needed. Most books, inducing this book, are also lacking in some way and are therefore never completely finished, and at some point, they are still presented to the readers at its current edit or version so as some hopeful and timely use can be made of what is expressed. Editing this large book like this is a lengthy process and it has become increasingly difficult, but what is presented here is reasonable, and more than I originally intended since many concepts then needed to be included for the readers sake. This book does not discuss any particular branch of mathematics in great depth, due to the huge number or pages that would be required, and then not having the particular or simpler style of this book. Still, this book does show you the essentials and power of mathematics. To acquire that power, the reader must give a reasonable effort. Be patient since math and science books are usually not known for being "fast" or "lite" reading material, and then we sometimes need to learn how to learn new things. The decimal number symbols and the language of mathematics is necessary, standardized and used world-wide.

Some form of mathematics is found almost everywhere these days, even within some home cooking recipes, and you need to have some knowledge of math to help feel comfortable when you do encounter it. If you like modern technology and science (to study so as to find and understand knowledge) and want to learn how it ticks, then a good place to begin is with some math. Each page or topic, when understood, and even applied, can be a potential achievement in itself, especially for the casual user or reader who may only need to learn a few things on occasion from this book. You can even have and store this book as an available and useful "knowledge resource" for when it is promptly needed rather than as an information overload, burden to complete, and easy to forget, hence there is no need, requirement or pressure to read this entire book just to have some basic and useful knowledge on just a few specific topics in need. There is probably enough material within this book for a course and-or a lifetime of usefulness if you are willing. Some may only have a partial need for this book, while others may consider all within. You should first skim through the table of contents and book pages so as to have a general idea of what is within it.

The homemade "grassroots effort" and thoughtful style of this book was especially written with compassion for the readers having some difficulty learning math and-or science, and as an effort to help prevent those who may otherwise fail or leave an education because they can't yet manage to understand something that has to do with math. It was also written for those who desire to reeducate themselves, and-or for those who lack the resources for other ways to learn, and yet still hope, desire and need to have something available to reach for and explore so as to move a step forward. From having just occasional interest, a beginner, master, or even a practical computer programmer at any level can benefit from at least some of the material within. All books have their own style, methods, material, and available knowledge within, and so if this book currently seems excessive to the reader, or perhaps not even sufficiently detailed enough for some, there are other fine, well written and printed on paper, math books available to consider at some point in your learning journey. Please check the books available at book seller websites such as **Amazon.com** and-or other websites that focus on a specific topic that you are interested in, and which may also offer more than books about a topic. Please take a visit to your local bookstore shops for there may be books there that are unavailable elsewhere. This relatively basic ebook may sometimes be considered as somewhat less than the higher standards set by some rigorous (strict, formalized, "pure mathematical science" - the study of math itself) books in several ways, and yet it still excels in simplified, practical ways for the average person. Due to the number of pages in this book, it is currently too costly to print into a paper book(s).

This book contains much, perhaps enough for several books (practical math, basic science, basic electronics, and some

C language example math programs) on their own, or a collective volume of books, and **you are in no way expected to read it all and-or to try to memorize it**, but rather at least have a minimal or basic reasonable idea of a topic in order to begin someplace when needed, and so enjoy this book at your own pace, interest and needs - even if its just one topic or page now and then for **this book is not a formal course** having specific educational goals and with many practice problems, and therfore, generally not having much of a variety as a book such as this. Placing these writing together into one book or volume also helps with the distribution of them, for it is easier to distribute just one book in one instance, rather than three (ex., math, science, computer programs) books and three instances over time and availability. This book started out to be a basic three chapter math book with many new helpful ideas, yet I still had to somehow make this book different enough to be even be considered as something to obtain, and so I then included many practical science topics and computer programs.

As for trying to learn and-or understand things, it is surely much better to learn slowly and easily, than not at all. Consider math as a helpful tool to learn, build and apply other knowledge, rather than just as a temporary goal to complete some kind of study or course. This book can be viewed before, during, and after any course (tutor, private or public course such as from a local college) as a helpful supplement to learning. One thing to always remember is that it is not how much that you know of a seemingly infinite or endless topic, but how you can apply what little you do know so as to make some type of practical and beneficial use of it for yourself and-or others. To learn more about the infinite subject of mathematics, just apply what you already know as the first step to begin leaning new concepts. This process could be called the "fundamental math learning concept" where each new concept is built upon previous concepts. It's like a logical chain, steps or progression of concepts from one to the next following one. Some concepts can be fascinating and an achievement to learn, but there is nothing within this book that is only for the magically gifted to attempt. Concepts are rather given in successive steps so as anyone could reach and learn them. Even the most highly advanced math topics are built upon and utilize the basics of math such as: **addition, subtraction, multiplication, and division** to a great extent, and therefore knowing just these, you can go a long way in terms of practicality, usefulness and learning new things.

This book also includes some example plain text, readable and editable, **computer source code programs** that are mostly based on the math material found within this book. The computer programming language used is the popular **C programming language**. Even if you may never program a computer, you are still encouraged to take a glance at them when your able for the sake of familiarization. A computer can quickly calculate many mathematical values that would otherwise be very difficult and-or time consuming to do. Computer programming is an interesting, joyful, artful, and rewarding hobby that could even become beneficial to others when making even relatively simple computer programs that can easily calculate values that others such as scientists, hobbyists and businesses could benefit from. Always remember that there is "strength in numbers", "numbers matter", and that nobody is magically born knowing how to do math, but they can learn the knowledge step by step at their own pace and needs.

Some history and facts were included in some topics so as to help provide a more practical understanding of what has previously taken place in our world so as to get to this modern level of understanding, and also to give some readers a "good read" of many things to consider further.

Book and Computer Safety Statement

This PDF (Public Document Format) ebook, and having the **.**pdf filename extension, is meant to be safe to obtain and read. It is a single file with no attachments and-or associated files needed. There is no active links within it to send you to some other website. You will have to actively copy and-or type a link or internet website address into your web or internet browser. This book contains no active code such as to play music, display an image, etc. ("**etc**etera" which means "and further", "and so on"), although your internet browser and-or .html webpage viewer system usually has these abilities to call or access when needed. This book contains a few internal hyperlinks to a few selected pages and-or topics within this book such as to easily go to the table of contents page, and the donate page.

Please help the author of this book

THIS FULL VERSION OF THE MATHHIZATION EBOOK IS FREE TO SHARE TO OTHERS IN NEED. PLEASE HELP THE AUTHOR WITH A DONATION FOR SOME HELPFUL LIVING NEEDS. YOU MAY ALSO DONATE ON BEHALF OF SOME OTHERS WHO ARE NOT SO ABLE TO DONATE AND-OR DO NOT HAVE A PAYPAL ACCOUNT, ETC.

YOU MAY HELP THE AUTHOR BY SHARING THIS BOOK VIA YOUR OWN EMAIL ACCOUNTS, ETC. TO YOUR RELATIVES, FRIENDS. GIVE A MENTION ON YOUR SOCIAL MEDIA CHANNELS AND WEBSITES THAT YOU ARE ABLE TO SEND SOME PEOPLE THIS EBOOK AND AT NO COST TO THEM VIA AN EMAIL ATTACHMENT, WEBSITE DOWNLOAD, DISK, ETC. THIS BOOK CAN ALSO BE USED AS A FREE GIFT SO AS TO HELP A WEBSITE OBTAIN SUBSCRIBERS, ETC.

I, the author of this book, am humbly asking for general donations for my wellbeing, and not in exchange for this book or any other item, service or debt. Even small donations of a few dollars can make the difference to help get some things I need to function day by day as a veteran in need. People should donate according to their own personal ability. The donation will be used for some basic living items such as for health, well-being, and other expenses such as for transportation to the hospital and other appointments. There is a saying that "If you do not ask, you will not receive". **You may kindly send your (non-tax deductible) donation for my wellbeing via this verified Paypal link**:

The Author's Donation Link Is: https://www.Paypal.me/JonAlbert

> **NOTE:** For both our records of helpful communication, please send me an email if you have donated or have a message, and so as to prevent any issues of your donation or message not arriving to me for some reason. It would help greatly if you leave a comment including the date you sent it, and at the text Post I made about emails, messages and donations on my YouTube.com channel called Mathization and as long as it still exists, and if not, my email should be sufficient. If I need your email due to a comment on my YouTube channel, I will then ask you in a reply so as to send it to my email if you do not yet know it. Resend emails and messages if I have not responded, and please leave another comment about it on my Post section on my YouTube channel if you want. I do not delete these messages, and so as to provide helpful communicatin and verification. Thanks in advance for any donation. If you like the ebook, it would be nice to hear from some people of what you think about it.

Some people wishing to donate might not yet have a Paypal or other electronic payment account, and those who are more able may also consider donating on their behalf (ie., for them). If you do not have a Paypal account, you may ask someone with an account so as to donate on your behalf. Those who support education may also donate whether they have received this book or not. If you do not have a Paypal account, there may be some other options so as to still donate to me through the Paypal website, etc. Please write and-or copy and paste the above link where needed.

My contact email is: **mathhization@gmail.com ,** and an alternate or carbon-copy email in case there is any communication issues is: **mathization@aol.com** Please notify the author of any issues. I try to read my emails in a reasonable amount of time, but due to spam emails, or a valid emails being placed into spam folder automatically by the email company, it makes everything slow down. I do not collect, misuse, or sell any email addresses or data other than for the purposes needed for this book effort and in the case that I have to responsibly contact you for some reason. I understand that some may wish to use a spare and-or alternate email address rather than their main email address. Please be patient when corresponding, and-or occasionally resend your message if I have not responded in a timely manner. I will not reply to people seeking to cause problems. I will generally only reply to the address of the sender of the email, and not to another one mentioned in the email. Occasionally, I may send a verification email so as to help prevent misuse and-or other issues.

If you want to be helpful to education, please let others know about this ebook on your website and-or social media, such as Twitter, Facebook, email, etc., so that some others in need may also obtain this ebook. This book was made out of necessity for people needing more accessible education and-or some assistance at work or with a course (public, private, tutor) they are currently taking or may take in the future. You may also email me about any significant and-or logical errors to be freely corrected, and that were overlooked during editing, and if so, thank-you in advance for your considerations and positive addition(s) which will help others who obtain any further editions of this ebook.

LEGAL DISCLAIMER: By using this book, the reader and-or user of accepts general and fair responsibility, and all liability for its use and-or application of.

This book effort is still an ongoing process, and there is some room to always correct and-or improve it. I apologize in advance for any possible logical errors, typos (spelling mistakes), omissions, amateur articles (usually topics beyond the full scope of this limited, practical book), and occasional sentences that could be rewritten. This book has become difficult to edit as of the year 2024, and new edit versions wilil take longer. I also have some health issues, and second-hand cigarrette smoke has made my situation worse throughout my life and living places, and even as I write this now - "challenging" my health, particularly my circulation, and "peace of mind", and it makes this book creation difficult. Please donate. This book does does not compete with the educational books commissioned and-or professionally made by others, and it was rather made to be an interesting and helpful educational supplement for any book, course, hobby, household needs, work, etc. Each writer and-or book has a style to appreciate in some way.

What is given in this book is worthwhile and can be enjoyed through the years and needs as they arise. This book slowly grew from being a basic math book to be now of a very large size, and therefore, it is very time consuming to edit, and it is the main reason to publish what is available in it as of now. In the current state of this book, I feel it is acceptable enough to help others in some way, even as supplementary material for any course, book or needs they may have. I believe this book can inspire others just like many other books can, and it might also put some helpful wind into the sails of some various educational assistants. You are also encouraged to take a course, public or private, in what you feel is needed or required, and regardless if you have this book or not as an additional source of helpful information and ideas. Many articles or topics in this practical book are not meant to be a full rigorous study of it, but rather just a practical introduction with just enough knowledge for the average person to consider and-or be satisfied with, and without it then being overwhelming. Some articles may contain a mention of previous topics and-or values, and so as to provide some assistance and convenience to the reader, although it does increase the number of pages in this book. There are many other nice math and science topics and details which could of been placed in this book, however, I know that it already has more than enough material for the average reader to consider from just one single book, and that all books of this nature can be lacking or incomplete in some way. I will continue to work on this book effort so as to improve it in a variety of ways just as any book already written may be improved.

Math books of all types, well written and presented by other authors are often available in some stores. This book is a helpful supplement or educational support for any book, course, hobby, work or home-learning that you already have or may then consider. This book is not a replacement for a formal and-or required education in math, and in fact, it probably falls short in many areas. This book is not to express or showcase any special mathematical topics, ability or knowledge so as to impress people or challenge their previously learned mathematical abilities with various unlearned, random and clever mathematical puzzles that perhaps would be generally difficult to solve at first, but once you know the solution it make you question your mental abilities. This book is rather another way to express the most common and practical math topics. This book was also written due to the mention by others on various media outlets that the average student math grades and worker abilities in the United States were lower than those of other countries. Some employers may require a training certificate and-or graduation certificate in some field of study, or perhaps from just a single course or lecture, and this book can not formally offer that, but it rather offers some additional education so as to help facilitate or supplement a more formal book, course, home study, hobby, work, or for inspiration to understand many things of math and science.

This book can also be placed on a modern phone so as to have it immediatly available for use if your phone or device has enough power remaining in it, or where the internet reception is not available such as during some hiking or camping trip.

This book is also very helpful for both new or experienced computer programmers regardless of the specific programming language of choice, and both the programming concepts of a computer programming language, and a program's source code (ie., the plain text, readable version of it) can be translated and applied wherever needed.

"Thank-You", from the author.

LINKS AND OFFERS

The following are some fairly stable links of many years of availability to some offers, causes, programs or apps, and websites I found, and thought I would then share them as an effort to help each other and give the reader somethings to go check if they would like to. Since this book may take a while to view and-or read, they were arbitrarily placed upfront here as part of the book introduction area. These links, which are like readable electronic addresses to (internet) websites and-or web pages are subject to possible change beyond the knowledge and control of the author of this book, and if so, you may sometimes need to do an internet search such as by using an internet web browser (access and viewer program or website such as Google.com) when considering a link. Simply type and-or copy and paste any links into your internet browser and-or email program to begin.

mathization@gmail.com The email address to contact the author of this book. Use something such as: ebook or math book on the email subject line. You may also use: mathization@aol.com

Scientific Calculator There are some free versions of many calculator programs and-or apps (applications) for modern phones. One for phones with the Android operating system is called RealCalc. This app is available from their website or at the Google Play Store. Search for **RealCalc**.

C Language Compiler **TinyC** is a fast C-language compiler that will take a plain text (.txt) file of C language, computer programming text source code, and creates an executable (.exe) program file from it. This works in a DOS or text computer command-line environment, even if you have a Windows ® computer operating system. The text source code programs in this ebook were compiled into computer programs with TinyC. For advanced programmers, there may also be some TinyC functions or code libraries available for basic Windows system accessing and programming. C++ is an advanced form of the C programming language that includes
a programming concept called classes which is somewhat similar to the struct data-type in regular C. The main website to get TinyC is: bellard.org , and select DOWNLOAD.

ELECTRONICS **Talking Electronics** is a popular electronics website for the electronics hobbyist. There are many educational articles, circuits and kits available: Their website is: talkingelectronics.com

WORD PROCESSOR The free program called **OpenOffice Writer**, a computer program for the (PC) Windows operating system was used to help edit the initial text, and then create this .PDF ebook. It has many other advanced features available, and was downloaded from: openoffice.org The Windows computer operating system, Paint computer program was used to help create and-or edit most of the figures or images in this ebook. Write a page a day, and you will have about a 300 page book in just 1 year, and editing it and so on could take as much time. This program has been later superseded by another program called **LibreOffice**, and you should then check that out also.

AFRICA WITHOUT BORDERS INTERNATIONAL

Please Donate to Africa Without Borders International. Any donations is significant and helpful to the cause of improving basic living conditions and lives in Africa. Jason, a learned Biblical scholar and author, and his wife have given much in terms of telling people about the Gospel religious message. Supporting those who a have a helpful message and-or community in need is a way for you to be a real and valued part of it. Their current website is: africawithoutborders.co.uk

MIRACLES STILL HAPPEN This is an ebook of the personal account and testimony of the Gospel message in the life of its author Marlies Zechner and the people encountered in various countries and circumstances, and so as to also share with and help inspire others. This book has the .pdf format and is about 133 pages. It is currently permitted as free to read and share with others so as to help improve our lives. Book contact is: m_zechner@hotmail.com To see and-or obtain this book online at a hosting website, the webpage's internet address is: https://www.archive.org/search.php?query=Miracles%20still%20Happen%20marlies%20Zechner

Basic Supplementary Income (BSI), or Basic Supplementary Assistance (BSA) is only concept created by the author of this book, and it is for the destitute in financial need, and so as to improve health and well-being, reduce physical and financial stress, potentially reduce crime and help prevent very high medical costs via a relatively low cost prevention method. This can create a better quality of life and social dignity. Perhaps $5 to $10 USD (2025), and depending on the specific location and its local costs for items, added per day on a debit card, and so as to help prevent misuse and to promote financial responsibility. This money will also directly improve many businesses in need, and this is very similar to how the "Food Stamp" program that helps maintain and improve society, and it indirectly helps the entire food industry, jobs and other businesses. Perhaps higher valued items that are in need such as shoes and clothing can be saved up for day by day. Surely, this value wont even come close to paying someones rent, but it can still do much, and it should then also be easier to pass into legislation. **BSI** is not the same concept as the **UBI** - Universal Basic Income concept which basically costs several times more, and it is usually then not made into legislation to help people, and then nothing is getting done in terms of UBI. The BSI concept should be more passable into legislation.

Animal Wellbeing - Support animal wellbeing and the banning of animal testing. Animals are innocent beings who can not speak as we do or hold fairness rallies against such matters. Try to not eat meat, and try to eat more vegetables, nuts and a variety of plant matter. There are many new alternatives to using animal testing. Peanut butter is said as being a complete protein. Nuts and-or nut butters are also high in certain minerals (ie., elements). Vegetables, etc, can be shredded using a grater, ground up in a machine and-or mashed in a soup, and so as to be easier to eat and digest, and then have more surface area for nutrient release and absorption into the body. This helps prevent overeating so as to get enough nutrients. A **vegetarian** may eat some animal products like milk, cheese and eggs, but a **vegan** does not eat any animal products, and both avoid animal meat for their health and-or conscience, nonetheless, everyone should have a goal of eating less or no meat. There is no joy in taking the life of a living being, and-or having it suffer its life in poor living conditions.. **PETA** (People For The Ethical Treatment Of Animals) is a nice organization.

Project Gutenberg - Various books, free to dowload and read in their electronic, digital form such as having the standard PDF format, etc., and some are free to distribute. There is a wide variety there, and some are old religious texts.

Van Nostrand's Scientific Encyclopedia - This is a very thick book, many topics available, old copies can be found for less, but I recommend purchasing a new, updated copy for your library.

A few other books, authors and websites are also mentioned in this book.

PLEASE TELL OTHERS ABOUT THIS BOOK

THIS EBOOK IS FREE TO HAVE AND DISTRIBUTE ("SHARE") AT NO COST TO THE RECIPIENT VIA EMAIL, WEBSITE DOWNLOAD, ETC. IN ITS ORIGINAL FORM. PLEASE MAKE A DONATION TO THE AUTHOR FOR SOME COMMON LIVING NEEDS. EVEN A FEW DOLLARS CAN BE ENOUGH TO HELP MAKE A DIFFERENCE TO THE AUTHOR WHO HAS PUT MUCH EFFORT INTO THIS BOOK SO AS TO HELP OTHERS, AND THEN THEIR COMMUNITIES.

This book can be a helpful part of setting people on a better path in life, and which then helps improve our communities in a variety of ways, either now and-or many years distant in the future. **Please tell others about this book, and that they will need to have or download a PDF ebook viewer and-or reader application** (ie., an **app** is a computer program, usually made for a modern electronic phone-computer device which is often called a "smart phone") such as from the **Google Play Store** (https://play.google.com) website, and so as to view this book on their **computer or phone device**. These ebooks should have the **.**pdf filename extension and are to be compatable and viewble on most modern computers and-or phones. There is even a convenient app that you can download and-or update there for this specific website mentioned, and it is called The Google Play Store App. While there, you may need to select which computer and or phone operating system that it will be used with or on. Many inexpensive phones usually have the Android operating system.

Math and science are knowledge and-or educational fields of growth which have taken many hundreds of years of previous growth of new ideas and discoveries by many other people, and so as others can access, learn, improve and build upon them. No one should ever feel that they should have been somehow born with knowledge and-or special abilities to do something which can only be learned over time and-or with some helpful course. A person who appears as "smart" is often just someone who has taken the time to memorized a few things already known, perhaps just a specific subject and probably just a niche in that, and to then simply recall them when needed. This book itself might even be one that a niche of people are also looking for and need.

This book is dedicated to my wife Elizabeth, and to our relatives, helpers, animal lovers and friends. Special mention to **Mr. Norman Borofski** for helping to raise me and my brothers, and also to **Mr. Dana Schweitzer** for his academic inspiration to many, both from Pennsylvania. This book is also dedicated to the future thinkers and tinkerers who may help the future of humanity in some way.

This Edition is 1.0 as of July 7, 2025. All previous beta versions are still very useful, but there are some new writings and edits available in the newer versions of this book. For the latest version number or date, etc., search the popular **https://www.youtube.com** video website for: **Mathization ebook or @mathization**

~ TABLE OF CONTENTS ~

INTRODUCTION

This book is intended for readers who are just beginning with arithmetic, algebra, and trigonometry, or for those who always wanted or needed another grasp on these subjects. Knowing how to work with numbers can enlighten you and give you confidence in problem solving, reading comprehension and discussions. This book is composed of four general mathematical topics and a generous science and appendix section, and each is given an entire section of this book. This book is intended for a rapid understanding of these topics by basically using a less formal or less critical approach to mathematics. Due to the style of this book, it can also be used as a basic reference, a helpful supplement or complement to another book or course you are currently taking, an aid for a teacher or those being educated at home, or as a step to a more formal or advanced mathematics course. If a topic or example seems of no certain need or interest, or perhaps too complicated at the moment, please skip over it to another useful topic or example and consider that which was skipped over to be reviewed at a later time. If a topic needs to be referenced at another time, please write down the topic and the page number(s) and-or formula(s). Some of the concepts are not explicitly noted in the table of contents, and are rather given "on the fly" and-or briefly, that is, they are given as you read and come upon them as necessary or helpful, but out of the general book order, and so you may need to write the topic and page number on a piece of paper.

With some available liberties of creating an e-book, such as having an unfixed length or number of pages, style, content, an effort to be different so as to be more desired, etc., this book contains many pages needed to convey many thoughts that can be roughly grouped into the following categories: main text and knowledge, examples, figures or graphics (many in a simple homemade form), computer programs, and numeric data tables. There is about 40 pages worth of "blank space" is either due to the leftover space of unfilled pages and-or pages intentionally left blank to help assist with the editing (ie., corrections and-or additions) of this ebook. The many pages helps to give the reader much material to have available and learn from just obtaining one book, especially if your access to other materials is limited and-or having a limited amount of money to purchase books, etc. There is a saying that can be adapted here, as that there is sometimes a certain quality to be found in having a large quantity or volume of material to access immediately when needed. For writers, if just two pages a day are written, a person could create about a 600 page book during just one year or less if the book contains many images or graphics.

Many topics that are frequently reserved only for algebra studies are shown in the first section: ARITHMETIC. Here, instead of using algebraic variables to show a concept, actual numeric values are utilized instead. By doing this, understanding basic algebra becomes easier since many of its concepts were already effectively shown using actual numbers instead of variables. Likewise, the transition from BASIC ALGEBRA to the BASIC TRIGONOMETRY section was made to be as smooth as possible. The concepts of trigonometry should also not be overlooked since they seem to arise everywhere in mathematics, and in the least expected places elsewhere in life.

A special section of some ADVANCED TOPICS is included at the end of this book. It is intended to mainly show you how to make some very important calculations when a scientific calculator (a preprogrammed, multifunctional calculator) is unavailable. An inexpensive regular "home" calculator can also be a great assistance throughout this book, especially for performing otherwise tedious and time consuming computations, such as finding the square-root of a number, and for checking results easily and quickly so as you can move on to other things without loosing your train of thought due to lengthy calculations. There are many calculator programs for computers, and apps (applications, programs) for phones such as RealCalc. The basic versions of these programs are often free to download, and you often will have a generous option of purchasing a fuller version and so as to fairly support the creators of it. If you already have a scientific calculator, or not, you will effectively learn throughout this book what the common buttons, commands or functions on most scientific calculators actually do. It should be noted that this section can still be considered as a continuation of the topics covered in this book. Don't forget the SCIENCE AND APPENDIX section, for it also contains much very useful information and derivations related to the other book sections, and is itself a good mathematical read.

At the beginning of the ARITHMETIC section, their is a discussion about the decimal number system. Here, you might find out that there is more to "plain old numbers" than you might think. After that topic, discussions about expressions and units (of reference or measurement) are given. To get through these discussions, you should (hopefully) already of had some initial thought, education, or understanding of the basic mathematical operations of addition, subtraction, multiplication and division. Those operations are given a more general discussion after these more fundamental concepts are first used to build upon.

SECTION 1: ARITHMETIC

THE DECIMAL NUMBER SYSTEM

The decimal number system is the common number system we are all taught to use as the accepted standard numeric or number system in the modern world. For many people, many of the fundamental concepts of numbers are either unknown, weak, and-or taken for granted. Because of a lack of a firm understanding of the basic concepts and fundamentals of numbers in general, this is where some problems may start in learning math and-or using math in a more practical manner with confidence.

We are first taught to count things, items or objects which may, or may not even be similar. To count (as a verb) things or items is a repetitive (to repeat, "do again, and again") process of steps of a measurement so as to numerically quantify (to express as a numerical representation) the total (all, entire) amount, "number of" or quantity of things or items being considered. Here, to measure is the act or process to find (often by comparing to some standard or reference) and give a certain type of "size" or "size of it all (things or items)", and that this measurement (the result of measuring) is called the quantity or "the count (as a noun, and a single number result)", sum or total of the items or things. The measurement result, or simply, "the count", is expressed or represented numerically as a single, symbolic and representative number. In a way, a number is much like a special type of word, and a unique word which has a unique meaning. With the decimal numeric system, a number can be a single symbol (0 through 9) called a single digit number or numeral, or a grouping of several of these symbols so as to represent larger counts, values or results of a calculation such as combining or summing two counts together so as to have another representative count (measurement) of things and a number to represent that count.

We measure a quantity or amount of items or things by considering (identifying or reckoning) each individual item or thing and then (numerically) summing each item as an increment of 1 to the total or previous count of items that were already considered. We will consider 1 thing or item can be numerically considered and represented as equal (=) to a count of 1 numerically. Summing (summation) is to take this numeric value or representation of 1 and mathematically or numerically successively combine it to or increment (increase, here by 1) the current count or number value so as to make an updated, larger and more accurate numerical (number) representation. Before the final or true total or sum is found of all the things, the active (in the process), or "running" sum is called an "intermediate", or incomplete or partial sum of the entire quantity being considered. We see that to count is a process to successively (ie., summing, addition), and numerically quantify (quantize, quantization, account for, calculate) so as to represent any quantity (several, many) or amount of items or things so as to produce a single numerical (number) representation of the total (including all, complete, sum, result) amount, "(final) count" or quantity of them. Each item, whether the same or not, can be assigned and represented as a numeric value of 1. For example, a count of several, here two items can be expressed as: "one and one" in written or spoken form, or (1 + 1) in numeric representation, and the result or sum is written or expressed as:
1 + 1 = 2, and is spoken as: "one plus one, equals two".

In Europe (or the "old world"), the decimal (based on 10) number system has only been in practical use since the 1300's AD, hence about 700 years ago. With their invention of the decimal (base 10, based on a count of 10), number system and positional notation in about the 5th century AD, about 1500 years ago, the people of the country of India ("Hindu's") made many initial advances in mathematical calculations. This superior (positional) counting and recording system is the main model and influence of the Arab (Arabian, middle-east area) numbering system with its more refined and standardized number symbols, and the decimal system eventually became known as the Hindu-Arabic (decimal and positional) numbering system. This system eventually replaced most other numerical systems in use throughout the world, such as the Roman Numeral system (with symbols: I=1, X=10, V=5, etc.) which could represent any number (after a possible calculation, hence not always explicitly, for example: IX=9, VII=7, XV=15, XVI=16) but was generally good for only very simple calculations. The Roman Numeral system is lacking and insufficient for these modern times, and is rarely used. For the decimal system, the name "decimal" is given due to the "deci"or "ten" (10) counting symbols it utilizes. Many people believe this system was brought about from the fact that we have ten fingers, and surely people counted with their fingers as placeholders (ie., as a memory) and-or to quickly express a value to someone via sight. Before writing as we know it was invented, ancient mankind in ancient Africa was already aware of the use and need for mathematics and was already using objects such as fingers, stones or notches (a primitive digital-like, binary system with something=set=1 and-or nothing=not-set=0) for a long lasting artificial memory or record, and a primitive form of writing to (symbolically) represent, store (record), and communicate things such as a quantity of something. For example, notches on a stick or stone, or perhaps dots on a wall were used for representing quantities or amounts of things like the number (quantity) of apples, people, and-or days. Each finger (often called a **digit** in ancient times) or notch symbolically (with a visual symbol such as | , a recording) represented a quantity of one. By using two hands, a single and unique quantity of one through ten could be represented by using that many fingers. Thereafter, such as in India, other simple or compact written (for expression and record) symbols were invented so as to easily represent these and larger quantities. Three items (| | |) and-or fingers could be expressed as 3. Four items and-or fingers (| | | |) could be represented and-or expressed as the (more compact) symbol 4. The initial seeds of math were planted long ago in Africa, and the usefulness of it are still being used ever since, and it was only a matter of time till mankind created machines like calculators and computers to quickly calculate values. It is interesting to note that computer and-or digital binary numbers are essentially composed of a series of notch and-or its absence of symbols. For example, a count of ten in the computer, binary is 1010.

Once writing was developed in ancient times before the decimal system, various written symbols (ex. such as an "X" for ten) could now represent and-or store (in writing as a written record or memory for later use) the 10 possible "finger" or "digit" representations of a quantity. When the decimal system was developed, the symbols were simplified as these incrementing numerical values and symbols of: 1, 2, 3, 4, 5, 6, 7, 8, and 9. A quantity of "no quantity at all" or "none" had to be considered and was assigned and represented as the a numeric symbol of: 0. We call this the "zero" symbol, and it was created by the Mayan people in the "New World", commonly known as the Americas. It was quickly adopted by the rest of the world as a standard decimal symbol, often replacing just a blank or empty space previously used for 0. Note that today, a value of ten (or larger) is not considered as one of the basic decimal (ten) counting symbols or numbers in the decimal number system. The ten symbols and values, typically called digits or the digits of a decimal number, used in the decimal system, where each next symbol represents a count or value of one (1) greater than the preceding value are: 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9. 0 will also sometimes be utilized to create numbers that represent quantities equal to or larger than ten (10) which is the next value after an increment (of 1) is applied to 9. 10 ("ten") is therefore now using two decimal symbols and places to represent one unique numerical value or number. A single symbol or even a large group of these numeric symbols placed together, so as to represent a unique count (number of items) and its corresponding numeric value, is sometimes called a (unique) decimal, or (decimal represented, or representational) number. Each particular number, displayed or written, mathematically represents a particular quantity (often just spoken as simply a "number" due to the common numeric or mathematical symbolic representation of quantities) of something. Numbers used for common counting are simply called as the "counting" (quantifying or measuring) or "natural" (individual units (ex. an apple) that often occur in nature) numbers. When the symbol 0 ("zero", none or nothing) is also considered along with the counting numbers, numbers of this type are classified as the "whole" numbers. For example, if you had 5 whole or individual things and gave them all away, you now have 0 whole or individual things remaining or left. Here, 0 (as a "logical" or "thought" number) is the valid numerical symbol and the representation for the quantity left or remaining. Including (ie., adding , combining, grouping) another whole object with 9 whole objects will create 10 whole objects.

A good method to understand and use these ten (10) basic numbers is to both physically and-or mentally visualize, think, memorize, compare, and draw each number as a group of similar objects (perhaps coins, fingers ("digits" is the equivalent old Roman word), a certain graphic shape, or simple pencil dots. Here below, arranged in arbitrary groups of 4 so as to have a nice orderly appearance and arrangement for faster recognition, counting, and so as to also reduce the possibility of error while summing. An advantage of this method below is that it is pure and without a number system needed.

See the following graphic:

zero	one	two	three	four	five	six	seven	eight	nine
0	1	2	3	4	5	6	7	8	9
	*	* *	* * *	* * * *	* * * * *	* * * * * *	* * * * * * *	* * * * * * * *	* * * * * * * * *

: English words for the first ten numbers. These are generally a form of the North European, Germanic area words. Sometimes, "zero" is spoken as "not".

The above dot numerical representation system can also be thought of and-or counted as:

```
1  2
3  4

5  6
7  8

  9
```

A common question then arises: How then are larger quantities or values greater than 9 numerically or symbolically represented using the decimal numeric system? The answer is to use what is called positional notation. To use positional notation, the symbols are properly (standardized) arranged and set next to each other in new locations or positions of the indicated number, These positions are also called "digit" positions. A digit of a number is composed of a one-symbol number (0 to 9) of the decimal system, and its (digit) position within the overall number. The quantity or value that this arrangement of digits of the number represents (being equivalent or equal to) is not simply the sum of its digits:

Ex.   35 does not represent, and is not equal to the addition of 3 an 5,   or = 3 plus 5,   or = (3 + 5) = 8

First consider that you have a count of 8 and add 1 to it. We know that the symbol to represent this new count is the nine symbol (9):

```
                         8          +  1   =          9
   8          : * * * *  * * * *   +  *   =   * * * *  * * * *  *   =  8 + 1 = 9 ,  "eight plus one is nine"
+ _1_                                                                              "eight and one equals nine"
   9                          "eight combined with one is nine"   ,    "one added to eight is nine"
```

If we add 1 to this value of 9, we will either need a new symbol (which doesn't exist in the decimal number system) or a combination of the existing symbols to represent this new value. What symbols that we already have should we use? The apparent choice is to let 9 "roll-over" (as if all the (incremented) symbols were all on a rotating and repetitive whee) or "reset" back to the lowest symbol of 0 (so this position can possibly be reused for representing higher quantities and for further additions) and increase the next leftward digit (considered 0 if not indicated or shown) or decimal number and-or position, by a count of 1:

```
   08                              : Leading 0's are alright to express some viewpoint about something
+ __1_        or        1            since it will not add any value to the total
   09          =       09
+ __1_               +_01_              9        +  1   =        10
   10                  10          : * * * * * * * * *  +  *   =   * * * * * * * * * *   =  9 + 1  =  10
```

The number 10, spoken as "ten", or sometimes "one, zero", represents the quantity of "nine and (plus) one", (9+1). It can also be said that for the decimal (based on 10) number system, each 1 or count in the next leftward position represents (9+1) = 10 ("ten") of the previous position - of which even for itself represents 10 of any previous existing rightward position in the number. This concept is called positional notation. Notation is an accepted or standard way to indicate or express something.

The specific value of representing 10, or "ten times", more of the previous position is called the positional weight, the digits weight, or simply the weight of that position. Note that weight has nothing to do with the specific digit value (0 to 9) or count in that single position or location. The product (multiplication) of the positional count (the digit shown at that position in the number) and its corresponding positional weight yields (produces) a positional product. The total value or quantity being represented by a series of digits of a number is simply the sum of their positional products, and which produces a positional sum which represents the entire number being considered. Don't forget to add in the first digit's positional product which has a positional weight of one (or (single) "units") only. For example, in the number 275, starting with 2, which is in the position or column having a positional weight of 100 ("one-hundred", or (a) hundred), the positional products are: 2 times 100, which is 200, and 7 times 10, which is 70, and 5 times 1, which is 5. The positional sum is therefore: 200, plus 70, plus 5, is or equals (=) 275, and this can be spoken of a in terms of its digits from left to right: "two, seven, five", or more often as: "two-hundred, and seventy, and five", or even more simply as: "two-hundred and seventy five".

Digits leftward in a number are called more significant digits since they represent a larger part of the value and positional sum. This is so since their positional weights are larger. The most leftward digit that has a value greater than zero is called the more or most significant digit (MSD). Likewise, digits more rightward are called less or least significant since they represent the least or smallest part of the positional sum. The most rightward digit having a value greater than zero is called the least significant digit (LSD). For approximations of a number, the least significant digits often become unnecessary and are not used or indicated since they only represent a small (as an insignificant small percentage or fractional part of the whole value) value and part of the total value or number. For example, if you have or counted 559 or 561 things, you could say something like "I have about, or approximately, five-hundred and sixty (=560) things". Here, a value of 1 was omitted from the sum, quantity or number, and this value of 1 is a very small value as compared to 560.

To be proficient in addition, a student must first know how to add (and subtract) any two of the basic (0 through 9) decimal numbers. Since addition is normally performed column by column (starting from the least significant digits), and the highest value for each digit is 9, the highest possible column sum is 9 plus 9 which equals 18, plus 1 possible count as a carry or "carry over" from the previous column making a total of 19. The series of whole numbers from 0 to 19 where the next number is a count of 1 higher is: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19

A good method to illustrate the concept of the addition of two numbers is to display or draw an object or group for each number, and then count or mathematically quantify and express them by successively recognizing (ie., "reckoning") the quantity that each number represents, and then increasing (repeated incrementing) the intermediate sum being found so as to find the total quantity or sum of the two numbers and-or the quantity of all of the objects those numbers represent.

```
Ex.     1    +    2     =     3      =     3
        *    +   * *        *  * *       * * *
```

As an aid to adding, or rather than use your fingers, you can discretely use dots on paper or in your mind as previously indicated for the basic decimal numbers. Usually a 4-dot system that has a square layout is a practical method.

```
*  *
*  *
```

For higher values, you can simply reuse the same 4-dot system locations, or start another one. For example:

5 would be something like this when expressed as items or dots:

```
*  *    *
*  *
```

Let's say you need to add 4 and 3. You can first put 4 (the initial running total) in your mind, and then tap or draw out 3 dots (of the 4-dot system) while adding one (1) to the running or incrementing (increasing) sum or total in your mind for each new dot considered. For this example we would not even need all 4 dots of the 4-dot system, but only 3:

3

* * : You can see that a "visualization memorization" method of knowing
* how many dots to make, and-or how many you are viewing needs to
available when needed.

The steps in your mind would be something like: You first have 4 in your mind, and you need to make 3 more dots to add to that value. Then make a dot and add 1, making a (updated, modified, intermediate or partial) total of 5. Then make another dot and add 1 more making a total of 6. Then make another dot (the final third dot) and add 1 more in your mind, making a total of 7. The result can be said as: "four plus three, equals seven" or perhaps written as: "4 plus 3, equals 7". This "dot system" might seem very primitive and almost silly to some, but I think many people, even advanced mathematicians, still utilize it to some extent. It's an alternative to counting with the help of your fingers, but that matter is up to you, so as to use whatever works best for you. Another tip is that you can switch the two values being summed and the result will still be the same. This method often helps to perform an addition. Consider adding 1 and 9. It is easier to start with 9 in your mind than then simply add 1 to it so as to have 10, rather than starting with 1 and then having to add or increment 9 to it.

The result of adding any number with 0 is that same number since nothing was effectively added to that number and the number should remain the same:

Ex. 7 + 0 = 7 Ex. 0 + 4.1 = 4.1

The basic "addition table" is a "look-up" table. With a table, you can view, seek and find corresponding values so as to find the answers or results already solved for. The addition table or chart is a good aid for learning the addition of small numbers. It can even be extended as needed to included larger numbers and their sums.

ADDITION TABLE

0	1	2	3	4	5	6	7	8	9	. . .
1	2	3	4	5	6	7	8	9	10	
2	3	4	5	6	7	8	9	10	11	
3	4	5	6	7	8	9	10	11	12	
4	5	6	7	8	9	10	11	12	13	
5	6	7	8	9	10	11	12	13	14	
6	7	8	9	10	11	12	13	14	15	
7	8	9	10	11	12	13	14	15	16	
8	9	10	11	12	13	14	15	16	17	
9	10	11	12	13	14	15	16	17	18	
.									.	
.									.	

To use the table, the sum of any two numbers is at the intersection (meeting, crossing or joining) of the horizontal (left and right direction) row, and vertical (up and down direction) column. For example, if you were to add 3 and 2 you would look for a row or column of 3, and then find the corresponding (here, this means the only other, single and unique part of the row and column pair) intersection of the 2 row or column, and the result (sum) seen at their intersection will be 5. Just the same, you could of also started by taking the 2 row or column, and then finding the intersection of the 3 row or column. The result will be the same value of 5. To be proficient in addition and subtraction, all the possible sums (for the basic (0 through 9) decimal number values) above should be memorized or available without too much difficulty. If you can't memorize all of it, then the "dot method" to help add two values, as described above, can be utilized as an aid to counting and-or summing to higher values.

If you are given a number from the table, you can then find two numbers (a corresponding pair) that were, or can be, summed up together to make that given number, hence the table above can also be used in a backwards or reverse type of manner for subtraction purposes. That is, given a sum (the total) and you have or take away either the row or column value part, you can arrive at the other corresponding value part required to make that given sum. Given one number (here the row or column number), you can find the other or "remaining part" corresponding row or column number that was part of that given sum or number. If you take a number in the table and subtract (or "reverse count", "reverse increment" which is called decrement) either the row or column value, you can then see the other corresponding row or column value (technically called the "difference" when subtraction is being considered) needed to make that number total (or sum). For example, take value 10, and you want to subtract or remove 6 from it. Look up 10 in the addition table, and then look for either the row or column of 6. The other corresponding row or column (required to make that specific pair with an intersection at 10) will be 4. You could say that subtraction is the "backwards" or "reverse" of addition since you are first given the result and are to find the other (corresponding) number of a pair (two) of numbers that will sum to that value or quantity.

Some examples of how to say multi-digit numbers, and the word "and" is often used for the word "plus" or "added to or with":

10 = "ten" , 10 + 1 = 11 = "ten plus, and or added to one"
11 = "eleven" , 12 = "twelve" , 13 = "thirteen" , 14 = "fourteen" , 15 = "fifteen" , 16 = "sixteen" , 17 = "seventeen" ,
18 = "eighteen" , 19.57 = "nineteen point fifty-seven" or "nineteen point (and) fifty-seven hundredths" ,
20 = "twenty" , 21 = "twenty-one" , 30 = "thirty" , 32 = "thirty-two" , 40 = "forty" , 43 = "forty-three" ,
50 = "fifty" , 54 = "fifty-four" , 60 = "sixty" , 66 = "sixty-six" , 70 = "seventy" , 77 = "seventy-seven" ,
80 = "eighty" , 89 = "eighty-nine" , 90 = "ninety" , 98 = "ninety-eight" ,
100 = "one-hundred" , 105 = "one-hundred and five" , 123 = "one-hundred and twenty-three"
1,000 = "one-thousand" , 1123 = "one-thousand , (and or plus) one-hundred and twenty-three"
10,437 = "ten-thousand, (**"and" or "plus"**) four-hundred and thirty-seven"
100,987 = "one-hundred-thousand, (and) nine-hundred and eighty-seven"
1,531,251 = "one-million, (and) five-hundred and thirty-one thousand, (and) two-hundred and fifty-one"
1,907,000,000 = "one-billion, (and) nine-hundred and seven million"

More examples of how to say various numbers:

0 = zero , 1 = one , 2 = two , 3 = three , 4 = four , 5 = five , 6 = six , 7 = seven , 8 = eight , 9 = nine

10 = ten , 11 = eleven = 10 + 1 , 12 = twelve , 13 = thirteen , 14 = fourteen , 15 = fifteen = 10 + 5
16 = sixteen , 17 = seventeen , 18 = eighteen , 19 = nineteen = 10 + 9

20 = twenty , 21 = twenty one = twenty plus one = twenty and one , 22 = twenty two = 20 + 2
30 = thirty
40 = forty
50 = fifty , 53 = fifty three = 50 + 3
60 = sixty
70 = seventy
80 = eighty
90 = ninety , 95 = ninety and five = ninety plus five = 90 + 5 = ninety-five

100 = one-hundred
125 = one-hundred and twenty and five or= one-hundred and twenty-five = 100 + 25 = 100 + 20 + 5

Spanish words for the ten number symbols:

0 = cero , 1 = uno , 2 = dos , 3 = tres , 4 = cuatro , 5 = cinco , 6 = seis , 7 = siete , 8 = ocho , 9 = nueve , 10 diez

French words for the ten number symbols:

0 = zero , 1 = un , 2 = deux , 3 = trois , 4 = quatre , 5 = cinq , 6 = six , 7 = sept , 8 = huit , 9 = neuf , 10 = dix

German words for the ten number symbols:

0 = null , 1 = eins , 2 = zwei , 3 = drei , 4 = vier , 5 = funf , 6 = sechs , 7 sieben , 8 = acht , 9 = neun , 10 = zehn

WHAT DOES MEASURE MEAN?

To measure is to find the size (length, weight or mass [amount of matter or material], volume or amount) of something, or the quantity of several things or objects in a group or collection of objects. Today, numbers are the most common way of (numerically and symbolically) representing a quantity or the result of a measurement. Other than that, it is possible to use words such as: "small", "medium", and "big" as measurements, but these can sometimes be ambiguous (unclear, uncertain) to someone else. To measure is done by the act of comparing, or the comparison of one thing to another (often similar) thing that is used as a reference for the comparison. The word of "meter" is similar to the word of "measurement" and "metrics", and is also the name given to the basic unit of length or distance in the metric (measurement, reference) system. A measurement value or number is the numeric result, count or sum of comparing. If the thing was a stone, or stick of a certain dimensions or qualities (ie. width, length, weight), that thing could be used as the basis (reference) of comparison or measurement for all other similar things. A common scaled ruler, having one to several unit sized markings (indications, steps) is basically a replica (a similar representation or copy) of something, such as another standardized or agreed upon reference ruler. The ruler or (measurement) reference gauge is then used as the "rule" or "standard (standard reference)" to consider and use with all similar types of measurements such as lengths, weights, etc. The simplest (non-numeric) kinds of comparison is to state that the things being compared are not the same or are equal, or that something is simply more or less than something else without giving a numeric quantity of some specific size or the difference in sizes and-or amounts. To measure quantitatively, numbers and some form of a standardized measurement unit which is one specific instance and-or identification of the reference and comparison value used for a measurement. More about units or "units of measurement" will also be discussed further ahead in this book. For measuring the weight of stones, the units could be some small reference stone, and this "reference-stone" would then be the units (of reference for the measurement) of weight and for measuring the weight of any other thing, including other stone weights and so as to also have a weight reference or unit that is twice or other multiples as heavy. Even the numbers in the decimal number (counting, quantifying) system that we use for everyday counting are in reference to something, and that something is number 1, the numeric unit. Each count greater, higher, or the "next higher or larger number", is based on this reference of 1. Given a number, to find the next higher number, add or combine this 1 to that given number. To measure something quantitatively is to express how many (ie., the number of) units (the standardized thing of reference, comparison to, and measurement of) that something has, or can be compared to something considered as the reference. [FIG 1]

Letting this length be the standard (reference) unit of measurement for all other measurements.

This will be the "rule" of measurement. It is a "unit ruler" or ruler that is only one unit long.

Joining several together will help us measure larger or longer lengths more quickly and prevent error:

The points indicate the start and end of each reference unit. Since they are the same, the ruler consists of many, or a multiple, of that unit.

Indicating how many in an increasing or incremental (integer) order:

: a ruler

The branch of science for the study of measurements, standards and references is called **meterology.**

The above discussion was how units of distance or length can be added so as to make a larger distance. In a similar way, this is also true for any other unit of measrment such as weight, mass, area, volume, time, or even for similar objects.

EXPRESSIONS

A mathematical expression is essentially another form or representation of a number, a process (such as a single formula [ie., a "mathematical recipe"]), some mathematical manipulations (such as to use the square root of a number), or steps (explicitly indicated or understood) so as to find a single number or result that represents the given expression for it. That is, the expression or representation, however it is written or contains, and the actual number that it represents, have exactly the same value, hence they are equal (equivalent, =) and either can actually take the place or be (mathematically) substituted for of the other. For example, 5, and the expression of (3 + 2) are equal, and either could take the place or represent the other. Even a representation of just a number can consist of mathematical operations (processes) such as addition (+, "plus" is the common symbol or instruction for addition), subtraction (-, "minus"), multiplication (x, "times") , division (÷ or /, "divided by"), and operands (the numbers or values to be acted upon by the operations), which when taken as one single group, it represents a single value (the given number). Some of this was previously indicated with the basic concepts of positional products and sums, hence, even a number can be "viewed", "thought of", or considered as being an (special) expression and vice-versa since they are equivalent.

operand operation operand : A basic technical format of a basic expression. The (mathematical) operation is to be applied to, or in reference to the operands (numbers). Some expressions might only have or need one operand.

The 4 most common mathematical operations and their corresponding mathematical symbol(s) are:

Operation	Symbol(s)	Example	Some Common Wording
addition	+	1 + 2 = 3	"one plus two, equals three"
subtraction	-	3 - 1 = 2	"three minus or take away one, equals two"
multiplication	x , ( ) , * , (dot)	5 x 2 = 10	"five times two, equals ten"
division	/ , -----	10 / 5 = 2	"ten divided by five, equals two" or "five goes into ten, two times, or twice" "5 can be subtracted from 10, a total of 2 times".

Ex. 30 + 5 This is an expression containing one operation and two operands. The operation is the addition operation, indicated by the "add", "plus", "join" or "combine" symbol of (+), and the operands are 30 and 5. The symbol usually chosen to indicate an addition (operation, "add") of two values is called the addition or "plus" symbol, and was made popular by **Michael Stiple** (~ 1554) and **Robert Recorde** (~ 1557), although the concept of addition, etc., was already known for thousands of years, and the (+) symbol was beginning to be used in the late 1400's as meaning "and". Recorde is also credited to the subtraction (-) operation symbol, and the equals (=) or equality symbol. This Math book uses the tilde symbol: **~** to mean **"about"**. **~=** means "about equal", and **=~** means "equals about", hence these mean nearly or approximately.

In a reverse type of manner, it is very possible for an entire expression to be considered as a single operand.

Ex. Considering the last example and having any expression that represents a value of 30 as an operand:

$$\begin{aligned} (20 + 10) + 5 &= 35 \\ 30 + 5 &= 35 \\ 35 &= 35 \end{aligned}$$

: (The entirety or grouping of: (20 + 10) can be considered as a single operand (to be first "simplified", or solved, to a value of 30) to be added to the operand of 5.

$$\begin{aligned} (31 - 1) + 5 &= 35 \\ 30 + 5 &= 35 \\ 35 &= 35 \end{aligned}$$

We see in both cases that the expression within the parenthesis is equal to (an operand of) 30 when it is "simplified" (by performing or processing the mathematical operations) or represented as a single value. More is said about this below.

TO REDUCE OR SIMPLIFY AN EXPRESSION

To reduce an expression or to "simplify" an expression is to perform the indicated operations within the expression, or arranging it in another manner to effectively produce less or no further operations on the remaining operands. This process is also known as "simplification". As shown above, the simplified expression is 35 after performing the additions. In a natural conversation, you would normally say something like "I have thirty-five of something", rather than say something like "I have thirty, and then I have five more of that something" - which is sort of an indirect or roundabout way of saying a total and single value of 35. So then, we often see the need to simplify things such as mathematical expressions by solving them or making them uncomplicated, simpler, and nicer (easier to work with).

Ex. Simplify the expression: 2 + 3 + 4

The simplified form of this expression is 9. That is, the entire value of : (2 + 3 + 4) = 9.

As previously indicated, even basic numbers can be expressed (ie. in a mathematical expression) as a positional sum (of the numbers' digits, or digits of that number). The positional sum is an expression containing the sum of each digit times the positional (decimal system) weight corresponding to that digit or (column) position within the given number.

Ex. Show 35 as a positional sum of its digits.

Here, we are to write an expression for 35. Use the positional notation concepts summarized below:

Positional Weight = Is 10 times the previous (next rightward) position's weight.
Positional Product = The value in that position times its corresponding positional weight.
You can consider this expression or its value as an operand in the final sum.
Positional Sum = Sum of all positional products. This expression represents and equals
the total value represented by the number.

Taking 5 as the first digit in question, the weight for this position is understood as 1. This is known as the (basic) "units" (of measurement) or "ones" position. Note that even this weight too is 10 times the previous (next rightward) digits weight which is 0.1. That is, 10 times 0.1 is 1. The second digit will also have a weight of 10 times the previous positions weight. Hence , its weight is 10 times 1, which is 10. This is known as the "tens of one" or simply the "tens" position. Breaking each digit into its' positional product (separated by the addition symbol needed for the positional sum):

35
3 x (10) + 5 x (1) : here, showing the expression for the sum of the positional products, or:
30 + 5 : here, after multiplying for some simplification, showing a positional sum
(of the positional products) expression

Note, we now know the second digit does not represent 3, but it actually represents 30, or 30 units, and in strict mathematical or numerical terms, this would be 30 ones.

Ex. Show the number 3215 as a positional sum.

Taking 5 as the first digit, the weight of the first digit is one (1). The weight of the second digit is ten times that of the previous (first digit's) weight or 1x10=10. The third digits positional weight is 10 times that of the second digits positional weight or 10x10=100. This is known as the "tens of ten", "hundreds of one" or simply "hundreds" position. Likewise, the fourth digits positional weight is 10 times that of the third digits positional weight or 100x10=1000. This is known as the "tens of hundred", "thousands of one" or simply the "thousands" position. Expressing this information as a sum of positional products of 3215, we now have:

3215

3 2 1 5

(3 x 1000) + (2 x 100) + (1 x 10) + (5 x 1) : an expression for the positional products. After some simplification:
3000 + 200 + 10 + 5 : expression for the positional sum of 3215
: "three thousand, two hundred and fifteen"

POSITIONAL WEIGHTS IN THE DECIMAL NUMBER SYSTEM

The discussion above about expressing a number as an expression has lead us to this. The names for the commonly used weights in the decimal system are summarized below. The commas used when writing the numbers, being a visual aid, are optional. Here, the value of one (1) is used only to indicate the position in question since the value in any position can be between and including 0 through 9.

Whole Portion Weights (In Increasing Weights)		Fractional (values smaller than one) Portion Weights (In Decreasing Weights)		
ones or units	1			
tens	10	tenths	0.1	(or 1/10 = 1/10^1 = 1 (10^-1)
hundreds	100	hundredths	0.01	(or 1/100) = 1/10^2 = 1 (10^-2)
thousands	1,000	thousandths	0.001	(or 1/1000) = 1/10^3 = 1 (10^-3)
ten-thousands	10,000	tenth-thousandths	0.000,1	
hundred-thousands	100,000	hundredth-thousandths	0.000,01	
millions	1,000,000	millionths	0.000,001	
ten-millions	10,000,000	tenth-millionths	0.000,000,1	
hundred-millions	100,000,000	hundredth-millionths	0.000,000,01	
billions	1,000,000,000	billionths	0.000,000,001	
etc.		etc.		

Ex. 5.2 = "five point two" := 5 + 0.2 , "point" is formally "decimal point" or "(decimal) number point"
Ex. 0.0015 or with helpful commas as: 0.001,5

This value above would be commonly spoken as: "one, point, five-thousandths". It is also possible for the value to be described in many other ways such as:
"one-thousandth and (plus) five ten-thousandths"
"one-thousandth and five-hundred millionths"

Considering just digits, rather than digits and their positional weights, this can be spoken or thought as::
"zero, (decimal) point, zero, zero, one, five".

The decimal point (written as a period character = .) is a separator that separates the number of whole units from the number or value that numerically represents some part, fraction or portion of only 1 single unit. Before the decimal point was introduced by John Napier, and who studied logarithms, other symbols and methods were used. A portion or fraction (part of) is only a part of 1 whole unit. A fractional part of a number is that part less than 1. The decimal point also means to the effect: to add this part or portion of 1 unit also to the total. A number that contains a decimal point, and a fractional value, is sometimes loosely spoken as being a "decimal number". The parts of a decimal number can be expressed or considered as:

whole_value decimal_point fractional_value
whole_value **.** fractional_value : Ex: 100.5 = "one hundred point five"
whole_value and fractional value
whole_value plus fractional value
whole_value + fractional value

A value can be a complete fractional value where that value is less than 1. That is, the value does not even have a whole portion except the value of 0.

Ex. 0.5 : The whole portion is 0, and the fractional portion is 0.5 = "zero point five" = "five tenths (of one)"

More advanced mathematics (that will be shown) shows that each positional weight can be represented as an indicated power of 10. In an expression form, this is a base of 10 with an exponent. The exponent increases by one for each digit position leftward and likewise decreases by one for each digit position rightward. The weights in the decimal number system using exponential notation, and the common decimal equivalent form are:

. . . ,10,000 , 1000, 100, 10, 1 . 0.1, 0.01, 0.001, 0.000,1, . . .
. . . , 10^4 , 10^3, 10^2, 10^1, 10^0 . 10^-1, 10^-2, 10^-3, 10^-4, . . .

Note for example : 10^2 = 10 x 10 = 100 : basically, the exponent means repeated multiplication, here twice (2)
10^3 = 10 x 10 x 10 = (10 x 10) x 10 = 100 x 10 = 1,000
10^4 = 10 x 10 x 10 x 10 = (10 x 10 x 10) x 10 = 1,000 x 10 = 10,000

Note also that 10^0 is the weight of the ones position. That is, 10^0 = 1. Notice that for the whole units weights, that each greater weight essentially has "another zero" placed onto the end of the previous weight. In fact, this is a simple method to multiply any value by 10; simply put a zero at the "end" (in the "ones position") of the number (also move the decimal point one position rightward of course). Ex. 7x10 = 7.0x10 = 70.0 = 70, Ex. 3.52x10 = 3.520x10 = 35.20 = 35.2
Notice also that when 10 is the base of a power, that the exponent indicates the number of zeros in the decimal equivalent. For example 10^4 equals one with four zeros after it or 10,000.

Ex. Here is the positional sum of 0.0015

0 (1) + 0 (10^-1) + 0(10^-2) + 1(10^-3) + 5 (10-4) or perhaps more commonly:

$0 + \frac{0}{10} + \frac{0}{100} + \frac{1}{1000} + \frac{5}{10,000}$: here, the first 0, is for the "ones" whole units position

For an extra note, the first three values in the sum are equal to 0 after simplification (ie, here solving or simplifying the fraction; no or 0 parts of anything is always 0. Also, anything times 0 is always 0), and for the sum, this then leaves us with just:

$\frac{1}{1000} + \frac{5}{10,000}$ combining (summing) these fractions to a single (fraction) value - the method which will be shown further in this book, we have:

$\frac{15}{10,000}$: "fifteen ten-thousandths" (= 0.0015 after performing the division expression)

Here is some more explanation of the weights that are less than 1. Let's begin at the weight of 1000. Since any weight is a product (result of multiplication) of and factor of 10 times more than the previous (lesser) weight, previous weights are always a factor of 10 times less, therefore divide this factor of 10 out of a weight to find the previous weight. Dividing 1000 by 10 results in 100. Dividing 100 by 10 results in 10. Dividing 10 by 10 results in 1 which is the weight of the "ones" column or position. Dividing 1 by 10 and expressing the weight in various forms, we have:

$10\overline{)1} = \frac{1}{10}$ or = 0.1 or = $10^{\wedge}\text{-}1$: weight of the tenths column
: a "tenth of one"

$\frac{1}{10}$ = " $\frac{\text{one}}{\text{ten}}$ " or simply: "one-tenth" or a "tenth" (of one)

Dividing the weight of the tenths column by 10 we have the weight of the hundredths column:

$\frac{\frac{1}{10}}{10} = \frac{\frac{1}{10}}{\frac{10}{1}} = \frac{1}{100}$ = 0.01 or = 10^-2 : weight of the hundredths column
: a "tenth of a tenth"
:Note, 0.1/10 = 0.01 = 1/100

$\frac{1}{100}$ = "$\frac{\text{one}}{\text{one-hundred}}$" or simply: "one-hundredth" or a "hundredth" (of one)

Many other counting systems such as hexadecimal (has a base 12 instead of the common 10 as used in the decimal system, and often used with machine language/computer programming), octal (base 8), and the binary (base 2) number system that is used for understanding computers and other digital electronic circuits, use the same concepts of positional notation as the decimal (base 10) number system. The basic difference among these systems is that they use more or less counting symbols. The ADVANCED TOPIC section of this book contains a short discussion about the binary number system.

UNITS OF MEASUREMENT

To add properly, you must add things that are similar. These similar things are mathematically referred to as having "similar" or "like" (ie. same or common) units (of measuring, measurement or reference). Consider the numeric part of a value as: "how many", and the units part of the value as: "of what". Units are said as being that to which the numeric quantity or value (expressed and represented mathematically as a number) is in reference or measurement to. For example, it could be an inch, a mile or meter of which a measurement is based upon or in reference to. For example, you can add (mathematically, or even physically combine or group together **similar items**, such as into a container) a quantity of oranges to another quantity of oranges, and get a larger net (final sum) quantity of oranges. That is, here the like units (or "identifiers" or "type") of the items or objects being added are oranges. When you see the word "units" used in mathematics, it is a short version of the phrase: "units of measurement".

Ex. 5 oranges + 5 oranges = (5 + 5) oranges = 10 oranges

This mathematical writing or expression also indicates that you can simply add the numerical values or quantities of "like things" that have "like" or similar or units, and the resulting sum will have those same units.

You cannot add a quantity of oranges to a quantity of apples or anything else, since their units are unlike or not similar, and get a larger quantity of either apples or oranges. Their will be more fruit, but the quantity of either apples or oranges will still be the same even when placed in the same basket.

Many times you will be working with "plain" or unitless numeric values. You can consider their units as being "units" or "wholes" as in an entirety or completeness of something, or as "ones" for a more numeric sense.

Ex. 5 + 2 = 5 ones + 2 ones = 7 ones
Ex. 20 + 10 = 20 ones + 10 ones = 30 ones

When the quantities or values being added are measurements, their units are correctly called units of measurement. Again, to add properly, their units, or the unit, of measurement must be the same. If they are not the same, such as when adding "apples and oranges" (unlike units), it is possible to convert one value (its numeric part) to an equivalent representation that will have the same units of measurement which is needed for their combining (addition) and to express the result as having just one unit of measurement or reference.

Ex. 5 ft. + 10 ft. = 15 ft. : ft. = feet, which is a specific length unit, or unit of length
Ex. 3 ft. + 12 in. = : in. = inches which is another length measurement unit :

This expression above cannot be simplified as is since the units of feet (ft.) and inches (in.) are unlike. One of the units must be changed to that of the other. For example, the quantity of inches can be converted to its equivalent measurement with units of feet, or the quantity of feet can be converted to its equivalent measurement with units of inches.

Since 1 ft. = 12 in., or likewise, 12 in. = 1 ft. , and substituting this into the expression above:
3 ft. + 12 in. = 3 ft. + 1 ft = (3 + 1) ft. = 4 ft.

Note, that which is said about having similar or like units for addition, also holds true for subtraction and other mathematical operations.

Occasionally, a values units must be the combination of unlike units that were used during the mathematical operation or definition. The concept of the (necessary) use of several units (as like one new unit) is sometimes called "derived units", and may or may not be identified as a single unit name. For example, speed (or average velocity) equals distance, which has units of measurement of length, divided by a time value with its own units of measurement of time.

$$\text{speed (length units/time units)} = \frac{\text{Distance (length units)}}{\text{Time (time units)}}$$

: ex. of a value that can have a combination of units or **derived units**. Mathematically: $D = s\ t = v\ t$

Hence, the units for speed is a length unit divided by a time unit which are unlike units of measurement.

Ex. $50 \text{ mi./hr.} = \frac{100 \text{ mi.}}{2 \text{ hr.}}$: perhaps you went 100 miles in 2 hours, your average speed is then 50mi/hr Why is the word average used? Because usually, or normally, you sometimes will go slower, and perhaps even a bit faster than 50mi/hr during your travel.

The units for speed in this example is (miles/hour), and the speed in this example is said to be "fifty miles per (1) hour".

Sometimes, combinations of units may be assigned a single unit name. For example, in physics (physical science) and electronic studies, a quantity or number of charged particles (Q), typically electrons from atoms, is measured in reference to a specific amount of charged particles called a coulomb (C) of charge. Hence, the units for charge are coulombs (C). Current (I) is defined as the amount of this charge passing a point per second (s) of time (T):

$$I = \frac{Q_c}{T_s}$$

Hence, the units of measurement for current is coulombs/second or (c/s). This quotient of c/s, or 1 coulomb per 1 second, is commonly assigned the new and single (derived) unit name, or identifier, of amperes (A), that is (c/s) = A.

Ex. $\frac{10c}{5s} = \frac{2c}{1s} = 2 \text{ c/s} = 2A$: Amps are a derived unit consisting of the units of coulombs, and time or seconds.

When dividing quantities or values that have like or similar units, the units are effectively "canceled out" (and-or reduced to 1, since anything times 1 does not change that value) as if they were some value or algebraic variable (an alphabetical symbol(s) representing, and as a "placeholder", a numeric value or quantity) by themselves. The result is said to be unitless or a ("plain", literal, "strict" and specific value only) numeric value.

Ex. The ratio (which essentially is, and resolves to a quotient, which is a division result) of 10 ft. to 5 ft. is 2, and not 2 ft.:

$\frac{10 \text{ ft.}}{5 \text{ ft.}} = 2$ since 5 ft. x 2 = 10 ft. also, = (5 x 2)ft. = 10ft.

The result is not indicated as 2 ft. since 5 ft. x 2 ft. = 10 feet x feet = 10 ft.^2 : "ten feet squared" or more commonly as "ten square feet"

Note: $\frac{10 \text{ ft.}}{5} = 2 \text{ ft.}$, since 2 ft. x 5 = 10 ft.

That is, the units of a result of a multiplication or division operation where only one operand has units, will have those indicated or expressed units, and for the division operation, the units must be in the "top number" or dividend operand.

Even the plain, unit-less numbers that we use are in actually reference to the value of 0. If given the number 5, it is a value that is in reference to 0, and is a count of 5 counting numbers and-or positions greater than 0 on the continuous, unbroken "string" or "line" of numbers called the number line.

BASIC MATHEMATICAL OPERATIONS

ADDITION

When we "add" quantities, we are performing a mathematical operation called addition which is essentially joining, mixing-in, summing, or combining; usually making something greater or larger. The standard symbol for the addition operation is the "plus" symbol (+). But remember, the quantities being added must be "like" or "similar" quantities. That is, they must have the same units or units of measurement to be added, otherwise, there will be an awkward "apples and oranges" situation where they can't be combined as needed to produce one numeric result having just one of those units of either apples or oranges. Formally (some accepted standard, though somewhat rarely used in everyday conversations), the operands or values of an addition operation are called the augend and addend. These both are infrequently called summands since they compose, or are part of their sum (result of a summation or addition process) value. The result of an addition operation is called the sum which means the total value of all the combined numbers.

number + another number = sum : This can be read or spoken as: "number plus another number equals (the) sum". "sum" is sometimes called the "total"

Ex. 5 + 2 = 7 : "five plus two equals seven" or "the sum of 5 and 2 is seven"

augend + addend = sum : formal or fundamental addition (symbolic) expression, expressed horizontally, or:

$$\begin{array}{r} \text{augend} \\ + \ \underline{\text{addend}} \\ \text{sum} \end{array}$$

: addition expressed vertically

: augend is a word somewhat similar to augmentation, and other similar words, most containing the letters aug, and has the basic meaning of increase or change. The words augend and addend are not heavily used today. Sum has its origins in the word summit as in the (noun, thing) peak (highest part) of a mountain, and (verb, action, "summation") to go to the top or peak.

When the units are different, as in feet and miles, a conversion of one of the quantities can be made so that the units are identical for the addition.

Ex. Add 5280 feet and 2 miles.

5280 ft. + 2 mi. : The above placed into or expressed as a mathematical expression

Since the values being added have different or unlike units, a direct addition cannot be performed such as would incorrectly result in either 5282 feet or 5282 miles. By converting (representing) 5280 feet as (equivalent to) 1 mile, we will have values with like units, and the addition can then be properly performed:

5280 ft. + 2 mi. After converting or expressing 5,280 feet to it's equivalent value in miles (with miles units), we have:
1 mi. + 2 mi. : The operands now have like units and can therefore be combined or added.
(1 + 2) mi. : An equivalent expression that indicates that the numeric parts (of the similar units) will be added.
3 mi. : After adding the numeric part of the values with like units, and keeping and expressing the same, common, identical or like units in the total.

Below is an example that shows mathematical expressions for both horizontal (left and right) and vertical (up and down) addition. Vertical addition, because of its practicality, is usually the preferred method to calculate the sum of any two numbers since corresponding digit positions can be aligned into columns having the same weight value. Adding the digit values of each column produces a sum having the same weight as the columns weight. The addition begins in the rightmost column. Showing horizontal addition, or other mathematical operations, is a good way to get comfortable with writing or presenting mathematical expressions or formulas (standardized or commonly accepted (known) expressions).

Ex. Add 35 and 24

Horizontally: 35 + 24
(3 x 10) + (5 x 1) + (2 x 10) + (4 x 1) : expression showing the sum of the positional products
30 + 5 + 20 + 4 : after some simplification we have this positional sum
59 : since: 30 + 5 = 35 , 35 + 20 = 55 , and 55 + 4 = 59

Vertically:
$$\begin{array}{r} 35 \\ \underline{+\ 24} \\ 59 \end{array}$$

checking (to help verify, locate any errors, and accept the result):

sum = (sum of tens columns positional products) + (sum of ones columns positional products)

((3 x 10) + (2 x 10)) + ((5 x 1) + (4 x 1))
(3+2) x (10) + (5+4) x (1)
5 x 10 + 9 x 1
50 + 9
59

Or: (30 + 20) + (5 + 4)
50 + 9
59

A carry or carry-over is produced when the sum of corresponding (same column) digit positions exceeds 9 as in the decimal system. This was also mentioned during the discussion of positional notation.

Ex.
$$\begin{array}{r} 35 \\ \underline{+\ \ 9} \end{array}$$

Here, by first adding the rightmost or "ones" column, we get 14 which is two digits, hence greater than the maximum digit value of 9. Simply "carry" or move the second digit (the 1), which has a positional weight of 10, to the second column which has a (corresponding) positional weight of 10, or 10 more than the previous, and continue to add.

$$\begin{array}{r} 1 \\ 35 \\ \underline{+\ \ 9} \\ 44 \end{array}$$

: this 1 could be shown as 10, but the zero is often not written since it does not contribute to/affect the sum.

Or the rarely used non-carry method: (summing corresponding positional products):

$$\begin{array}{r} 35 \\ \underline{+\ 09} \\ 14 \\ \underline{+\ 30} \\ 44 \end{array}$$

: In this method, you need not start adding at the ones column.
: (5 x 1) + (9 x 1) = 5 + 9 = 14
: (3 x 10) + (0 x 10) = 30 + 0 = 30

Again, each unit (1) of carry is 10 of the previous digits positional weight.

checking:

35 + 9
((3 x 10) + (5 x 1)) + (9 x 1) with some simplification of the expressions:
(30 + 5) + 9
30 + 5 + 9 : expressed as a sum of the positional products
30 + 14
44

Note above, in the expression (30 + 14), that this is an intermediate simplified expression showing that the 5 ones and 9 ones were combined (added). Often intermediate expressions like this are not shown, but it can assist you in understanding or remembering the steps you took to simplify an expression or to solve an equation (two different expressions that are equal each other).

Another, more popular, method to check an addition problem is with subtraction. Subtracting either operand from the sum should yield the other operand of the addition operation. This was mentioned during the discussion about the "addition table". Using the last example:

$$\begin{array}{r} 44 \\ -\underline{\ 35\ } \\ 9 \end{array} \quad \text{or:} \quad \begin{array}{r} 44 \\ -\underline{\ \ \ 9\ } \\ 35 \end{array}$$

: instead of "carries" (of 10) as used with addition, we now have "borrows" used with subtraction. Essentially, these are reverse concepts of each other. In common speak, people may say "a borrow of 1", or "a carry of 1", however, this 1 is actually 10 of the smaller weight, next rightward position that receives it.

Extra, an advanced technical note: The "(calculation and result comparison) checking process" for an addition operation can be formally expressed as subtracting either operand from both sides of the addition (operation) expression or formula:

augend + addend = sum   subtracting the addend value from each side:

augend + addend - addend = sum - addend   since subtracting or removing a value from itself (the same value) results in, and is equal to, 0:
value - value = 0, therefore, addend - addend = 0 :

augend + 0 = sum - addend   since adding 0 to any value or sum does not change it, we can express this as simply:

augend = sum - addend   by "switching sides" (for clarity) this can be expressed as the examples indicated:

sum - addend = augend   in more generalized or representative expressions:

From: sum = value1 + value2   therefore,   sum - value1 = value2   and   sum - value2 = value1

About the fancy words used in mathematics:

The fancy word terms used above, like augend, are for some formality and knowledge, and in case you read some rare math text. In general, you will not encounter many of these rare-like words in your mathematical journey. In short, you do not have to worry about memorizing them, but at least have a basic idea about them and what they may mean. On occasion, it helps to know what a math word or concept is and means, and so as to express it in writing and-or verbally. Many English math and science words are based on old Greek and Roman words of which the English audience is not exactly familiar with, but they can eventually become familarized to and accept them.

SOLVING FOR AN UNKNOWN VALUE OF AN ADDITION PROBLEM

This discussion is about solving addition problems where the sum is not necessarily being found, but one of the numbers (ie. operands; formally the augend or addend) that is part of the given sum. As you will see, the method may seem trivial at first, but has far reaching potential as the basis for solving equations ("equa" is from "equate" and "equals" meaning that which is equivalent or the same value) as in math and-or algebra. To equate is to make or state an equivalence to, usually with the "equals" (=) mathematical symbol, and it can be interpreted as "is", "is this", "is equals or equivalent to this", "is the same as this". Some of this discussion was mentioned in the last topic.

If you add 2 to 3, you get 5:

3 + 2 = 5 : the (entire) expression of: (3 + 2) is being equated to 5, and vice-versa.
Commonly spoken as: "three plus two equals five", or
"three plus two is the same as five"

Hence, if you take or remove that 2 back out of the total sum of 5, by subtraction, you should arrive at the other number that is part of the sum (here, 5), which is 3. Or, if you take 3 out of the 5, you should arrive at the other number which is 2.

5 - 2 = 3 and 5 - 3 = 2

Therefore, we see a method of solving problems such as the following that is identical to 3 + 2 = 5 that was first given above , except that one operand here is now unknown and is to be found:

3 + ____ = 5 or as: ____ + 3 = 5 : after simply switching the operands being summed, and:
2 + ____ = 5 or as: ____ + 2 = 5

Instead of ____ which means "blank", "unknown", or "find this value", you might also have the word "number", or a letter symbol such as used in algebra for a symbolic (ie. a placeholder or representative) number, such as ?, n , x, or whatever happens to be used to represent and express a value that is to be found.

Ex. Solve this equation : ____ + 4 = 7 : To solve this equation, we are to find the number which makes the equation true, hence we are to find the correct "unknown" value that makes the equation true so as to have a balance (equivalence) on both sides of the equals symbol. To have this balance, both sides must always be kept equal.

To find the other specific or corresponding number that is part of the sum, remove or subtract the known or given (operand) number, the 4, which is the known other part (operand) that made that sum, from 7 to see what is the remaining or other part that made up or is part of that sum of 7:

7 - 4 = 3 , hence, ____ = 3 : we find that the "unknown" or "unknown value" equals 3

Checking by substituting the value of 3 into the "unknown values" placeholder or position:

____ + 4 = 7

3 + 4 = 7 : this equation is correct since both sides, or expressions, of the equality sign, equal 7:
7 = 7

In the formal methods of equation solving, which will be describe further ahead in this book, 4 will actually be subtracted from the total values on both sides of the equals signs, and not just from 7, during the process of solving for the unknown value. This formally keeps both sides of the equation always in "balance" (equivalent or equivalence) when they are both mathematically acted upon or processed together:

left-side = right-side : a simple description of an equation. Each side can be any valid expression, and that both expressions equal the same value or number.

____ + 4 = 7 : the (incomplete, unsolved) equation in question

____ + 4 - 4 = 7 - 4 : expressing the subtracting of 4 from both sides of the equation

____ + 0 = 3 since any value, known or unknown, plus (+) zero is itself or still the same value, this can be expressed as:

____ = 3 : this indicates that the unknown value is equal to 3, and it is the same result as shown above

If 4 was not also subtracted from the left-side, and only subtracted from the right side, we would of created an unacceptable "inbalance" of the equation, and which would lead to an incorrect result than the true or actual result such as when given:

____ + 4 = 7

____ + 4 = 7 - 4 : an incorrect method to solving this equation for an unknown, because 4 is being subtracted from just one side of the equation, rather than both:

____ + 4 = 3 : more advanced math (where signed numbers are considered) will show that the solution here is: (3 - 4)= -1. and -1 is obviously not equal to 3, the true result being found. In short, an unbalance (non-equivalence, error) and incorrect result was created by not applying the same mathematical operation to or upon each, and entire, side or expression. The application and incorrect process used here could be said as being wrong since it was only "one-sided"; applied to just one side of the equation, and not correctly to both sides of the equation.

ADDITION WITH FRACTIONAL PARTS

The decimal point (.) within a number is used to visually separate the number of "whole" (complete) or unit values from that which is a fraction ("part of", or "portion of", you can also think of the word fracture [break/shatter into pieces or smaller parts]) of one single "whole" or unit. That is, (true) fractional parts of 1 are always less than 1. A piece of a whole thing is always less than the whole or entirety of which it came from. If you like, you can consider the decimal point as meaning "add this (fraction part) also", or as a small hidden plus (+) symbol. For example, 5.2 can be considered as 5 + 0.2, or 5.0 + 0.2. This is also the positional sum expression for 5.2. Addition (or subtraction) of values that may contain fractional parts is performed in exactly the same manner as those without. Just be sure to add corresponding columns, that is, they must have the same weight (as when units must be identical) to added properly. A quick and simple method to do this is to align the decimal points of the two or more values (and of the resulting sum), and then all the corresponding columns will be in alignment and easier to work (process, add, combine) with.

Note that even if one or both numbers do not have a decimal point, you can still place one there. Adding leading or trailing zeros to a number will not change the value of a number.

4 + 2 = 4.0 + 2.0 , 4.3 + 2 = 4.3 + 2.0

Ex. Add nine-tenths (0.9) and one-tenth (0.1)

```
  1
  0.9        : nine-tenths, plus
+ 0.1        : one-tenths, equals
  ---
  1.0        : or= (nine + one) tenths = (9/10) + (1/10) = (9 + 1) / 10 = (10/10) = ten tenths = one = 1
```

Ex. Add 1043 and 2.1005

```
   1043.0000   : Any leading zeros in the whole number part, or trailing zeros in the fractional part
+     2.1005     are insignificant and will not change the numbers or the result after using them in
   ---------
   1045.1005     mathematical operations.
```

SUBTRACTION

Subtraction, or to "subtract", is to reduce, remove, deduct, take-away, take-out, or decrease a value, quantity or its representative ("quantized", "quantization") numerical value or number by some amount. The accepted symbol for a subtraction operation is the "minus" (-) symbol. The word minus is based up or "rooted" in the words and meanings of: "tract" (to pull, remove or take away from), "smaller", "subject", "piece" ("sub" word prefix), "less" or "lesser", "minimal", "minimum", "minor" (for "minus"), and "diminish" (to "lessen", "reduce"). The general "formula" for a subtraction operation is:

minuend - subtrahend = difference : The difference is sometimes called the remaining or value "left over". In monetary use, such as at a store, it is often called the "change" value. Change has another more important or technical meaning such as how much did a value, such as the minuend value, change in value so as to be equal to that difference value. The answer here is that the subtrahend value is equal to that change value of the minuend value. The word difference is rooted in the words "different" and "diverse".

Minuend and subtrahend represent the operands of a subtraction operation or problem, and the difference represents the result or output of the subtraction operation. You can think of the subtrahend as that which is being subtracted. Actually, a difference or difference value is the simplest, and perhaps the greatest mathematical measure or representation of the comparison of two values. Given the values of the minuend and subtrahend, we can say that the minuend is difference larger than the subtrahend, and the subtrahend is difference smaller than the minuend. The mathematical measure of the comparison of two similar values by division is called a ratio which yields a ratio value or result, and this will be discussed further ahead in this book, and it basically indicates how many times larger one value is than the other value, or how one value changes when another value changes by some amount (usually by 1, so as to have a fundamental rate or ratio).

Note that by "switching (the left and right) sides" of the equality sign, or equation, that this could also be correctly expressed or written as:

difference = minuend - subtrahend

To advance your math skills, and in particular, for solving for some unknown value in an equation, you should try to feel comfortable with switching both sides of an equation.

A good method to illustrate the concept of subtraction is to display a group of objects that represents the larger number (the minuend) and remove (perhaps circle or cross-out the objects if paper is being used) the number that is to be subtracted, the answer, formally called the difference, will be that which is "left over" or remaining.

Ex. Show 3 minus 2 = 3 take away 2 = ~~*~~ ~~*~~ * = 1 , and-or:

3 - 2 = 1 : "three, take-away two, is one"
* * * - * * = *

To be good at subtraction, you first need to know the sum of any two of the basic (0 through 9) decimal values. These values may represent groups of objects. For example if you were to add a group of 3 and a group of 4 together, you could create a new and larger group of 7 objects:

3 + 4 = 7 : (* * *) + (* * * *) = (* * * * * * *)

If you had a basket containing 7 apples, you could say, for example, that in the basket there is a group of 3 apples, and a group of 4 apples, and a total of 7 apples if you added those two groups together, perhaps to make just 1 group. If you took out, or mathematically subtracted, either group of apples, you would be left with the other group of apples. To illustrate this point, "grouping symbols" (here, parenthesis) are used around each group of which can be regrouped into two smaller groups, of which a group can be removed or taken away during the subtraction:

7 - 3 = 4 + 3 - 3 = 4 = 4
7 - 3 = 4 : (* * * * * * *) - (* * *) = (* * * *) + (* * *) - (* * *) = (* * * *) = * * * * and:

7 - 4 = 3 + 4 - 4 = 3 = 3
7 - 4 = 3 : (* * * * * * *) - (* * * *) = (* * *) + (* * * *) - (* * * *) = (* * *) = * * *

When both groups (here, groups of apples) are combined together into one new (and larger) group, either physically or mathematically with addition, you will then have the sum of objects of both groups, and the number of objects in the new combined group:

4 + 3 = 7 : (* * * *) + (* * *) = * * * * + * * * = * * * * * * * = (* * * * * * *)

Above, parentheses were used to express each group being considered. Parentheses ( ), and brackets [ ], are common grouping symbols used in math. Grouping symbols are sometimes used to clarify an expression, and-or to treat it as like one value.

Like addition, subtraction problems are often expressed horizontally, but are usually solved vertically "by hand" (manually):

minuend
- subtrahend
difference

To check the result (the difference) of a subtraction problem is to sum (add) the subtrahend to the difference. If this result is equal to the minuend, the result is correct. As done in addition, in subtraction, values or quantities with only like units can be subtracted.

In "vertical subtraction", to borrow is to "reverse carry". That is, the borrow of 1 is equivalent to 10 times the positional weight which receives it.

Ex. 45
- 7

Here, without using signed number concepts that will be discussed ahead, 7 cannot be taken from or out of 5 since "5 does not have enough", or 5 is simply less than 7. We can make enough by borrowing 1 (or 1 tens) from or "out of" the second digit (the 4). We are actually taking 10 ones since the positional weight there is 10. The digit value which gave us these 10 ones must then be reduced by one. These 10 ones borrowed are added to the 5 to make a sum of 15. Now, 7 can be taken from 15, leaving 8.

checking: 15 - 7 = 8 since 8 + 7 = 15

3
4(15)
- 7
3 8

checking: 1
38 : difference
\+ 7 : **+** subtrahend
45 : = minuend

Ex. Subtract 7 from 105

$$\begin{array}{r} 105 \\ -\ \underline{\quad 7} \end{array}$$

Obviously, 5 is less than 7. Since the second digit position has no value other than 0 in it, there is nothing immediately there to borrow from. To place a value there to borrow from, the second digit can borrow from the third digit (the 1 shown). Borrowing 1 from the third digit leaves zero. Since the weight of the third position is 100, it is actually borrowing 100 which is 10 times that of the previous digits weight (the second digits weight) of 10.

$$\begin{array}{rl} & 0 \\ & 1(10)5 \\ - & \underline{\qquad\ \ 7} \end{array}$$

Now that there is a value in the second digit position, the first digit can borrow from it. Borrowing 1 from the 10 leaves 9:

$$\begin{array}{rl} & 0\ \ 9 \\ & 1(10)(15) \\ - & \underline{\qquad\quad\ 7} \\ & \ \ \ 9\quad 8 \end{array}$$

: difference = minuend - subtrahend = difference

checking:

$$\begin{array}{rrl} & 1 & \\ & 98 & :\ \text{difference} \\ + & \underline{\ \ 7\ } & :+\ \underline{\text{subtrahend}} \\ & 105 & :\ \text{minuend} \end{array}$$

: minuend = difference + subtrahend = minuend

When several zeros are "in a row", and you need to borrow, start the borrowing at the first leftward non-zero value.

Ex. Subtract 5 from 3002 Showing this with enumerated (numbered) steps of the calculation process:

1)
$$\begin{array}{rl} & 2 \\ & 3(10)02 \\ - & \underline{\qquad\quad 5} \end{array}$$

2)
$$\begin{array}{rl} & 2\ \ 9 \\ & 3(10)(10)2 \\ - & \underline{\qquad\qquad\ 5} \end{array}$$

: showing some intermediate steps

3)
$$\begin{array}{rl} & 2\ \ 9\quad 9 \\ & 3(10)(10)(12) \\ - & \underline{\qquad\qquad\quad\ \ 5} \\ & \ 2\ \ 9\quad 9\ \ 7 \end{array}$$

checking:
$$\begin{array}{rr} & 111 \\ & 2997 \\ + & \underline{\quad\ 5} \\ & 3002 \end{array}$$

The result of subtracting 0 from any number is that same number since nothing was effectively subtracted or removed:

Ex. 7 - 0 = 7

If any number is subtracted from 0, the results are somewhat similar to that mentioned above, but since the concepts of signed numbers, particularly negative numbers, have not been discussed yet in this book,, examples will not be presented here. We all seen or heard of 0 degrees on the thermometer, and even "negative temperatures" where the temperature is actually less than the reference value of 0. For example, -10 ("negative ten") degrees Celsius or Fahrenheit. Anyway, without these more advanced concepts, it is common sense that nothing can actually be physically (as opposed to logically) subtracted or taken away from nothing or 0.

Extra: The checking process for a subtraction operation can be formally expressed as:

minuend - subtrahend = difference , after adding the subtrahend to each side of this equivalence (same values):

minuend - subtrahend + subtrahend = difference + subtrahend

If you subtract value2 from value1, and then add that value2 back, the net result is that you have added or subtracted nothing or 0:

value1 = value1 + value 2 - value2 = value1 + 0 = value1 = value1 - value2 + value2 = value1 - 0 = value1

minuend = difference + subtrahend or = difference + subtrahend = minuend here is a generalization:

value1 + value2 = value3 : a generalized addition formula, solving for value1 by subtracting value2 from each side:
value3 - value2 = value1 : a generalized subtraction formula, also:
value3 - value1 = value2 solving for value3, here, as the minuend, from either of these two equations:
value3 = value1 + value2 : minuend = difference + subtrahend or = subtrahend + difference

SOLVING FOR AN UNKNOWN VALUE OF A SUBTRACTION PROBLEM

This discussion is about solving subtraction problems where the difference is not necessarily being found, but one of the numbers, either the minuend or subtrahend operand of a subtraction operation or problem. This discussion is similar to the previous discussion of SOLVING FOR AN UNKNOWN VALUE OF AN ADDITION PROBLEM.

For example, if we take 3 away from 7, the value of 7 is reduced to a value of 4:

7 - 3 = 4

If we do the exact reverse and add (rather than subtract) or combine this value of 3 (that was taken out of the 7) back with or to the value of 4 (the difference, or "remainder" if you will, of which 7 was reduced or changed to), we should effectively arrive at the original value in which 3 was subtracted from.

4 + 3 = 7

Now, with this information in mind, if given:

7 - ___ = 4 : "Seven minus some number is equal to 4.". We know that 4 added to some number, that we are to find, will sum to 7 and that this is the value that was subtracted from 7. Expressing this mathematically, we get, and are to effectively solve the new (addition) problem or equation of:

4 + ___ = 7 : "Four plus some number is equal to seven."

Actually, in more formal equation solving, which will be discussed further ahead in this book, this new equation shown above is easily arrived at by taking the original equation given: (7 - ___ = 4) and adding ___ (which represents some unknown value that we are solving for) to each side. If you want to, you can also substitute (replace) the ___ symbol with ?, x, n or something to symbolically (ie. a symbol) represent a number to be found. When any value is both given to or added (even if its 0 or nothing), and then taken away, removed, reduced or subtracted (regardless of the order of events), it results in a value of 0, and effectively eliminating that value. We do this to eliminate a value from one side of an equation and effectively move it to the other side of the equation. Again, that which is done to one side of an equation, must also be done to the other side of the equation so as to keep the equation in mathematical true (equals) balance. Now, simply solve for ____ just like the method shown previously for solving addition problems (hint: subtract 4 from each side):

____ = 7 - 4 = 3

The problem above may have been stated as:

___ - 3 = 4

Usually, we have been told verbally how to solve this when checking a subtraction problem: "add the difference and subtrahend" to find the minuend, hence:

___ = 3 + 4 or: 4 + 3 = : Which is effectively the result of adding 3 to each side of the above previous equation, and eliminating the 3 on the left side since 3 - 3 = 0. Simplifying the right side we have:

___ = 7 or: 7 = ___

Now, let's give some more reasoning to this, and it's based on the above discussion. If we reduce or takeaway a number by 3 and get a smaller number (the difference), we can do the reverse and add or combine that which was taken away back to this new or reduced number to get the original number before any subtracting had taken place.

Before moving on to other topics, it must be mentioned that addition and subtraction are logically, inverse operations of each other. You can think of an inverse operation as an operation that will "undo" or "reverse" the last operation.

Ex. Starting with 10, and then performing an addition operation on it:

$10 + 5 = 15$

To solve for the original value of (10) given this value of (15), you must perform the inverse operation of addition on it, which is a subtraction operation:

$15 - 5 = 10$: Subtracting 5 is the inverse process or operation of adding 5.

If you first started with (15) and then subtracted (5):

$15 - 5 = 10$

To solve for the original value of (15) given this value of (10), you must perform the inverse operation of subtraction on it, which is an addition operation:

$10 + 5 = 15$

This is exactly what we did at the beginning of the example. Notice that the value of (5) was used in both inverse operations. Performing an inverse operation is also a way to check a mathematical problem. Likewise, most other mathematical operations have a corresponding inverse operation:

addition and subtraction,
multiplication and division,
powers and roots,
logarithms (basically an exponent) and antilogarithms (basically a power),
trigonometric functions and inverse, "arc" or "angle" trigonometric functions

A lot of ideas have just been mentioned above in this current topic which may very well seem a bit complex or overwhelming, and perhaps even unnecessary at first. Just give it a look over once in a while, and you will begin to find more and more reasoning, justification and understanding of it.

MULTIPLICATION

Multiplication, or to multiply, is a "short-hand", or quick method of representing, expressing and performing repeated addition. "Multi" is a word prefix that means: many, such as in the word multiple, hence multiplication basically means many or multiple repeated additions of a value or something. Similarly, multiplication means a combination of the words: "multiple" or "many", and "apply" or "application", hence to apply addition multiple times or repeatedly.

The symbols for multiplication are (x), (**.**), or sometimes parentheses or other grouping symbols surrounding the operands. For example: 5 + 5 = (5)(2), here 5 is being added twice, and which is the same as 5 multiplied by two. (5)(2) = (5) x (2) = 5 x 2. The basic, general expression, format or "formula" for multiplication is:

operand1 x operand2 = result : the operands of a multiplication problem are called factors, and the result is called the product, therefore, this can be expressed as:

factor1 x factor2 = product after assigning formal names or identifiers to each factor:

multiplicand x multiplier = product : common multiplication expression or formula

The symbol for the operation of multiplication is often called and spoken as the "times" symbol. It means repetition or the number of times to repeat the addition of the given number, here the multiplicand. The (x) symbol for multiplication is thought to be a plus sign that is turned or turning as if in a repeated process. At about 1700, the dot (.) symbol was sometimes used between two factors being multiplied so as to avoid using the (x) symbol which looks like the variable or "(number) placeholder" (x). This book does not use the dot symbol (**.**) for multiplication very much, but rather uses the parentheses around each factor or operand of the multiplication expression. Computers programs often use the star or asterisk symbol (*) between two factors of a multiplication expression, and this symbol was already sometimes used for multiplication, possibly to look like a modified (x) symbol for multiplication. The multiplicand and multiplier are the operands of a multiplication operation. The product (means something that was "produced") is the result of a multiplication and-or an expression to multiply.

The multiplier is the number of times the multiplicand is to be repeatedly added (summed) to an initial sum or starting value of zero or nothing. The multiplicand and multiplier are also called "(the) factors" of that result or product since these factors will have influence (effect) on the resulting value (the product).

Adding any number just once (to a starting or initial sum of 0) is the same as multiplying that number by 1:

7 + 0 = 7 and,
7 x 1 = 7 : multiplying any number by 1 does not change it's value. 7 is being added to an initial working sum or total of 0, only 1 time, and the result is therefore 7. Note that this is also equivalent to 1 x 7 , and 1 multiplied or increased 7 times, or added to itself 7 times is : 1 + 1 + 1 + 1 + 1 + 1 + 1 = 7

Adding 5, ten times would result in an addition expression or problem (to solve for the result) looking like this:

5 + 5 + 5 + 5 + 5 + 5 + 5 + 5 + 5 + 5 : sum = 50

That is a very long addition problem or expression, and a "running total" of many "intermediate sums" would have to be written down or remembered as you try to simplify or solve it. Since the above expression is of the repeated addition of the same value (5 added to the running (processing) total (sum), or to itself, 10 times), transforming this expression into an equivalent and simpler multiplication expression, we get:

5 + 5 + 5 + 5 + 5 + 5 + 5 + 5 + 5 + 5 = 5 x 10 = (5)(10) : multiplication is repeated addition

Since both expressions are said to be equivalent in value, they are shown as equated (ie. equals) together.

5 x 10 : product = 50, and this is a much "shorter" expression for 5 added to itself 10 times.

Multiplication with a zero operand: The product of any value multiplied by 0 is 0.

Ex. 4 x 0 = 0 : With respect to addition, four added zero (or none) times is equal to zero.
Remember that 4 x 0 is also equal to 0 x 4 = 0 + 0 + 0 + 0 = 0

Ex. 0 x 20 = 0 : With respect to addition, zero added to itself twenty times is zero.
20 multiplied to itself zero (or none) times is equal to 0 since no addition to the initial starting sum of 0 has taken place.

To solve common multiplication problems, you must know from memory, or by using a multiplication table, the products of many factors. Usually, all the products of factors between 1 and 10 are memorized, such as shown in the multiplication table below:

A MULTIPLICATION TABLE

	1	2	3	4	5	6	7	8	9	10
1	1	2	3	4	5	6	7	8	9	10
2	2	4	6	8	10	12	14	16	18	20
3	3	6	9	12	15	18	21	24	27	30
4	4	8	12	16	20	24	28	32	36	40
5	5	10	15	20	25	30	35	40	45	50
6	6	12	18	24	30	36	42	48	54	60
7	7	14	21	28	35	42	49	56	63	70
8	8	16	24	32	40	48	56	64	72	80
9	9	18	27	36	45	54	63	72	81	90
10	10	20	30	40	50	60	70	80	90	100

To use the table, the resulting product of any two factors (indicated at the top row, and at the left column) is the value at the horizontal and vertical intersection. This table can also be used for division where the value at the intersection becomes the dividend. Also notice in the table that there are two methods to find the same product:

multiplicand x multiplier = product
multiplier x multiplicand = product : the product will be the same for both expressions and-or equations

Either value at the top and left side can be considered as either the multiplicand or multiplier. This can be very easily verified by representing the multiplicand and multiplier in a physical or graphical form (such as with objects). For example, 3 x 2 can be represented by 3 objects and 2 groups of those three objects and which is the same as adding three to itself twice: 3 x 2 = 3 + 3. Expressing this physically or graphically, where an object represents 1:

* * * : (3 objects, first group)
* * * : (3 objects, second group)

Since multiplication is repeated addition, the product is the sum of all the objects. Since there are 6 objects, the product or repeated sum is 6.
Without removing or adding any objects, the product of 3 x 2 can be represented by tilting the above objects on to their side, producing 2 objects and 3 groups of those 2 objects, hence 2 x 3 = 2 + 2 + 2 :

* * : (2 objects, first group)
* * : (2 objects, second group)
* * : (2 objects, third group)

The sum is still 6. Hence: 3 x 2 = 2 x 3 = 6 : Verifies that the multiplicand and multiplier factors can be exchanged and still produce the same product or result, just like the numbers (augend and addend) of an addition problem can be exchanged.

Ex. There are 7 piles with 10 stones in each pile. How many total stones are there in all the piles?

Since we are totaling (summing) the number of stones, we are to add each (identical) group, or pile, of stones a total of 7 (piles) times. Since this is a repetitive or repeated addition problem, we can represent and solve this more easily as a multiplication problem:

10 stones x 7 = 70 stones : or more advanced as: (10 stones per [for each] pile) x 7 piles = 70 stones

The are all sorts of rhymes and apparent "tricks" to remember, and-or to check, the basic multiplication table and problems. For example, to remember the 9's products, take that specific multiplier (or multiple of 9) and subtract 1 from it. This will be the first or most significant number of the product. The other digit (if any) of the result will be that number which when combined to the first number found sums up to 9.

Ex. 9 x 4

Subtracting 1 from 4 leaves 3. and the number that when added to 3 that creates the sum of 9 is 6 (you can simply use subtraction to find this next digit value: 9 - 3 = 6).

9 x 4 = 36 : note that for the product, here 36, that its digits sum to 9: 3 + 6 = 9

Ex. 9 x 7

The first digit will be (7-1) = 6, and the second digit will be 9 - (7-1) = 9 - 6 = 3

9 x 7 = 63 : note that the sum of the two digits of the product is 9: 6 + 3 = 9

Perhaps the most simple method to use as an aid to basic multiplication is the fact that if you already know:

multiplicand x multiplier = product

Then you can easily solve for:

multiplicand x (multiplier + 1) = product : Increasing the multiplier by one to find the next product.

Ex. If you already know that 6 x 4 = 24 , and you then want to know what 6 x 5 is, then simply add one more 6 to the value of 24, since after all, multiplication is still repeated addition, and that you can use a previous sum or product as an intermediate sum of another multiplication operation. Expressing this method and example in mathematical statements:

Find 6 x 5

6 x 5 = 6 + 6 + 6 + 6 + 6 : expressing the multiplication as its equivalent addition
6 x 5 = (6 + 6 + 6 + 6) + 6 expressing the first 4 additions as multiplication we get :

6 x 5 = (6 x 4) + 6 : equivalent expressions, and what this discussion is about
6 x 5 = 24 + 6 : If you knew 6 x 4 = 24, you can then find 6 x 5 with just another addition of 6.

6 x 5 = 30 : If you knew 5 x 6, you would have the same result of 30.
: If you knew 5 x 5, then 5 x 6 = (5 x 5) + 5 = 25 + 5 = 30

Multiplication, like addition and subtraction, when done without a calculator, is usually performed vertically. To multiply this way, the positional product of each digit of the multiplicand is multiplied to (or by) the positional product of each digit of the multiplier once, producing an intermediate product (or intermediate sum to be added together, since a product is technically a sum of repeated additions) that will be part of the sum.

Ex. Multiply twenty and seven together.
(This example also shows how to multiply values (factors) greater than 10 that are not listed in the basic table.)

20 x 7 : expressed horizontally

$$\begin{array}{r} 20 \\ \times\ \underline{\ \ 7} \end{array}$$: expressing this vertically

$$\begin{array}{rrl} & 20 & \\ \times & \underline{\ \ 7} & \\ & 0 & : 0 \times 7 = 0\text{ , a positional sum of }0 \\ + & \underline{140} & : 20 \times 7 = (2 \times 10) \times 7 = (2 \times 10 \times 7) = (2 \times 7) \times 10 = 14 \times 10 = 140,\text{ a positional sum of }140 \\ & 140 & : \text{summing up these positional products (or intermediate sums)} \end{array}$$

Ex.

$$\begin{array}{rrl} & 28 & \\ \times & \underline{17} & \\ & 56 & : 8 \times 7 = 56 \\ & 140 & : 20 \times 7 \\ & 80 & : 8 \times 10 \\ + & \underline{200} & : 20 \times 10 \\ & 476 & \end{array}$$

A more popular vertical method is to not use the positional products, but to use just the single digits of the multiplicand and multiplier, and utilize any carry's:

Ex.

$$\begin{array}{rr} & 28 \\ \times & \underline{\ \ 7} \end{array}$$

First, the 8 is multiplied by 7. The resulting product is 56. The 6 is placed into the "ones" digit position of the product (which may be an intermediate product that will be used in the final sum). The second digit of this intermediate result, the 5, is a "carry" to its corresponding "tens" column and is added to the product of the next multiplication. That is: 7x2=14, and then 5 is added to 14, making a sum of 19. This result is placed in the next leftward and significant available position as the product of that multiplier digit is constructed:

$$\begin{array}{rrl} & 5\ \ & \\ & 28 & \\ \times & \underline{\ \ 7} & \\ & 196 & : \text{steps of: } 8 \times 7 = 56,\ \ 7 \times 2 = 14,\ \ 14 + 5 = 19\ \ \text{(or a 9 with a carry of 1 into the next column)} \end{array}$$

The basic reasoning that the carry of 5 was not added to the 2 before performing the multiplication is that, like above, 8 is being multiplied by 7, and 20 (not 70) is to be multiplied by that 7 also giving:

28 x 7 = ((2)(10) x (7) + (7 x 8) = 20 + (8 x 7)   or: (20 + 8)   : "both twenty and eight, multiplied
x 7   by seven, and their products
added together"

(20x7) + (8x7)   : or expressed as: (8 x 7) + (20 x 7)
140 + 56   56 + 140
196   196

Continuing with the above discussion, multiplying by the positional products (such as the 20 indicated above) is not necessary as long as you place an appropriate amount of "trailing" zeros onto each next intermediate product(s) and continue multiplying with just the single value or digit in that digits position. This is perhaps the easiest and most popular method to multiply. The reason behind this method is that when you multiply with just the value in that digits position, instead of the positional product, you are effectively dividing the correct intermediate product by the positional weight of that digit, and placing in the "trailing zeros" will correct this (effectively multiplying, the intermediate product, by the positional weight that was effectively "divided out" using this process). Excluding the first time, each time another digit of the multiplier is used for multiplying, the intermediate product or sum is shifted leftward one digit position which essentially means placing in another trailing 0 and effectively multiplying the result by the positional weight of the multiplier digit. This multiplication by 10 is often thought of as simply shifting the decimal point one digit rightward. That is, when any value is multiplied (or divided) by 10, or some power of 10 such as 10^2 = 100, the resulting digits are always the same, and only the decimal point will moved. Leading or trailing zeros may sometimes be needed, and placed before (such as when dividing by 10) or after (such as when multiplying by 10) the number, and only if needed. For example(s):
3 x 10 = 3.0 x 10 = 30 , 25 x 10 = 250 , 2.5 x 10 = 25 , 2.615 x 10 = 26.15 , 350 / 10 = 35.0 ,
3 / 10 = 3.0 / 10 = 0.3 , 3 / 1000 = 3.0 / 1000 = 0.003 and 0.003 x 1000 = 3.0 = 3

Ex. Multiply 28 by 17

5
28
x 17
196   : 8 x 7=56, carry the 5; 2 x 7=14, 14+5=19
+280   : First, place a trailing zero=0; 8 x 1=8 (instead of 8 x 10 = 80), and 2 x 1=2 (instead of 20 x 10 = 20)
476

also note, 196 = 28 x 7 = (20+8) x 7 = (20 x 7) + (8 x 7) = 140 + 56 = 196
also note, 280 = 28 x 10 = (20 x 10) + (8 x 10) = 200 + 80 = 280

Ex. Solve 107 x 304

107
x 304
428   : 7 x 4 = 28, carry the 2; 0 x 4 = 0 and then that 0 + 2 = 2 and place it ; 4 x 1 = 4 and place it
0000   : place a trailing 0. Here, all three products will also be 0.
+ 32100   : now place another, or 2 trailing zeros here, then continue multiplying
32528

It should also be mentioned that some of the steps presented in the above discussions about multiplication imply a mathematical concept formally known as the distributive property or simply "distribution". It will be described and used further ahead in this book, but here is a simple explanation:

Ex. Given 5 + 5 = 5(1) + 5(1) ,   We know this repeated addition can be expressed using multiplication as:
5 x 2 = 5(1) + 5(1)   and this can then be expressed as:
5 x (1 + 1) = 5 (1) + 5 (1)   hence:

5 (1 + 1) = 5(1) + 5(1) : This has the general format of the concept of distribution, where a product of two factors, where one contains several terms (here as expressed additions or a sum), is equal to the sum of the products of each term and the multiplying factor . Here both sides and expressions equal 10.

Rather than simplify the second indicated factor of (1+1) to a value of 2, with the distributive concept, we can use a reverse type of process to that mentioned above, 5 can be multiplied to each number that is a part of the sum that comprises this factor of (1 + 1):

5 (1 + 1) "distributing" (essentially multiplying) the factor of 5 to each term (ie. a partial sum of the second factor) to create a new expression:
5(1) + 5(1) : this equivalence was also shown above
5 + 5

The main point to remember is that an initial factor multiplied to another factor that is composed or expressed as sum of numbers is equal to the sum of all the products of that initial factor and each member of the factor that is composed of a sum of numbers.

Ex. 7 (1 + 1) = 7(1) + 7(1)
7(2) = 7 + 7
14 = 14 : checks

Ex. 7 (1 + 2) = 7(1) + 7(2)
7(3) = 7 + 14
21 = 21 : checks

Ex. 15 = (10 + 5) = 3 (10 + 5) = 3(10) + 3(5) = (10 x 3) + (5 x 3) = 30 + 15 = 45
x 3 x 3
45 15 : 5 x 3
+ 30 : 10 x 3
45

Here is another helpful discussion about multiplication, especially with multi-digit operands, and it is intended to give more clarification and understanding to using a "left-shift" in the intermediate sums during vertical multiplication solving. A left shit by one digit position is equivalent to multiplying a number by 10. This discussion is somewhat detailed, and you may skip over it till perhaps another time.

Ex. Given 1, if we left-shift this one position to the left we have: 10 , and this is the same as multiplying 1 by 10 and the product is 10. If you were to repeatedly sum 1 a total of 10 times you would have:

1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 = 1 x 10 = 10 : Hence, simply left-shift the digit leftward one position and place a trailing 0 into the ones position or column.

Ex. Given 2 and we left-shit this one position, we get 20, and this is the same as multiplying 2 or= 2**.**0 by 10.

Notice that the result has the same digits used, but they are essentially shifted to the left one position and a trailing 0 is put at the end of the number (in the ones position or column). This new value is 10 times more than the given value. 20 is ten times more than 2. If you were to repeatedly sum 2, a total of 10 times you would have:

2 + 2 + 2 + 2 + 2 + 2 + 2 + 2 + 2 + 2 = 2 x 10 = 20

Hence, simply left-shift the digit(s) leftward one position and place a trailing 0 into the ones position or column.
Extra: 2 can be expressed as (1+1), and, we would have: (1 + 1)10 = 10(1+1) = 2(10) = (10)(2) = (1)(10) + (1)(10)

The right hand expression is an example of what is known as applying the "distributive law" (essentially multiplication) to the left hand expression. The left hand expression is essentially a "factored form" of the right hand expression. The factors are (1 + 1) and 10 which is the common factor in both indicated (sum of) products or terms on the right hand side.

2 x 10 = (1+1) + (1+1) + (1+1) + (1+1) + (1+1) + (1+1) + (1+1) + (1+1) + (1+1) + (1+1) which could be expressed as:
2 x 10 = 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 with some grouping:
2 x 10 = **(**1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1**)** + **(**1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1**)** which could be expressed as:

2 x 10 = (1 x 10) + (1 x 10) : which results in 1 left-shifted once, plus, 1 left shifted once (and not 1 left-shifted twice), and this is: 10+10, and these are a group of "partial (part of) sums" of 20.

Now consider this, let symbol N symbolically represent the value of any basic number that you can think of:

$$\begin{array}{rcrcrcr} N & = & N & \text{or} = & N & = & N \\ \times\ \underline{10} & & \times\ \underline{(10 + 0)} & & \times\ \underline{(10 + 0)} & & \times\ \underline{(1 \times 10)} \\ & & N(10) + N(0) & & N(0) & & \\ & & & & +\ \underline{N(10)} & & \end{array}$$

N x 10 = N (1 x 10) = N ((1)(10)) = N(10)
Note, we **cannot** use distribution above, since the second factor: (1 x 10) is not a sum of values such as: (1 + 10)

These can also be expressed as:

Nx10 = N(10) = N(10 + 0) = N(1 x 10) : note, you cannot use distribution on the right expression to simplify it, since the second factor (1 x 10) is not a sum of terms. N(1x10) = N((1)(10)) = N(1)(10) = N10 = 10N
The result is **NOT**: 1N + 10N = 11N

Considering the indicated product on the right hand side, we essentially have 1 with a left-shift being multiplied to N: That is: N(1x10) = (N)((1)(10)) = N(10). Anything multiplied by 1 is that same number, such as 10(1) = 10. Hence we have: N(1)(10) = N(10), and when we left-shift all the digits of N, we have the product of it and 10. Symbolically using an appended 0 to indicate a left- shift or multiplication by 10:

N(10) = N0 : When N is a plain "integer" number that does not contain any fractional portion past the decimal point, when it is multiplied by 10, N is left-shifted, that is, every digit in the number of N is shifted 1 position leftward, and a trailing 0 is placed rightward of N's last digit. If N does contain a fractional decimal number part, then simply move the decimal point one position rightward when multiplying by 10, for example: If N=3.49, N(10) = Nx10 = (3.49)(10) = 34.9
If N=5 , N(10) = 5(10) = 5.0(10) = 50 = 50.0

Ex. N(11) = N(1 + 10)

We see that N will be summed 11 times, and this is equivalent to summing N once, and then combining that (partial) sum to the summing of N ten times.

N(11) = N + N + N + N + N + N + N + N + N + N + N which can be expressed as:
N(1 + 10) = **(**N**)** + **(**N + N + N + N + N + N + N + N + N + N**)**
N(1 + 10) = (1xN) + (10xN) : this notation is also an example of the "distributive law" that will be discussed

Hence, the result is N, plus N left-shifted once. If N=15, N(11) = N(1 + 10) = N + N0 = 15 + 150 = 165

Ex. To multiply a value by 20. Since 20 = (2 x 10) , this expression indicates that the summing of a value twenty times (ie, repeated addition, which is multiplication) is equivalent to summing up that value twice to first produce a (partial) sum, and then summing up that new (partial) sum a total of ten times to find the final sum or product. We now know that we can left-shift a value one digit position to quickly have the product of it and ten:

N x 20 = N(20) = N(2 x 10) = (Nx2)x(10) = (Nx2)0 : here, the last expression indicates the left-shift of the value of: (Nx2), and putting, or appending, a trailing 0

Ex. N x 23 = N(23) = N(20 + 3) = N((2x10) + 3) = 2(N)(10) + Nx3 = 2(N0) + Nx3

To multiply a value by 100, simply perform two left shifts on that value and place on, or append, two trailing zeros since:

N(100) = N(10 x 10) = (N(10))10 = (N0)10 = N00

Ex. 573(100) = 57300

Clearly, the number of left-shifts when multiplying by a power of 10 is equal to the number of zeros in that value. For example, to multiply a value by 1000, simply perform three left shifts on that value and place on three trailing zeros.

To help multiply (or divide) by or to a large constant (steady, unchanging in value) number that has many digits quickly when not using the assistance of an electronic calculator, it is very helpful to first make a table of values of all the products (or repeated additions) of that constant value and all the single digit decimal values from 0 through 9.

Ex. If 307,629 is to be multiplied by any other value:

Table Of 0 through 9 Multiples Of The Given Value

307,629 x 0 = 0
307,629 x 1 = 307,629
307,629 x 2 = 615,258
307,629 x 3 = 922,887
307,629 x 4 = 1,230,516
307,629 x 5 = 1,538,145
307,629 x 6 = 1,845,774
307,629 x 7 = 2,153,403
307,629 x 8 = 2,461,032
307,629 x 9 = 2,768,661

Or by adding 307629 to each previous product to find the new product **:**
307,629 + 307,629 or = 307,629 x 2 = 615,258 :
615,258 + 307,629 or = 307,629 x 3 = 922,887 :
922,887 + 307,629 or = 307,629 x 4 = 1,230,516 :

```
      307,629
    x   57249
      2768661
     12305160
     61525800
   2153403000
+ 15381450000
  17611452621
```

: write down the corresponding products in the table, and any trailing 0's needed, then sum these intermediate products so as to have the resulting product

The above is also one method to use when the number of digits of the operand(s) and-or the result is excessive for the device and cannot be directly entered into and-or displayed as a result by the computer or calculator.

MULTIPLICATION WITH DECIMAL FRACTIONS

Multiplication by a number with decimal fractional values, with, or without. a whole or fractional part is performed in the exact same manner as when multiplying just whole or "integer" values that do not contain a fractional part. The fractional part of a decimal (system) number numerically represents a part less than one (1), and this is expressed numerically to the right of the decimal point in a decimal number.

Example of a number containing a whole part and a fractional part: 7.32 = 7 + 0.32 = whole part + fractional part =
= whole part **.** fractional part Here, the whole part is 7, and the fractional part (of 1) is 0.32

Simply multiply the values and (initially) ignore any possible decimal points as you process or calculate the result. The decimal point of the result must then be properly placed or positioned. Simply add up the number of digits that were not only indicated, but actually used (during the calculation) rightward of the decimal point in each of the operands, and this is the number of places to move the decimal point leftward in the product. Verification of this procedure is shown below, though it requires some slightly more advanced concepts of fractions. Commonly, the words "decimal digits" or "decimal places" are taken to mean the digits of the fractional part of a decimal number that are to the right side of the decimal point.

Before continuing, you may first want to consider this about the basic concepts of both the decimal number system and fractions or fractional values. This paragraph section may seem a bit complicated at first to some, and they may skip over this till perhaps a later time. In the decimal system, when we count up to 10, each of the ten steps, each being an equal or equivalent step, and here for this specific example,will result in an increment or increase of 1 to the entire number of which the increment is being applied to. Note that the actual value (applied to the entire number that is being incremented) of each step is technically, the (decimal system's) actual or specific value that the increment represents to the entire decimal number, and this value is the numeric weight of that (digit, or column) position in question or reference when just the decimal numeric system itself is being considered. and each step is one of the ten possible steps (before digit or column position "rollover" back to the start or 0), or "one of ten (steps)" for each digit, column or ("decimal") position, and this can therefore be expressed numerically as: 1 of 10. This concept, and each step or one increment out of ten possible increments (per digit position or column), can be mathematically expressed as an indicated fractional part as: 1 of 10 = 1 per 10 = (1/10) or simply: 1/10, and this does equal 0.1 as expressed using the most basic or fundamental decimal numeric form as just one value or number. Notice that the expression (1/10) does look like a common division expression or problem, and that the value of 0.1 is also equal to the result of the indicated division expression. Since each step is only part of the entirety or whole thing, the actual value of each step is said to be only a fractional part. Considering even the number 1, it too, for example, can be, or considered as being composed of ten equal steps. It need not be exactly ten steps, and another example or number system could have more or less steps, but we are now just considering the basics of the decimal system with its common 10 steps in each digit position or column. Ten increments or (fractional) steps, each being (0.1) numerically, will produce the numeric values or sums, starting at 0.0, of 0.1 through 0.9, and 1.0 = 1. Remember, that in the decimal system, each count or step in the next greater or leftward position is equal to ten, "ten more", or "ten of", steps, and therefore, each step or increment in the next lesser or rightward position is "ten less", or "a tenth" of each step in the current or reference position. Some more will be explained about the fundamentals of fractions later, and we will now continue with the current multiplication discussion.

Ex. 1   1.0   : one decimal digit used and,
x <u>1</u> = x <u>1.0</u>   : one decimal digit used
1   00
\+ <u>100</u>
1.00   : decimal point has been moved two places leftward

Ex. (1)(0.1)

Note that multiplying anything by one is always equal to that same value. Here, a tenth of one is being multiplied by one:

(1)(0.1) = (0.1)(1) = 0.1

$$\begin{array}{rl} 0.1 & \quad\text{: one decimal place used} \\ \times\ \underline{\quad 1} & \\ 0.1 & \quad\text{: after moving the decimal place one position leftward} \end{array}$$

The "one-tenth" (of one) description is easily seen when this decimal (fractional) value is converted to a standard fractional form with some help from the concepts of positional notation and-or scientific notation (SN) which will be discussed ahead.

0.1 = (1)(0.1) = $(1)\left(\frac{1}{10}\right)$ = (1)(10^-1) = $\frac{1}{10}$: "a tenth of one", and since any value multiplied by 1 is that value

Ex. (0.1)(0.1)

A good knowledge of the decimal system, which can happen with some routine practice, will quickly give an answer of "a tenth, of a tenth", or "one-tenth, of one-tenth", or simply, "a hundredth" or "a hundredth of".

$$(0.1)(0.1) = \frac{(1)(1)}{(10)(10)} = \frac{1}{100} = 0.01$$

standard method:

$$\begin{array}{r} 0.1 \\ \times\ \underline{0.1} \\ 01 \\ +\ \underline{000} \\ 0.01 \end{array}$$

Ex. (0.5)(2.0)

$$(0.5)(2.0) = \frac{(5)\ (2)}{(10)\ (1)}$$

After simplification (using multiplication) of the indicated factors in the top (the numerator) and bottom (the denominator) values of the fraction or division problem:

$$= \frac{10}{10} = 1$$

standard method:

$$\begin{array}{r} 2.0 \\ \times\ \underline{0.5} \\ 100 \\ +\ \underline{000} \\ 1.00 \end{array}$$

For another check, multiplying any value by 2 is equivalent to adding that value twice:

$$\begin{array}{r} 1 \\ 0.5 \\ +\ \underline{0.5} \\ 1.0 \end{array}$$

Ex. (0.3)(0.5)

$$(0.3)(0.5) = \frac{(3)(5)}{(10)(10)} = \frac{15}{100} = \frac{15}{10^2} = 15(10^{-2}) = 0.15$$

checking:

standard method:

$$\begin{array}{r} 1 \\ 0.3 \\ \times\ \underline{0.5} \\ 15 \\ +\ \underline{000} \\ 0.15 \end{array}$$

Ex. (1.5)(0.2)

(1+ 0.5)(0.2)

First note that any number divided by itself is equal to 1 or 1/1. Below, 10/10 = 1/1 = 1 will be used. Also, if you have "ten-tenths" of something and add "five-tenths" of something, then it's obvious that you have "ten plus five tenths" of that something, hence "fifteen-tenths" as shown below. The tenths are used here as the same or "like" (or common) units, and the numeric parts can then be combined.

$$\left(\frac{1}{1}+\frac{5}{10}\right)\left(\frac{2}{10}\right) = \left(\frac{10}{10}+\frac{5}{10}\right)\left(\frac{2}{10}\right) = \frac{(15)(2)}{(10)(10)} = \frac{30}{100} = 0.30$$

standard method:

$$\begin{array}{r} 1 \\ 1.5 \\ \underline{0.2} \\ 30 \\ +\ \underline{000} \\ 0.30 \end{array}$$

DIVISION

Division is to divide (separate or split into groups) something into two or more smaller parts. The symbols to indicate or express a division operation are shown below. The separate parts may possibly not even be the same value. For example, you could divide a bag containing 6 apples among 2 people. Perhaps you will give one person 4 apples, and give the other person 2 apples. Here, the apples would be completely (but not balanced or evenly (equally)) divided out among the people. Formally, in mathematics, division is to separate that something into smaller parts all having the same size and-or numeric value, hence the result of a division operation is generally thought to be "even" (equally, the same, or in balance).

For the example noted above, to have an even division, each person would receive the exact same value of 3 apples. With 6 apples for 2 people, we can divide the number of apples by the number of people to see how many apples each person will receive. 6apples / 2 people = 3 apples / 1person = "3 apples per person". (6/2)=3. If there were 3 people, for an even division (or "distribution" of and-or to) of the 6 apples, each would receive 2 apples since 6apples / 3people = 2apples /1people = "2 apples per person". (6/3) = 2. The apples are then said to have been "evenly divided (of-and) out" to the people. We see that the word "even", or "evenly", actually means that each part or portion is in balance to any other parts, that is, each part and-or its numeric value is the same or equal to all the other resulting parts after the division is completed. For example, if something was divided into 3 parts, each part will have the same numeric value, and for example, if 30 was divided into 3 parts, numerically expressed as: 30/3, each part of the three total parts will have the same numeric value of: (30/3) = 10 = "ten". The sum of each of each smaller parts (same) value will equal the original or total value before division was performed on it: (10 + 10 + 10) = (10)(3) = 30, and this multiplication is actually a way to check a division problem, and here it's: (30/3) = 10.

Mathematically, division is the "inverse" of multiplication (repeated addition), hence, dividing is essentially performing repeated subtraction. Essentially then, the "starting minuend" is called the dividend, and the divisor is effectively the subtrahend. A quotient is the result or output of a division operation, and it is how many times the divisor can be subtracted from (or "go into") the dividend.

In relation to division, you will often hear the question that is similar to: "How many times can value1 (the dividend) be divided by value2 (the divisor)?", or in other words: "How many times can value2 (the divisor) go into value1 (the dividend)?" A way to state the division process (that is somewhat like a factoring process) and result (quotient), is that it is how many times that value2 (the divisor) must be increased or multiplied so that it equals value1 (the dividend). This is the same as saying how many times bigger that value2 (the dividend) is than value1 (the divisor).

Consider: let: value1 = factor1 and value2 = factor2

(factor1)(factor2) = product

$\frac{\text{product}}{\text{factor1}}$ = factor2 : "product is factor2 times bigger than factor1" , product = (factor1)(factor2)
: "factor1 can go or divide into product a total of factor2 times"

$\frac{\text{product}}{\text{factor2}}$ = factor1 : "product is factor1 times bigger than factor2" , product = (factor2)(factor1)
"factor2 can go or divide into product a total of factor1 times"
: product = (factor1)(factor2) = (factor2)(factor1)

The symbols for division along with the general "division formulas" or expression formats are:

dividend ÷ divisor = quotient : quotient is a word derived from quot and quota which basically means the current numerical value or size as in "how many (times)" or "how much"
dividend / divisor = quotient You may sometimes hear something like "Today's quota is 7 sales", which means to the effect: "Today's goal or output of selling is to make 7 sales".

$\frac{\text{dividend}}{\text{divisor}} = \text{quotient}$: In this "fractional like" form or expression, the quotient is and represents how many times greater (or sometimes, less) that the dividend is compared to the divisor.

$\begin{array}{r|l} & \underline{\text{quotient}} \\ \text{divisor} & \text{dividend} \end{array}$: this is often the form to use when manually calculating division by hand

Before the concept of division by using repeated subtraction is shown, perhaps the simplest way to understand the process of division or how to divide, is by observing and comparing. For example, if you had 6 objects (such as coins, or dots on paper), how many times (ie. comparisons) can 1 of those objects correspond (ie. match) to all of those objects? In other words, what is 6 divided by 1, hence how many times can 1 be subtracted or taken away from 6? The question may also be stated as something like: How many times can 1 thing "go into" (or compare to) 6 things?

6 divided by 1, graphically:

* * * * * * : 6 now repeatedly compare to, or matching to 1 (or "1 to 1"):

* : 1 time (1 comparison or correspondence, there are now 5 dots left)
* : 2 times (2 comparisons or correspondences, there are 4 dots left)
* : 3 times
* : 4 times
* : 5 times
* : 6 times (there are now 0 dots left, the division process must stop)

We see that 6 divided by 1 is 6. It could be said that "1 can go into 6, a total of 6 times". Any value divided by 1 is always equal to that same value. If you are using objects such as coins, you can physically remove the necessary coins, or if you are using objects drawn on paper, you can circle or cross-out the objects after each comparison to indicate that they have already been used or considered.

Ex. 6 divided by 2:

* * * * * * : 6 repeatedly comparing 2 (the divisor) to each 2 new and remaining parts to be considered of the 6 total parts:

* * : 1 time
* * : 2 times
* * : 3 times

6 divided by 2 is 3. "2 can go into 6, a total of 3 times" or "2 can be subtracted from 6 a total of 3 times"
or perhaps something like: "6 can be divided by a group containing 2, a total of 3 times",
, or "there are 3 groups of 2, within, or out from, 6"

Ex. 6 divided by 3:

* * * * * * : 6 repeatedly comparing to 3 (comparing 3 to each new 3 and remaining parts of the 6):

* * * : 1 time
* * * : 2 times

6 divided by 3 is 2. "3 can go into 6, a total of 2 times"

Ex. 6 divided by 6

* * * * * * : 6 repeatedly comparing to 6 (or the 6 smaller parts to the 6 total parts):

* * * * * * : 1 time

6 divided by 6 is 1. Any value divided by itself (the same value) is always equal to 1. Notice in the examples that the larger the divisor is for a given division problem, the smaller the result or quotient, hence it could be said that the divisor and quotient are (mathematically) inversely related, that is, as one value goes larger in value, the other or corresponding value goes smaller in value, and vice-versa.

6/2 = 3 As the divisor goes larger, the quotient goes smaller. This is an (mathematical) inverse relationship.
6/3 = 2 A direct (mathematical) relationship is where if a value grows, a corresponding value also grows.
6/6 = 1

If you had a quantity of 30 and kept removing or subtracting 5 from it, you will make 6 "even subtractions". The word "even" here essentially means a full or complete division and that there was no part, difference or remainder (r), of the 30, left over after all the subtractions.

1.	2.	3.	4.	5.	6.
30	25	20	15	10	5
- 5	- 5	- 5	- 5	- 5	- 5
25	20	15	10	5	0 = r

Or: (((30 - 5) - 5) - 5 - . . .) (. . . means "and so on") : expressing 30 divided by 5 as a repeated subtraction expression

Or: 30 - 5 - 5 - 5 - . . .

An easier way to express this subtraction problem is with division. The problem could be written as:

$5\overline{)30}$: "thirty divided by five", or = 30 divided by 5

You can check the result (the quotient = 6) for correctness by repeatedly subtracting it from the dividend (30). If you get the original divisor (by getting 5 even subtractions = 5), the result is correct. Since division is essentially repeated subtraction, you can check a division problem with another division problem where the dividend is divided by the quotient. If this quotient value is equal to the original divisor, the division was correct and the quotient (result) is correct.

Ex. $5\overset{\underline{\ 6\ }}{\overline{)30}}$ is correct since $6\overset{\underline{\ 5\ }}{\overline{)30}}$ This is so since:

$$30 = 30$$

$5 + 5 + 5 + 5 + 5 + 5 = 6 + 6 + 6 + 6 + 6$: "sum of six, fives" = "sum of five, sixes"

$5 \times 6 = 6 \times 5$: the repeated addition, expressed as a multiplication

Given just the left hand side of the equation, 5 can be removed (ie. subtracted) from 30, a total of 6 times.
Given just the right hand side of the equation, 6 can be removed from 30, a total of 5 times.

To perform and check the results of division without using the slower and more tedious method of repeated subtraction or performing another division, you can use multiplication (which is repeated addition as seen above). To check if the quotient is correct, multiply the divisor and quotient, and if the result (a product) is equal to the dividend, the division problem was performed correctly:

Since $\frac{\text{dividend}}{\text{divisor}} = \text{quotient}$ We mathematically have after multiplying both sides by the same value (so as to keep both sides of the equation in balance, or the same value), here, the divisor:

$\frac{\text{dividend}}{\text{divisor}} \frac{(\text{divisor})}{(1)} = \text{quotient (divisor)}$ After some canceling, this can be simplified or reduced to just:

dividend = (quotient)(divisor) : CHECKING A DIVISION PROBLEM (using multiplication). We see that the quotient and divisor are essentially two (of the many possible) corresponding factors of the dividend. If one of these factors is wrong, their product will not match or check (be equal to) with that dividend.

Since 5 can divide into, "go into", "sum into", "be taken from", or be part of the total sum of 30, a total of 6 times, repeatedly adding 5, to an initial sum or start of 0, six total times can be represented by a simple multiplication problem:

$0 + 5 + 5 + 5 + 5 + 5 + 5 = 30$ or simply:
$5 + 5 + 5 + 5 + 5 + 5 = 30$ which can be (mathematically) written or expressed in a simplified form as:

5 x 6 = 30 : Note, both 5 and 6 are factors of their product, or 30. Dividing 30 (as a dividend) by either factor will yield (produce, or result to) the other factor. Multiplying these factors together will yield that dividend.

As noted above, dividing 30 by 5, we get 6, and if we divide 30 by 6, we get the other factor which is 5. So if then given a multiplication problem of the form:

____ x 6 = 30 : or = 6 x ____ = 30 or:

____ x 5 = 30 : or = 5 x ____ = 30

To solve these for the unknown factor, simply divide 30 (the product of factors) by the given factor, so as to find the other (corresponding, correct) factor.

Division with a zero as an operand: 0 divided by any value, results in a quotient that is same value of 0.

Ex. $\frac{0}{3} = 0$: "zero or no thirds, equals zero thirds, or simply zero". In reference to subtraction, 3 cannot be subtracted from 0 even once, since there is nothing there to subtract from that dividend. Zero, or no parts of 3 parts is 0.

This checks when multiplying the quotient and divisor together, yielding the dividend of 0.

3 x 0 = 0

The quotient of any value divided by 0 is not definable, hence this form of a division operation is often called "undefined". This comes from the reasoning that their is no quotient, that when multiplied by a 0 divisor, that will yield a product equal to the given dividend. Also, all values multiplied by 0 result in a product of 0.

Ex. $\frac{10}{0}$ = undefined since: $0 \times \mathbf{?} = 10$:here, ? does not represent a specific value, but rather indicates an endless question, or one that can't be answered, hence an unsolvable or undefined value, and equation.

Note that when checking the product of a multiplication by or with a 0 factor, that when using 0 as the dividing factor, that other non-zero factor of that product cannot be confirmed:

Ex. $4 \times 0 = 0$

Using what was mentioned previously: product / factor = other factor of that product:

checking: $\frac{0}{4} = 0$: checks and $\frac{0}{0} = ?$ (not 4) : here, ? means undefined

When using a modern electronic computer or hand-held electronic calculator, division by zero is usually noted as the symbol (E) displayed, and which means "Error" because division by 0 as a dividend or factor does not have any result.

How would you solve for the unknown, here a divisor (or denominator), represented as $\underline{\quad\quad}$, of a problem of the form:

$\frac{10}{?} = 5$: 10 divided by what number is 5 ?
(here, 10 is the dividend, and 5 is the quotient)

First, we know that to check a division problem, we multiply the quotient and divisor to get the dividend, (that is, the quotient and divisor are both (corresponding) factors of the dividend) hence:

$5 \times \underline{\quad\quad} = 10$

And by the above discussion, dividing a product of two factors by either factor will give the other corresponding or correct factor. Therefore, to find the value of the other factor (here, being equal to the divisor in question), we divide 10 by 5:

$\frac{10}{5} = \underline{\quad\quad}$

$\frac{10}{5} = 2$

checking: $\frac{10}{2} = 5$: checks since $5 \times 2 = 10$

Let us now estimate the value of a quotient. Consider this problem:

$6\overline{)15}$

From the multiplication table or our memory, we know that the quotient is greater than 2 and less than 3 since $6 \times 2 = 12$, $6 \times 3 = 18$, and 15 is numerically located someplace between 12 and 18. 2 will be chosen as a start since 6 can go into 15 at least 2 times (but not 3 times) and there will now be a remainder (the value or difference "left over" or unprocessed amount of the dividend, here 15) of the quotient or "starting minuend" since the division has not been completed yet. Hence, the result or quotient will be 2, plus some fractional value of the divisor, here 6. That is,

quotient = number of times the entire divisor can be used in the division, or evenly divide into the dividend
+ any portion (fraction) of a possible one single division by the divisor to account for any remainder

or quotient = number of even (whole or entire) divisions + any portion (fraction) of one division ,and for the example:

quotient = (2 + some fractional value of 6) : and for checking: (this quotient value) x 6 = 15

> "Some multiple (a value between 2 and 3) of 6, equals 15". Since it's a value between 2 and 3, its not one of the whole or "counting numbers" (sometimes called "integers" for incrementing or incremental "steps" of numbers). Here, the quotient value will have both a whole part and a fractional part, and this kind of a decimal number is sometimes called a "real number". Consider that values are not always incremented by 1, but could be incremented or changed by smaller values such as a part or fraction of 1, and hence the need for real numbers to both represent these increment values and results (such as a sum).

Here, the whole part (the value of 2) of the quotient, can be interpreted as being 2 whole or entire sixes, hence "twice" or occurring 2 times in that dividend, and therefore, at least 2 even divisions are possible. Since there is a remainder "left over" to account for the entire dividend, added (or "plus") to this quotient value is some numeric (fractional, less than 1) value that represents this fractional part of a partial division, and not a complete division. This division is applied to the remainder or what is left of the dividend. The numeric representation, using decimal positional notation, of a fractional part of anything or any value is always less than the entirety or whole thing which can be represented numerically as 100% ("one-hundred percent") or just 1.00 = 1, and hence any fractional value or part will be less than (< is the "less than" mathematical symbol) 1.0

Here is how much of the dividend (here for this example, it's 15) is "left-over" or remaining after all the "whole divisions" by 6:

15 - (6 x 2)
15 - 12
3 : remainder of the dividend

or:

$$\begin{array}{r} 15 \\ -\underline{\ 6} \\ 9 \\ -\underline{\ 6} \\ 3 \end{array}$$

: here, optionally using a repeated subtraction method

: 3 is the remainder of the dividend of 15, and 3 is only a part of one whole or entire value of 6. It could also be said that since only 3 is remaining, that only 3 of the parts, of the 6 parts of the divisor, can evenly divide or "go into" this value of 3. Hence, there will not be a (1) full or complete division upon the remainder.

This remainder (here, it's 3) of the dividend (here, it's 15) is clearly less than 6 and it is therefore numerically only some part or fractional value of 6. Even though 3 is not less than 1, it is still only some fractional (part) value of 6 since 6 is being considered as a single (1) "whole quantity" of reference now and 3 is only a part (portion, or a fraction) of it. The fractional part of the quotient, which represents the numeric value of an incomplete, fractional or partial of one complete possible division, can be said as (and equivalent to) "3 parts of the 6" are left over or remain. The whole part of the quotient is 2.

The quotient can be said to be:

"Two plus three parts of six" = $2 + \frac{3}{6}$: a quotient is expressed in terms of the divisor, that is, how many times the divisor can go into that quotient.

That is, $\frac{15}{6} = 2 + \frac{3}{6}$: note also that 3 is equal to half of 6
The quotient could be expressed as "Two and a half" of that divisor value, hence two and (plus) half of a (one) complete division by the divisor.

.

The quotient is always considered as being in reference to the specific divisor that divided the dividend. The fractional part of the quotient is, and numerically represents 3/6 = 1/2 = 0.5, and is not, for example: 3/5 or 3/7, or 3/15 or any other value. That is, the remainder of one complete division is expressed as a fractional part (or remainder left) of the divisor used for the division, and is not expressed as a fractional part that the remainder of the dividend is to, or of, the entire dividend, (ie. here, not as 3/15 = 0.2).

The quotient can be expressed as equal to:

Since: $\frac{\text{dividend}}{\text{divisor}} = \text{quotient}$ and dividend = (divisor)(quotient)

$$\frac{15}{6} = 2 + \frac{3}{6} \qquad\qquad 15 = (6)\left(2 + \frac{3}{6}\right) \quad \text{or=} \quad \left(\frac{6}{1}\right)\left(\frac{2}{1} + \frac{3}{6}\right)$$

quotient = 2 whole divisions (or subtractions) + numerically expressed or indicated part of a one division by the divisor since a complete division is no longer possible. In short, this value will be and represents a fraction of 1 division.

quotient = 2 whole divisions (or subtractions) + 3/6 = 1/2 = 0.5 = "half" of a 1 complete division by the denominator

The representation (halfs, thirds, fourths, tenths, thousandth, etc.) of the dividend is often not so apparent given a strict numeric decimal value that has a fractional value, and then again, just how do you numerically represent half or any other portion anyway, especially at this stage in the book? The simple trick to overcoming this problem is to increase the remainder, and any further remainders, so that the divisor can divide into it at least once, rather than some fractional portion. At each stage of this "continued division", one extra (lesser weight) digit will be placed in the quotient. This is the basis of "long division" which will be discussed next. Observe the actual quotient of the division problem above, expressed in various forms or expressions:

$$2 + 6\overline{)3} = 2 + 6\overline{)3.0} \quad , \text{ or } = 2 + \frac{3}{6} \quad , \text{ or } = 2 + \frac{1}{2} \quad , \text{ or } = 2 + 0.5 = 2.5$$

Now, another example and more analysis will be shown below so as to give a fuller understanding of the basics of division.

Ex. 31 divided by 5

$5\overline{)31}$ Since 5 x 6 is 30, and 5 x 7 is 35, we will start with 6 times that the divisor of 5 can go into, or be subtracted completely from this quotient of 31.

$$\begin{array}{r} 6 \\ 5\overline{)31} \\ -\underline{30} \\ 1 \end{array}$$

: 5 x 6 = 30

: 1 is the remaining (or remainder) portion of the dividend which cannot be evenly divided by 5. The division cannot continue normally, and is therefore an incomplete division remains. This 1, by itself, is NOT part of the quotient (the result of the division). A quotient is a value that is how many times the divisor can go into, or divide into, the dividend. Hence, a quotient is how many times the dividend can be divided by the divisor. Having said this, the remainder of the quotient is NOT be added to, or expressed as to be added to, the quotient. Here, for this example, the quotient is NOT: 6 + 1, 6.1, or "6 with a remainder of 1 (one more division?)", since 1 is part of the dividend, and is not part of the quotient. Hence the quotient is also NOT: 6 + 1/31 , or 6 + 1/6.

Sometimes the quotient might be expressed as: Quotient and Remainder of the dividend left over
Q and R , and for the above example:
Q=6 and R=1
R is technically, not part of the Quotient

Here, 6 is the number of ("multiple") times the divisor can "go into (wholly, completely, entirely or evenly)" the dividend. Since there is a remaining part (the 1) of the dividend left, and 5 cannot go into 1, this "last", incomplete or "partial" division is simply expressed or indicated and added to the quotient (as a fraction or part of a (one) complete division). The quotient is therefore:

$$6 + 5\overline{)1} \quad = \quad 6 \text{ and } \frac{1}{5} \quad = \quad 6 + 1/5$$

: Note that the added in, division of 1 by 5, to the quotient, is essentially adding in a fractional part of the divisor value. One-fifth of a whole (one) division by the divisor is one-fifth of the 5. One-fifth of five = ((1/5) of 5) = 1 which does equal the remainder of the dividend left over due to an incomplete division.

And for an even deeper understanding:

$5\overline{)\ 31}$ The dividend can be expressed in many ways such as:

$5\overline{)\ 30 + 1}$ which can be expressed as:

$\frac{30 + 1}{5}$:a division expression, and it is also considered a fraction (here, of 5) which is equivalent to: (Knowledge, understanding about fractions may be needed here, and is discussed further ahead.)

$\frac{30}{5} + \frac{1}{5}$ simplifying the first division in this sum, we have the same quotient as shown previously:

$6 + 1/5 = 6 + 0.2 = 6.2$. Checking: $(5)(6.2) = 31$

It's easier to learn manual (by "hand") division by example, so as to solve (find, arrive at) the result (the quotient), rather than by "wordy" and seemingly complex explanations. An example is shown below. This example is sometimes referred to as "long division". Even though the dividend, divisor, or quotient values may contain both an integer (basically a whole part) and fractional part (a value less than 1), the process of performing the operation with "long division" is usually done completely with (single digit) integers (basically whole numbers or the "counting numbers"). The fractional part of the dividend is of course still considered and utilized during the division, but it will be first included as part of the dividend expressed as only a whole number. If the divisor has some number of "decimal places", the decimal point in both the divisor and dividend is moved the same number of decimal places rightward, essentially ridding the fractional part of the divisor and possibly the dividend. Doing this to the divisor, and then the dividend, the decimal point in the quotient will also be adjusted correctly to its proper position. The actual division of the dividend by the divisor begins at the most significant (leading) digits of the dividend and continues to the least significant (trailing) non-zero digit. If the divisor cannot divide at least once into the remaining portion of the dividend yet to be processed, the result or remaining part of the division process is called the remainder (of one division) and is expressed as being part (a fraction of 1 to be added into the quotient, and not a full increment of 1) of the quotient.

About moving the decimal point in both the divisor and dividend, and the same number of places:

Since: $\text{quotient} = \frac{\text{dividend}}{\text{divisor}}$

Mathematically, the same quotient will result if you multiply both the divisor and dividend, or both numerator and denominator of a fraction - creating an "equivalent (same quotient value) fraction", by just the same value, for example, 10 or some other power of 10, such as 100, 1000, etc. When you move a decimal point rightward in a value, each time you move it rightward, you are essentially multiplying each new value by 10, and-or multiplying the original value by another (incremental, integer) higher power of 10. First consider that any value divided by itself is equal to 1. Ex. (10/10) = 1, and that multiplying any value by 1 is that same value:

$$\text{quotient} = \frac{\text{dividend}}{\text{divisor}} = \frac{(\text{dividend } (10))}{(\text{divisor } (10))} = \frac{\text{dividend}}{\text{divisor}}\ \frac{(10)}{(10)} = \frac{(\text{dividend})}{(\text{ divisor })} \times 1 = \frac{\text{dividend}}{\text{divisor}}$$

As an introductory example of the actual working method of dividing "by hand", first consider any value divided by 1. The result, the quotient, is surely and always that same value as the dividend:

1 | 123 : one-hundred and twenty three divided by one

_123_
1 | 123 : the divider of 1 can go into the first digit of the dividend once, put a 1 in the quotient
- _1_ : 1 x 1 = 1, then subtract this, and then "bring down" a remaining digit of the dividend, and
02 : continue to divide, here, 2 divided by 1, is 2, put a 2 in the quotient
- __2 : 2 x 1 = 2, subtract this, and then bring down a remaining digit of the quotient
03 : continue to divide, here, 3 divided by 1 is equal to 3, so put a 3 in the quotient
- __3 : 3 x 1 = 3, subtract this, and the remainder of the dividend is 0, therefore, the division is complete,
0 and it was an even or perfect division with no remainder of the dividend left over, and therefore,
no partial or incomplete division will be expressed as part (summed to) of the quotient.

Ex. Divide 172 by 5

First, 5 cannot divide into the first leading, significant digit (the 1), so then check if it can divide into the first two leading digits (17):

__3_._ __34._ +
5 | 172.0 or 5 | 172.0 5 | 20.0
15 170 : (34x5=170)
22 20

17 - 15 is 2. If this difference was greater than or equal to 5 (the divisor), an error has obviously been performed. The error would be that the corresponding digit in the quotient is too small, yielding a product that is too small, and then a difference that is too large and being greater than the divisor itself. Since 2 is less than 5, we can continue the division by first "bringing down" the next digit of the dividend. Here, 22 is an intermediate difference or remainder (of the dividend). To verify this, we note that the 3 in the second digit (from the decimal point) of the quotient actually represents 30, and 30 x 5=150, and 172 - 150 = 22. Since 22 can be divided by 5, it is not the final remainder of the dividend, and that must always be less than the divisor. The (integer or whole number) division continues:

__34.__
5 | 172.
- 15
22
- 20 : 5 x 4 = 20
2 = r : r = remainder of the dividend left (here, r or R = 2,of the dividend of 172)

Since any integer multiple of 5 cannot divide "evenly" (at least once) into 2, then 2 is the remainder (r) left of the 172. 2 is obviously less than 5. The remainder is always less than the divisor.

When checking a division problem where there is a remainder (of the dividend) left over, the remainder is added to the product of the quotient and divisor, so as the total or sum will equal that dividend. For the last example:

$$\begin{array}{rl} 2 & \\ 34 & : \quad \text{quotient} \\ \times\ \underline{\ \ 5} & : \times\ \text{divisor} \\ 170 & \\ +\ \underline{\ \ 2} & : +\underline{\text{ remainder }} \\ 172 & : =\ \text{dividend} \qquad : \text{checks} \end{array}$$

The quotient in the last example may also be written or noted as:

$34 \text{ and } \frac{2}{5}$ or = 34 and 2/5 or = 34 + 2/5 or more simply and commonly as: 34 2/5 = 34.(2/5) = 34.4

We see that a quotient is sometimes explicitly expressed as:

quotient = (even, whole or entire divisions) + (remainder/divisor) which equals:
quotient = (even, whole or entire divisions) + (partial or fraction of 1 division) : as an expression, or as:
quotient = (even, whole or entire divisions) **.** (partial or fraction of 1 division) : as one (numeric, decimal) value

Using this notation, checking to see if the product of the quotient and divisor equals the dividend requires knowledge of more advanced mathematics (that will be shown ahead), specifically the use of adding or combining fractions. Note that the remainder is expressed in the notation above as part or fraction of the divisor (not as a part of the dividend or quotient). The value of this fraction though is equal to the value of the fractional part of the quotient when it is expressed as just a single standard decimal number.

The division does not have to stop at the remainder of the dividend left. If you "bring down trailing zeros" and continue to divide, you will automatically get the decimal equivalent of the remainder as part of (and added directly to) the quotient.

$$\begin{array}{rl} \underline{\ \ 34.4} & : \text{Note, 0.4 is the fractional part of the quotient, and this part equals 2/5 as indicated above.} \\ 5 \mid 172.0 & \quad \text{Also, } 5 \times 0.4 = 2 = \text{whole value remainder of the dividend, and } 2/5 = 0.4 \\ \underline{15\ \ \ } & \quad \text{Again, at this point, 2 is the remainder "left over" of the dividend, and is NOT the remainder of the} \\ 22\ \ & \quad \text{quotient. 2/5 (or 0.4) can be considered as the numeric expression for the remainder or final part of} \\ \underline{20\ \ } & \quad \text{a one (incomplete) division, and which is to then be added to as (a fractional) part of the quotient.} \\ 20 & : \text{bringing down a "trailing" 0} \\ \underline{20} & \\ 0 & : \text{here, 0 indicates the division is complete when there are no more digits of the quotient left.} \\ & \quad \text{172 has been fully divided by 5.} \end{array}$$

checking :

$$\begin{array}{r} 22\ \ \ \\ 34.4 \\ \times\ \underline{\ \ \ \ \ 5} \\ 172.0 \end{array}$$

Ex. Divide 1 by 0.2

$\frac{1.0 \text{ units}}{0.2 \text{ units}}$ or = $0.2 \;\big|\overline{\ 1.0\ }$: here, strict numeric values with unexpressed units can be understood and-or treated as having units of "ones" or "wholes".

Here, we can multiply both the numerator and denominator by 10 to clear or rid any of them of a fractional portion, or simply by moving the decimal point in both the divisor and dividend one position rightward: Note, that 10/10 = 1, and multiplying anything by 1 is still that same value numerically, and is without issue or worry of obtaining an incorrect result:

$$\frac{1.0 \text{ units } (10)}{0.2 \text{ units } (10)} = \frac{10 \text{ units}}{2 \text{ units}} = 5 \quad \text{or commonly as: } = \quad 2 \,\overset{\underline{\;\;5.0\;}}{\big)\,10.0}$$

As seen above, when dividing one quantity by another quantity whose units are the same, the result is a simple or "unit-less", plain and "strict", numeric value only. The problem could also have been expressed as:

$$\frac{1.0 \text{ units}}{2 \text{ tenths of a unit}}$$

Since there are 10 tenths of a unit in each 1 unit, after multiplying the numerator by 10 for the (converted to) equivalent number of tenths of a unit in that value given (here it's 1 only) , we will have like or similar units to properly work with:

$$\frac{10 \text{ tenths of a unit}}{2 \text{ tenths of a unit}} = \frac{10 \text{ tenths}}{2 \text{ tenths}} = 5 \quad , \quad \text{checking: } (5)(2 \text{ tenths}) = (5 \times 2) \text{ tenths} = 10 \text{ tenths}$$

This new (derived) units of: "tenths of a unit", or simply "tenths" is verified below:

$$1 \text{ unit} = \frac{10 \text{ units}}{10} = \frac{10\,(1 \text{ units})}{10} = \frac{10\,(\text{units})}{(10)}$$

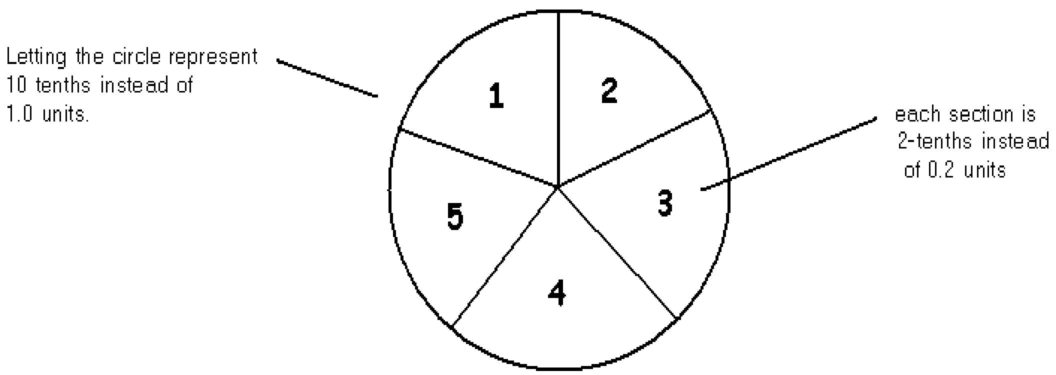
The value of : $\frac{(\text{units})}{10} = \left(\frac{1}{10}\right)$ units , is commonly called: "one-tenth of a unit" , a "tenth of a unit", or simply "tenths". (1/10) unit = 0.1 unit

1 unit = 10 tenths of a unit or simply :
1 unit = 10 tenths

This unit of tenths could have been called something else, but they are kept as is to reflect that they are derived from a whole (1) unit, and that the decimal system is based on ten = 10.

For the above example, it is perhaps easier to also visualize the division when the dividing is by a whole or integer number of units (like 2 tenths) rather than some fractional (like 0.2 units) or mixed (whole + fractional) number of units: [FIG 2]

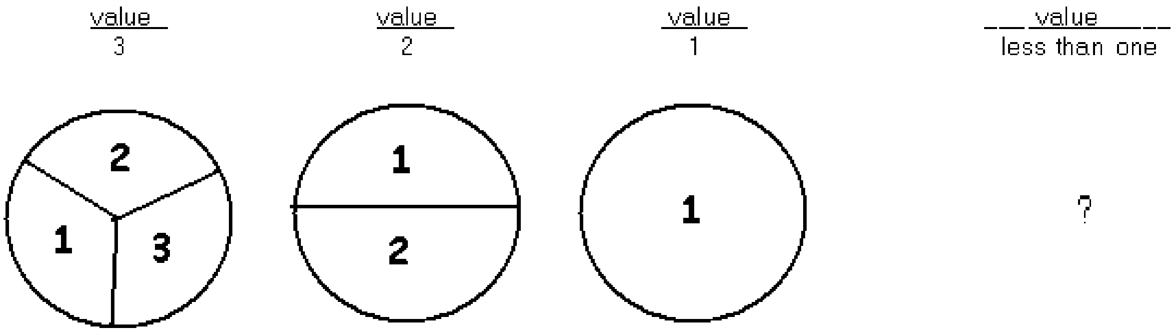
(1/ 5) graphically:



1 is the numeric representation of the whole or entire thing in question, and is graphically represented as one complete or whole circle. Note here that 2-tenths is equal to or composed of 1 tenth and 1 tenth. Each section of the circle divided into 5 parts or sections, has a numeric value or representation as (1/5). (1/5)=0.2 and this can be considered as:

$$\text{quotient} = \frac{\text{dividend}}{\text{divisor}} = \frac{1}{5} = 0.2$$

Consider these general graphics or visualization representations below of the division of any specific value greater than or equal to 1. The entire circle area represents the specific value used as the dividend, the number of segments of the circle represents the divisor value, and each equivalent segment size or (area) portion of the circle represents the quotient value: [FIG 3]



For the first 3 values divided, the quotient (represented as a portion or segment area of the circle, and is equal to the size of each portion or segment of that circle) is clearly less than the value in the dividend or numerator, but for the circle or value on the right, the quotient or result is actually a bigger circle or value, that is, the quotient is actually larger than the dividend value. This is a reason why we changed the divisor numbers to be greater than or equal to 1 for the divisions in the above examples, such as when the dividend and divisor are first multiplied by 10 before the division starts.

A very helpful method to perform "long-division" (a manual division computation, by pen and hand) is to take the worthwhile effort to create a table of all products of the divisor and integers from 1 to 9 before performing the division calculation by hand. Some of these products may not be needed due to the specific values used in the division expression or problem, but they will be there (already calculated) if needed. This will eliminate a lot of possible guesswork, and therefore it can save some time, and may even prevent some errors.

Ex. Divide 5.2 by 741,279

Below, rather than use multiplication to create a useful table for division, repeated addition is utilized since it (addition) is easier in itself and requires one less repetitive step to create the table. When the division cannot be complete (as like it with an "even division" that would be complete at some point, and not have an "endless" quotient composted of unending digits), there is a good chance all the multipliers (0 to 9) will be needed and used in the quotient. Sometimes, one or several specific digits repeat over and over in a quotient:

```
     741279    (1)       :  741,279 x 1
+    741279
    1482558    (2)
+    741279
    2223837    (3)
+    741279
    2965116    (4)
+    741279
    3706395    (5)       : 741,279 x 5
+    741279
    4447674    (6)
+    741279
    5188953    (7)
+    741279
    5930232    (8)
+    741279
    6671511    (9)       : 741,279 x 9
```

Using this created table shown above of the single digit integer products (or multiples) of the divisor:

```
               0.0000070149
741279 |  5.2000000000
        -  5188953         : 7    , optionally indicating each new digit of the quotient during this process.
             110470             : each difference here should always be less than the divisor,  then "bringing down"
          -        0        : 0      a zero will essentially multiply this difference by 10 so the division can continue
             1104700
           -  741279        : 1
              3634210
            -  2965116       : 4
                6690940
              -  6671511     : 9
                   19429
```

For practicality, here, the quotient is "rounded" (basically means limited to, and approximated) to only 9 decimal places is: $0.000,007,01\underline{5}$ The underlined 5 means that this value was rounded at that decimal place and precision.

Division can be used to check the result (a product) of a multiplication operation. Given the product of two factors, divide the product by one of the given factors, and if the result (a quotient) is equal to the other factor, the product is correct.

Ex. 5 x 4 = 20 now checking with: 20/4 = 5 and, or 20/5 = 4 : we get the other factor or operand

Some Devices To Help Make Numerical Computations

Before fast electronic calculators and-or computers there were mechanical computers of all sorts, with some just being adding and subtraction machines. The first programmable mechanical computer design is credited to **Charles Babbage** (1791-1871), from England, when he proposed the **Analytical Engine** machine in 1837. Some of the ideas Babbage incorporated into his machine were based on the punch cards for the **Jacquard loom** (essentially a machine for weaving or inter-twining strings of fabric so as to a larger fabric or cloth) which were cards with holes in them, and where each hole represented some data for a desired (ie., programmable) pattern for the loom to automatically make with fabric. The cards were essentially or effectively the memory (ie., storage, record) medium, and were also used as steps (or statements) to then instruct the machine via the data (ie., coded information [ex. numbers] and-or instructions) on it. This machine had input, memory, logic (ie., truth statements), (conditional, ex: "IF" and "DO") program flow and-or control, looping (ie., repetition) and output ability such as with a mechanical printing machine. With his computer machine, Babbage wanted to make more accurate (ie., correct) and precise (ie., mathematical precision, fineness, resolution) mathematical tables for many others to utilize. It is of note that people who made calculations since the days of antiquity were sometimes called as "computers" or "calculators". Babbage invented a type of user programmable computer, and due to the holes (ie., a binary value of 0 or 1) and no-holes (ie., opposite binary 1 or 0) actually being data and or-an part of an instruction (ie., a step in the computer or calculating program), the computer functioned as a binary functioning computer.

The mechanical power and "timing" (ie., for individual steps, processes, calculations, and the speed of it mechanically functioning and-or computer processing) for this machine came from human power via a physical or mechanical force (technically, the application of energy, and which can be indirectly calculated by an equation such as: Force = mass times acceleration) applied to a mechanical hand-crank or turning handle. The faster this could be turned, the faster the computer could perform its internal steps and calculations to produce a result. In theory, his machine is much like a modern computer and would calculate a binary result. Babbage also created a printer with numbers 0 through 9 (in reverse image for printing) on the edge of each wheel, and many wheels were placed side by side so as to create and print large valued numbers having many columns and-or digits. The machine converted its binary number and-or notated result to its decimal system equivalent, and then set the corresponding wheel with the number to be printed. The number and-or result was then printed onto paper after applying ink to the numbers on the wheels. Most likely, this machine could be built so as to also display an immediate visual (ie., non-printed) result like a modern day calculator does. His assistant, lady **Ada Lovelace** (1815-1852), from England, is often noted as being the first computer programmer. Lovelace had a good mathematical education by various tutors, reasoning skills, and a thoughtful imagination that was helpful for new problem solving and progress. She also created some of the algorithms **(**steps and-or procedures, a guide or plan, "program formula", and of which resulted in instructions for input, output, calculations (math functions such as add, subtract, etc,), logic (ex. compare two values), and program flow and control such as "jumping" or starting at another location in the program**)** for the computer to follow so as to utilize and process the specific program and-or calculation in it.

It is interesting to note that electronic computers can perform multiplication by repeated addition. Subtraction is performed using a special form of addition known as complement (value(s)) addition. Division can be performed by repeated subtraction. Hence, it is possible for a computer to perform all the basic mathematical operations by using addition, and Charles Babbage knew this, and this would simplify the design of the machine. Electron computers could then be designed to contain just the electronic circuitry to perform one main mathematical operation such as addition, and therefore eliminate or reduce some circuitry and complexity needed for the other mathematical operations, and making the computer less expensive.

It is also of note that a computer program user does not need to understand all about computer science and-or computer programming (ie., a specific computer language for that machine), and a computer programmer does not need to understand the internals (ex., gears, circuits) of how the machine functions, and the machine maker does not need to know how the metal was mined and manufactured.

USING MULTIPLICATION AND DIVISION TO MEASURE OR COUNT SMALL THINGS

Here is an example of using division to find that which is normally not practical. Something small, such as a grain of sand or rice, cannot be weighed using many weight measuring ("scales") devices. A method will now be shown as to how to weigh these small objects. This method utilizes the fact that if you magnify (increase) something either physically or mathematically by a multiplication, that you can find that original something by a corresponding "demagnification" (a decrease, factorized) using division.

Given 1 grain of hard, dried rice, if you multiply the number of grains of rice by 500, you essentially have also multiplied its' weight by the same value. Now, this total weight of 500 grains of rice can be measured by using a commonly available fine scale. If these 500 grains of rice weigh 1 ounce, you can use division to find 1 grain of rice and the weight of 1 common, "average", typical, or usual grain of the type of rice being considered.

$1\text{ grain} \times 500 = 500\text{ grains}$

mathematically ("solving for 1 grain") :
(dividing the product by one factor, to find the other factor)

$$\frac{500\text{ grains}}{500} = 1\text{ grain}$$

Considering the weight of each grain of rice:

$\text{weight of 1 grain} \times 500 = \text{weight of 500 grains}$

Mathematically solving for the weight of 1 grain:

$$\text{weight of 1 grain} = \frac{\text{weight of 500 grains}}{500} =$$

Now substituting the numeric values given or measured:
(weight of 500 grains = 0.333 oz, [depends on the type of rice])

Note: **This book uses ~= or =~ to mean "about equal to" and-or "equals about".**

$$\frac{0.333\text{ oz.}}{500\text{ grains}} = \frac{0.000667\text{ oz}}{(1)\text{ grain}}$$

: Weight of 1 grain **=~** seven ten-thousandths of an (1) ounce".
: After dividing both numerator and denominator by 500 we get less than a thousandth of an ounce per (one) grain. Later in this book, it will be shown that the entire numerical equation shown is called a "proportion" (for a given problem or system) and can be re-used, for example, so as to now find the weights of any number of grains of rice. Though the known reference weight (of either 500 grains, or 1 grain of rice) and the weight you will be trying to find will be different; not in balance, mathematically, both sides will still be in balance, and that balance is that each side has the same exact quotient value. Here, each side is equal to (0.000667 oz/grain). 0.000667oz = about 0.0189 grams = about 0.019g = 19 milligrams.

Also, given:

500 grains of rice = 0.333 ounces

If we divided both sides of this equation by 0.333 we can find the number of grains of rice per ounce of weight:

$$\frac{0.333\text{ ounces}}{0.333} = \frac{500\text{ grains of rice}}{0.333}$$

1 ounce = (about, ~) 1500 grains of hard, dry, uncooked rice

: For the type actually measured, it was a white rice variety, that was almost 1/4 inch long, and about 3/32 of an inch wide at the thickest part in the middle. It appeared to be a "medium grain" sized of rice. The rice was also hard, dry, and uncooked.

As a check of calculation correctness, and a possible improved value, the above process should be repeated with another set of near randomly selected rice grains so as to have an average value will be as correct as possible for the weight of a rice grain, for most future circumstances. Scales to measure low weights, perhaps a hundredth of a gram, are available, and it is possible to construct your own. If you multiply the number of grains per ounce by 16, you can calculate an estimate of the number of grains per pound (16 ounces). Doing this, we find that there is about 24000 grains of rice in a pound of rice.

To weigh something such as a grain of sand, the basics of the above method can also be utilized. First, you would have to count many more grains of sand just to have a weight of usable value for a scale. This is a very impractical method for most people. To overcome this, you can first find out how many grains are in a certain volume (a measure of 3 dimensional space) of sand, say one cubic centimeter or inch. A cube as shown in this book is a solid with all it's 3 dimensions, length, width, and height all being the same value of length, and for our purposes here, they will have the same length of 1 inch. A cube shape is like that of a square area, an (bounded or specific) area of plane, hence a planar area which has then been moved upwards a height equal to the length of a side of that square shape. This creates a volume or (3 dimensional) spacial area called a cube. A cube is the basic or standard unit of measurement for volumes or spacial areas. For this example, if you find that there are 50 grains of sand lined-up per ("in a", "in one", "for", or "equivalent to") half and inch = 0.5in, then there are (50 x 2) = 100 grains of sand lined-up per 1 inch. There are then (100 x 100) = 10,000 grains of sand per square inch, of course, this assumes that the each grain of sand is roughly the same (average) size in the length and width dimensions, if they were not, you would have to first count and then estimate or average how many are actually in the length and-or width dimensions. Continuing, there are (100 x 100 x 100) = 1,000,000 grains of sand per cubic inch, again, assuming each grain of sand is roughly the same height.

weight of 1 grain x 1,000,000 = weight of 1,000,000 grains mathematically:

$$\text{weight of 1 grain of sand} = \frac{\text{weight of 1,000,000 grains}}{1{,}000{,}000}$$

:after dividing (each side of the equation) by 1,000,000

If this cubic inch of sand weighs 3 ounces, that is:

weight of 1,000,000 grains of sand = 3 oz: again, dividing each side by 1,000,000:

$$\text{weight of 1 grain of sand} = \frac{3\text{ oz.}}{1{,}000{,}000} = 0.000{,}003\text{ oz.}$$

: 3 millionths of an ounce

A note on how similar atoms of a given element are typically counted. Since there are so many atoms in a given mass (a measurement or measure of actual, physical matter) of atoms, and which therefore cannot even be seen so as to be counted by a person, the number of atoms in a given mass are counted by the weight of that given mass. This is because, for each gram of mass of a certain given element, there is a known corresponding weight and amount of atoms.

Summarizing this discussion, many identical things of small size and-or weight can be easily counted by using a calculation with their total weight and-or their total volume. Shown here is a more advanced note due to its relevance with this topic: A quantity of atoms of a certain element can be counted by knowing their total weight, and which is directly proportional to the total amount of mass of each atom, hence total mass of a quantity of atoms can be calculated by knowing the total weight: At twice the weight there will be twice the mass, and twice the number of similar objects such as rice, and twice the volume.

Weight = force = (mass)(acceleration = gravity = g). Mathematically: mass = weight / g.

The number of atoms can be calculated as: (total mass of the atoms) / (mass / 1 atom) = atoms

SOMETHING ABOUT INFINITY

Infinity (ie. "non-finite", "non-ending", "endlessly", "without end") does not, and cannot, have a specific value, and is rooted in a concept of something that is, and can be or conceived (but perhaps not necessarily easily provable) to be as possibly and probably unending. Outer space is not a process, but rather a thing, and is said to be infinite in size, "unending" and can therefore be without any specific measurement or value of a size or distance. A process can be repeated without end, hence that process is said to be an infinite process or simply infinite. If there will always be a "next second" of time, or at least in thought or theory, time can therefore be said as being something that is infinite. Something, even when counting or using numbers, can be infinitely large (without bounds) or infinitely small (almost 0, or almost nothing). The digits of Pi (3.14**...**), that is mathematically part of all circles, are said to be unending and therefore infinite. Some conceivably infinite processes may have just recently began, such as some machine that just started counting higher from an initial value of 0, and hence an infinite process may have not always been in existence, and hence it was not always infinite in some way, but perhaps infinite in only one kind of way, direction or ability now.

Ex. Since 1 can always be added to a number to create or find the next larger number, this is an infinite process, and here, the sum is also infinite in value:

0 + 1 + 2 + 3 + 4 + 5 + **. . .** : an infinite process of summing, and here the sum is not any specific value, but is an unknown value that could be described as infinitely high and-or unending value

Below are some more notes and ideas about the topic of infinity to perhaps consider and inspire some further thoughts, and perhaps may flare the temper of a few strict mathematical purists. If you are new to math, you may simply skip over this topic without any problem, and return when you are able.

When the divisor of a division problem gets smaller and smaller (said as "approaching 0", "becoming near to 0", "nearing 0", "approaching a limit of 0", but never actually being equal to 0 because that would mean the divisor and a real valid division problem no longer exists, and also that division by 0 is undefined or an error) you could conceive that the quotient can possibly have an aspect of infinity (its mathematical symbol is: ∞; which somewhat looks like the decimal number 8 symbol tilted on its side), and rather than speak in terms of theory, its' (largest possible, or conceivable) numeric decimal system integer value can be practically conceived or imagined as a never ending series of 9's or: 9999 **. . .** , even though infinity is a unending process and not a specific numeric value. The **. . .** ("ellipses" = "and so forth") symbol essentially indicates to repeat the process unendingly. Sometimes, when a result in an unending process is sufficient or acceptable, the process can be stopped.

There is also no limit to how small something can be. Things and-or numbers such as this are said to be "endlessly or infinitely" small. The smallest numeric value can be conceivably expressed as a process of an endless number of zero's between the decimal point and the number 1 such as: 0.00000 **. . .** 001 , or using other expressions such as 0.1^n, or 1^-n, as integer (n) approaches infinity. Consider when the divisor of a division problem gets larger and larger, and-or the dividend gets smaller and smaller, the quotient will become (infinitely or endlessly) smaller and smaller.

It is widely accepted now that 0.9999... = 1 since 1/3 + 1/3 + 1/3 = 0.3333**...** + 0.3333**...** + 0.333**...** = 0.999**...** = 3/3 = 1. If it can be (maybe controversially) conceived that 0.3333**...** can be represented as 0.3333**...**3, then it should also be conceived that 0.0000**....**1 can be thought of as that infinitely small number, something or part (here represented with common decimal, base 10, notation) that when summed to 0.9999**...** will mathematically express and cause that value to "finally roll over" and sum to 1. Note also that whereas 0.9999**...** = 1, we now likewise conceive that 0.0000**....**1 = 0 since it will approach and effectively be a value of 0. Some will argue that 0.333...3 and 0.000...1 have or express a "last value or digit", and hence, the notation does not represent or express an infinite value, but by using the **...** symbol, the infinity concept still exists, and therefore, the "last digit" argument does not hold since there isn't a last digit due to the infinite process. Though 0.9999... will approach 1 which is a finite value, 0.9999... represents an unending a process to approach and reach that finite value

For some extra ideas on the above concepts of infinity, there are two types of infinity, and it's best to think of them as a non-ending process without any specific numerical value. The largest (decimal system) number or the number that could represent the infinitely big could be written as: (9999...9) The number that could represent the infinitely small could be written as: (0.0000...1) Why use the 1 digit at the end? Because in our number system we begin counting with 1, and therefore, the conceivable number, expression or notation that represents the infinitely small should include this first digit that is at least greater than 0 or nothing, and using 1 indicates that there is "something" and numerically represented. The two closest numbers next to 1, one being smaller, and the other one being bigger can be conceived or imagined as: (0.9999...9) and (1.000...1). Their conceived difference is (0.0000...2) which is larger than the conceivably smallest possible decimal (infinite) number (0.0000...1) greater than 0. Some would argue that (0.9999...9) is the same as 1, but that is like saying (1.0000...1) is the same as 1, and then that is like saying (0.9999...9) is then equal to (1.0000...1) which, as just mentioned above, has a difference between them of (0.0000...2), and not 0.0 as when they are actually equal. Still, you could argue that (0.0000...2) is an infinite process and that it will also approach a value of 0. It is fair to equate 0.9999....9 to 1.0 since in theory, there is to be no empty space between two adjacent points and no other number between two adjacent numbers, and even though 0.999....9 is expressed as (an infinite) process and not a specific decimal number, and which rather "zeros in" or converges to 1.

THE ORDER OF OPERATIONS

The order of mathematical operations is a commonly accepted and basic plan for simplifying and solving mathematical equations. It is accepted and used so that there is a formal-like consistency and less chance of misunderstandings and error. The plan states which operations of an expression should be performed first or have precedence (ie., more importance or priority). Due to this, it is also a consideration and guide for expressing equations so as they may be correctly solved by someone who is observing the order of operations plan. The 4-step plan is given below in steps of precedence.

1. Simplify powers, roots, and logarithms.

Ex. 5^2 = 25 : a power example, , here: "(a base of) 5, "raised" to the second (2) power" or "5 square"

Ex. $\sqrt{25} = 5$: a root example, , here: "the second (2) or square root of 25"

Ex. $\log_{5} 25 = 2$: a logarithm example, here: "the log of 25, using a base value of 5, is 2" , 5^2 = 25

The concepts of powers, roots, and logarithms will be covered further ahead in this book. A logarithm expression is simply an expression for the mathematical operation to find or solve for the exponent of the base value of an indicated power value.

2. Simplify expressions that are in grouping symbols.

Grouping symbols surrounding an expression indicate that the expression is to be possibly simplified first before any other mathematical operation can be performed on the resulting (and usually simpler) expression or value. Grouping symbols are often used to force precedence and-or to bound and clarify an expression so as to prevent a misunderstanding and error. If there are other grouping symbols contained within or between grouping symbols, sometimes this situation or expression is said as having "nested" or "inner" grouping symbols, the expressions within them are simplified first and from the innermost to the outermost (ie. inner to outer). That is, each corresponding pair of grouping symbols will be successively cleared or canceled (canceled-out or removed) if possible. Hence, this step may also be called: **Cancel or clear grouping symbols.**

Some examples of grouping symbols are:

( ) : parentheses and other similar shapes such as brackets: **[ ]**

---- : division symbol or fraction symbol
Here, the dividend or numerator represents one value, and the divisor or denominator represents one value. That is, either or both might be expressions that can be simplified first, and then the division operation can be performed so as to produce a quotient.

3. Perform multiplication and division.

This is done (for conformity to avoid any confusion or ambiguity) from the leftward side to the rightward side of the expression. Usually, performing division has slightly more precedence than multiplication since it contains the division grouping symbol. Performing the division will effectively clear that grouping symbol, producing a quotient value which can then be possibly used as an operand for another operation.

4. Perform additions and subtractions.

Like multiplication and division, these are also done from leftward to rightward in the expression.

Note that for the second step, simplify expressions in grouping symbols or clear grouping symbols, that steps 1,3, or 4 may be needed first, during, or "along with" for this process.

It is possible to express the concept of the order of operations using just a few words such as: "perform the most advanced operations first". Another plan to simplify expressions is what I call the CDC plan which is closely related to the plan given above, and will be presented further ahead in this book. Below are some basic working examples of using the order of operations.

Ex. 5 +1 x 7

Without following the order of operations method, and simplifying or solving from left to right, 5 would first be added to 1, and then this sum would then be multiplied by 7. This is how some "chain-logic" (evaluated left to right, as written, entered or processed) "home-use" or "4-function" calculators, and even some outdated or simple computers, would evaluate the expression, but for conformity, we are encouraged to use the order of operations from now on that considers the (order of) precedence or importance of the mathematical operations, rather than their (left to right expressed) order.

Without following the order of operations:

5 + 1 x 7 When explicitly expressed and evaluated as: (5 + 1) x 7 using "chain-logic" :
6 x 7
42

Following the order of operations:

The 1 would first be multiplied by 7, and then this product will be added to 5. The result is very different than the last result even though both original expressions are the same. This method is the preferred method used by "algebraic logic" or "scientific" calculators and computers to evaluate an entered expression.

5 + 1 x 7 is evaluated as, using the order of operations: = 5 + (1 x 7)
5 + 7
12

To achieve this same result using a chain-logic calculator, evaluate the higher-ordered or most advanced operations of the given expression first. If you want, you can also rewrite the expression with some grouping symbols to clarify how it is to be evaluated (processed, simplified or solved):

5 + 1 x 7 by using some grouping symbols:
5 + (1 x 7) or perhaps by switching the two operands of the addition operation:
(1 x 7) + 5
7 + 5
12

When an expression inside grouping symbols is simplified to a single value, it is possible and desirable to remove (clear or rid) the grouping symbols that surround it as long as it does not change the intended order or operations and therefore, the result.

Ex. 5 + (2 + 3)

5 + (5) : after using step 4 and performed the addition operation expressed within the grouping symbols
5 + 5 : step 2, basically cleared/rid the grouping symbol that are not needed now
If you want, you can consider 5 + (5) = 5 + 1(5) = 5 + 5 , so as to remove the grouping symbol
10 : step 4, addition

Ex. 5 + 3(3(7x4)) + 2

5 + 3(3(28)) + 2 : step 3, after simplifying the innermost grouping symbols, here (7x4) = 28
5 + 3(84) +2 : step 3 and 2, multiplication (to clear grouping symbols), here 3(28) = 84
5 + 252 + 2 : step 3 and 2, using multiplication which then clears the grouping symbol
259 : step 4, using addition, here, the order of the summing of the values, does not matter

Ex. Simplify 5 + 3 x 10

Since multiplication has more precedence than addition, this expression is usually written or expressed, and simplified as:
5 + (3x10) : for some basic home use calculators you might have to use these steps in the order of: (3 x 10) + 5

Here, the grouping symbols clearly indicate or "force" a precedence of performing the operations. That is, here 5 is to be added to the entire value enclosed in the grouping symbols. This value within the parentheses is an expression which must be simplified first whether you are using a calculator or not:

5 + (30) : after performing step 3
5 + 30 : after performing step 2
35 : after performing step 4

Ex. $5 \times \frac{10}{2} + 3$

or $\left(\frac{5}{1} \times \frac{10}{2} \right) + 3$: due to the precedence of multiplication, a grouping symbol is shown here for visual clarification

(5 x 5) + 3 : after performing step 3, (division, here, 10 divided by 2)
25 + 3 : after performing step 3, (multiplication), then step 2
28 : after performing step 4, addition

The more you practice with the simplification or "simplifying" expressions, and the order of operations, the more "natural" it will feel and become to you.

COMMUTATIVE AND ASSOCIATIVE LAWS

Multiplication and addition are said to be commutative (based on the word "(to) commute" which means "moveable", "changeable", "transportable"). That is, if you exchange or "switch" the operands (values the operators are to be applied to) of the operation, the result will still be the same. This may be done to help clarify, express, or evaluate an expression.

5 + 2 = 2 + 5
Ex. 5 + 2 = 2 + 5 : * * * * * + * * = * * + * * * * * : somewhat like a mirror image.
7 = 7 * * * * * * * : both have the same sum.
7

Ex. 4 x 9 = 9 x 4 : maybe you don't know 4 x 9 offhand, but perhaps you have already memorized 9 x 4
36 = 36

Multiplication and addition are also said to be associative (to associate, join, pair, connect, align or group with). That is, you can associate any two or more operands together by grouping (usually with parenthesis; ( ) , or backets; [ ]) and the result will be the same.

Ex. 5 + 2 + 3 = (5 + 2) + 3 = 5 + (2 + 3)
10 = 7 + 3 = 5 + 5
10 = 10 = 10

Ex. 2 x 4 x 3 = [2x4] x 3 = 2 x [4x3] = (3 x 2)(4)
24 = 8 x 3 = 2 x 12 (6)(4) = 6 x 4
24 = 24 = 24 24

FRACTIONS

A part is less-than the whole of which it comes from. The whole thing is "100%", all, complete, entirety or "one" (oneness and numerically 100%=1, or the undivided something). When only a part or parts of a whole are to be expressed mathematically, fraction or fractional notation (simply called "fractions") is used to numerically represent this part or fractional value of the whole. A fraction of something is a piece, portion, segment or part of that whole something that was essentially broken or divided into parts or pieces. The part(s) in question is said to be a fraction, or fractional part of the whole. A fraction or part is numerically represented as a value that is likewise less than the whole (or entire) thing or amount expressed numerically. If we let 1=1.0=100% numerically represent the entire thing, then a value less than 1 will represent a lesser or smaller part(s), portion, or fraction of that whole thing.

Symbolically: (fractional part(s) of the whole part) < (whole part) : A fractional part(s) is less than (<) the whole part of which it was from.

Numerically: (value(s) or sum of fractional or part values is less than 1) <= 1.0

Ex: $0.5 < 1.0$: Here, a part numerically represented as 0.5 is less than the whole (1)
Ex: $0.5 + 0.5 = 1$: Here, the sum of two parts numerical representations sum to 1.
Ex: $0.3 < 1.0$
Ex: $0.3 + 0.5 = 0.8 < 1$

We can often recognize that a given part is only a fractional part of something. For example, 5 is only a part of 8. 5 is the part or portion of the entire, all or whole value of 8. 5 is different and less than 8, and this can be mathematically verified by subtracting the two values to show that there is a difference in values: 8-5 = 3. 3 is the difference or amount of separation between those two values of 5 and 8. For example, 200 is only part of 203. 200 is a fraction of 203, and their difference is 3. Rather than express a numerical relationship of two values as a difference, a better way to quantify and express their numerical relationship is to show how many times bigger or smaller one value is to the other (reference) value. The resulting value will show the decimal equivalent value that the part is with respect to the whole which can be expressed numerically as 1.0 (= 100% = all, entire, whole). 5 of, from, or out of 8 and expressed as a fractional expression is: 5/8 , and this value = 0.625 after division is performed , 200 out of 203 = 200/203 = 0.985 Even though the difference was 3 for each example, this difference value of 3 does not numerically represent how much the part or portion of the whole is numerically. 3 doesn't quantify the portion, but rather only the difference. The values of 0 .625 and 0.985 just shown do. The value of 0.985 is much more than 0.625, and is therefore a larger fractional part. 200 is therefore a larger part or portion of 203, than as 5 is to 8. Since 0.985 is close in value to 1, it indicates that the part or portion in question is almost the entire value in question. 8 or 8 parts = 8/8 , or 203 of 203 parts = 203/203, would result that the fractional value in question can be represented with and has a value of 1, and this indicates that the fractional value in question is equal to the entire, whole part or value.

We have seen that quantifying and expressing the numerical relationship of a part to the whole by using the difference value does not numerically represent how much that the fractional portion is of, represents, or how much it is of the entirety or whole part, but it rather just expresses or indicates how much different, and not the similar, the two values are. As just seen in the two examples above, the difference may be the same, and yet the portions of the whole are much different. A difference value does not quantify or numerically express a portion value. A quotient value can quantify or numerically express a portion. The mathematical operation will be same as a division problem, but the concept and terminology is different since we are not actually trying to divide any parts up into even smaller parts, but rather expressing just the numeric relationship of one part in relation to, or with respect to, another part or the whole part.

The basic mathematical (standard) "formula" or expression for a fractional value is a numerator value divided by a denominator value.

$\frac{\text{numerator}}{\text{denominator}}$: The word numerator is from the word numerate, meaning to count or assign a number to or of.
: The word denominator is from the word denominate. Nominate means to assign a name to, and here it's a number name or identifier. To denominate is to completely assign a name,

hence denominator means the complete number to or of. The numerator number used is in reference to the denominator number used.

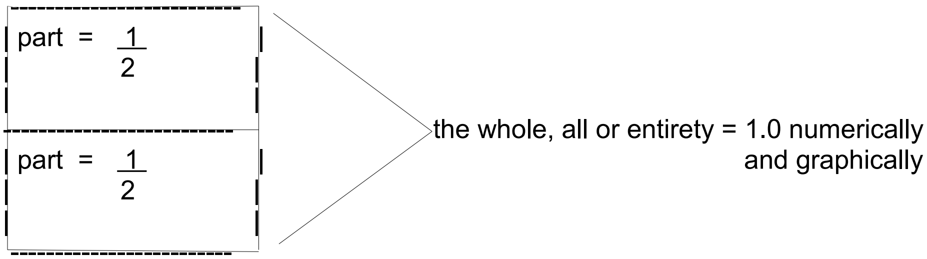
You can roughly think of this as: $\frac{\text{parts}}{\text{total parts}}$: "parts to total parts" or "parts of the total number of parts"

We see that this is essentially the same as a division expression and problem, except for the names used. Comparing the two types of expressions, the numerator is similar to the dividend, and the denominator is similar to the divisor. When something is divided, such as into (fractional) parts, it is somewhat obvious that a division type of expression will be used to express this.

If a whole (1) thing or quantity is evenly split or divided (a division problem) to 2 equal parts, we can represent this numerically as this division expression:

$\frac{1}{2}$: this also expresses the numerical representation or value of each similar (fractional) part. This numeric expression is therefore called a fraction. After dividing, the quotient is called the fractional (in decimal number form) value. Each identical fractional part is equal in value, here, (1/2) = 0.5

The numerical value of, or given to, each separate (and identical) part is the value of this fraction (but only when a whole or 1 is divided). Each part is said to be "one-half" of the whole. Numerically, each part has a value of (1/2), or the equivalent decimal value of 0.5, when the 1 is divided by the 2. 0.5 is clearly less than the whole of 1. [FIG 4]



The sum (mathematical, and-or physical combining) of all the fractional parts will always equal that which was divided into those fractional parts. For the example just shown:

part + part = whole, all or entirety that was divided up into two parts
(1/2) + (1/2) = 1/2 + 1/2 = 0.5 + 0.5 = 1.0

Here is how to express the whole (1) of something divided into 4 equal sized parts: $\frac{1}{4}$

Each part will also have this numeric value of (1/4) or= 0.25 Considering just two of these four parts taken, put or summed together as a group, then what fractional part of the whole does this represent? Clearly, since two parts is twice as much as one part, the fractional value must be twice as much:

one-fourth and one-fourth equals two-fourths or: 2 x one-fourth = $2 \times \frac{(1)}{(4)} = \frac{2(1)}{4} = \frac{2}{4}$: "two-fourths"

$\frac{1}{4} + \frac{1}{4} = \frac{2}{4} = 0.50$

0.25 + 0.25 = 0.50 : or= 0.25(2) = 0.50 since repeated addition can be represented as multiplication

Though it is possible, do not interpret the value of 2 in (2/4) as meaning 2 wholes being divided up into 4 parts, since for this problem we are dealing with only one whole, or entirety of a thing, numerically expressed as 1, that was divided up. So therefore, a numerator can be defined as the number of (all similar) parts in question or being considered of the whole, and a denominator is said to be the total number of parts that the whole was evenly divided up to. You can visually read the mathematical notation of the fraction symbol as meaning "of", "out of" or "from".

Ex. $\frac{1}{2}$: "one, out of two" or "one part, out of two parts" or simply as "one, out of two" or "one, of two" , or "one-half" = "one-half of the whole" = (1/2) of (1) = (1/2) of (1/1) = (1/2) (1/1) = (1/1) (1/2) = (1) 1/2 = 1/2

Ex. $\frac{2}{6}$: "2, out of 6" or "2 parts, of something divided or separated into 6 total parts" , This can be considered as equal to: (1/6) + (1/6) = 2 (1/6) = (2/1) (1/6) = 2 / 6 and-or = 1/3 = 0.333...

If given a fraction and you perform the indicated division, the resulting quotient is the decimal equivalent of that fraction.

Ex. $$\frac{1}{2} = \begin{array}{r} 0.5 \\ 2\overline{)1.0} \\ -\underline{1\;0} \\ 0 \end{array} = 0.5$$

Below is another ex. where the numerator is half the denominator, and that the total fractional part(s) in question is also numerically 0.5 = 50% of the whole or denominator:

Ex. $$\frac{3}{6} = \begin{array}{r} 0.5 \\ 6\overline{)3.0} \\ \underline{30} \\ 0 \end{array} = 0.5$$

: checking, 6 x 0.5 = 3

Ex. $$\frac{4.5}{6} = \begin{array}{r} 0.75 \\ 6\overline{)4.50} \\ \underline{42} \\ 30 \\ \underline{30} \\ 0 \end{array} = 0.75$$

: Compared to the last example, this larger quotient indicates that the portion or fraction is larger. As the numerator comes closer and closer in value to the denominator, with little difference, the fractional value will approach (become nearer and nearer in value to) that of the whole or value of 1=100%. The closer this value is to 1, the fractional part in question becomes greater and nears the whole part. For this example, the part(s) in question could be said to be 0.75, or 75% of the whole (or entirety, entire) part. The portion of the whole part is 0.75.

Ex. $\frac{5.4}{6} = 0.9$: 0.9 is close in value to 1.0, and it indicates that 5.4 is a large part or portion of the whole (100% = 1) or entirety of 6 parts.

Ex. Of the following fractions, which fraction is larger, that is, which represents a larger value and hence a larger portion of the whole, all, or entire thing?

$\frac{2}{3}$ or $\frac{3}{5}$ after performing division to find their decimal equivalents we can often compare them more easily:

0.66666... and 0.60

Therefore, the part, portion or fraction of 2/3 is (slightly) larger than 3/5. 0.666666 > 0.60 and (2/3) > (3/5)

If the denominators of the fractions are the same (or mathematically made to be the same as done when adding fractions), you can then easily find the largest fraction simply by observing which numerator is the largest. Actually, one quick method of adding fractions is to first convert each of them to their decimal equivalents value, and then perform the addition. Though the addition of fractions has not been covered yet, here is the above example solved with the "addition of fractions with the same (or "like") denominator method" so as to find which fraction is larger:

$\frac{2}{3}$ and $\frac{3}{5}$ Converting each fraction to an equivalent (valued) fraction (numerically, it will still have the same value) where the denominators of both fractions are identical or the same:

$\frac{2(5)}{15}$ and $\frac{3(3)}{15}$: both denominators changed to 15, hence the fractions can be visually compared easily

$\frac{10}{15}$ and $\frac{9}{15}$: Note 2/3 = 10/15 = 0.66666... and 3/5 = 9/15 = 0.6
These are the same values as shown above, and this is because these new fractions created from or using each are (mathematically, in value) equivalent fractions. It is also incorrect to think that a fraction can only have one equivalent fraction associated with it since there is actually an infinite number of equivalent fractions possible for any fraction or portion of the whole (1).

Now by just observing the two numerators in the fractions above, since 10 is obviously greater than 9, then 2/3 is the larger fraction.

Given any two fractions and knowing the process of converting each of those fractions to an equivalent valued fraction, and both with like denominators, observe that you can quickly see which is larger by what is called "cross multiplying" the numerators and denominators of the two fractions. For the give example, since (2)(5) = 10 is larger than (3)(3) = 9, and both of these values will have the same denominator (here 15 which is the product of both denominators), the fraction of 2/3 is therefore larger than the fraction of 3/5. Another method, perhaps not so obvious, to find which fraction is larger, is to subtract one fraction from the other. You can first convert both fractions to their decimal equivalent, or to fractions that have identical denominators so they can then be properly subtracted. Assuming both fractions are greater than 0, if the resulting value (the difference) is greater than 0, then that minuend fraction is larger than the subtrahend fraction.

This book tries to avoid the (weak, but practical) concept of "cross multiplying" because, it is often taught, accepted and-or taken for granted, without first knowing the mathematical verification as to why it can be used. The "just do this and you will have it" attitude, should in many cases, be unacceptable when you want to have a firm grasp or understanding of math and what you are doing with it, and so as to then understand more advanced concepts that are built upon the previous concepts.

The whole part, all, or the entirety of something can be thought of as, or represented by, a complete circle which can represent and be noted as equivalent to and expressed as any numeric value. Given a certain or specific fractional value of any entire value (entirety, all, whole), each part, portion, or fraction is numerically the same regardless of the specific whole or entire value being considered. For example, given a fraction of (1/3), or "one-third" of any value, (1/3) = 0.33333... =33.3% of that whole=1=100% value or circle. The actual numeric value corresponding to that indicated fractional value of (1/3) depends on what the whole value actually is. A portion or fraction of something is always less than the whole or complete value, however, the actual numeric value of that portion may be less than or greater than 1. For example, consider this:

Whole, all, entirety or complete value	Indicated fractional value.		Actual numeric value of the indicated (here, (1/3)) fractional value of the whole.
1.0	(1/3) of 1	=	1/3 = 0.33333... = whole part divided by 3 = (whole part)/3
1.5	(1/3) of 1.5	=	1.5/3 = 0.5 : an example showing that the "whole part or entirety, may not always be an integer or counting number value, and may be greater than 1

2	(1/3) of 2	= 2/3 = 0.66666...	: note that this is the same as having (1/3) and (1/3), or (1/3) + (1/3) which is (2/3) = ""two-thirds" when summed: (1/3) + (1/3) = (0.33333...) + (0.33333...) = 0.66666... = (2/3)
3	(1/3) of 3	= 3/3 = 1.0	
4	(1/3) of 4	= 4/3 = 1.3333...	: here we see that the actual "fractional value" or portion of 4 is actually larger than 1
5	(1/3) of 5	= 5/3 = 1.66666...	
6	(1/3) of 6	= 6/3 = 2.0 = 2 parts of 6 , which can be expressed as: 2/6 = 1/3 2 parts of 6 equals 1 part of 3 = 0.33333**...**	

MIXED NUMBERS

A "mixed number" is an expression of a numerical value that (explicitly) indicates both the number of complete or whole parts (hence a multiple of a whole, completes or entirety), and a fraction value that expresses the parts or portion of just one whole value.

mixed number = whole part + fractional part

Mixed numbers are often found in food recipes, such as for example, to indicate "two and a half cups of flour" or= "two cups plus a half of a cup", and the numeric representation of this using a mixed number method is:

2 1/2 cups of flour, or perhaps just as: 2 1/2 cups flour : 2 is the whole number of filled or complete cups or cup units, and 1/2 is a fraction of 1 cup full.

If the decimal value of a fraction is less than one, the fraction is said to be a proper fraction. When the numerator is larger in value than the denominator of a fraction, the fraction is said to be an improper fraction since it represents a value greater than one, (1), since at the fundamental level, fractional numerical values are usually meant as, or understood to be less than the whole, or 100% of something = 1 numerically. A fraction is (usually) meant to be only a (smaller) part or portion of something. A mixed number has both a whole part and a fractional part, hence it has a mix or several values.

First consider values such as 0.1 and 0.95. Any value that numerically represents a part that is less than the whole (entirety, all, 100% = 1.0) is only a fractional value, part or fraction. 10 by itself is not, or does not represent, a fractional part, however when you (only) have 10 of 100 entire things, which can be expressed numerically as 10/100, that value of 10 is now only a fraction or part of the whole (considered as 1=100%) or entire 100 things. Expressing this in the most basic decimal form, we see that 10/100 = 0.10, which clearly is less than 1, and hence it is only a fractional part of the whole. It can be said that "10 is (only) a fractional part of 100".

Ex. $\frac{9}{4} = 2$ with a remainder (of the dividend) of 1 : 9/4 is an improper fraction

Expressing the above quotient, of the indicated division, as a mixed number (containing both a whole value and a fractional value of the divisor), this is written as:

$2\,\frac{1}{4}$ which actually means: $2 + \frac{1}{4}$:"two and one fourths". This is a mixed number. 2 is the whole part, and 1/4 is the fractional part. The addition of both parts, is not always explicitly indicated and is "understood" as being so.

That is, 2 is not being multiplied, but added to $\frac{1}{4}$: If 2 was being multiplied to 1/4, the multiplication would have to be explicitly indicated such as: 2(1/4), or = (2)(1/4), or = 2 x (1/4)

Also note that when division is performed on the fractional part of a mixed number, we get the decimal equivalent of the mixed number. The value will also equal the improper fraction:

$\frac{9}{4} = 2\,\frac{1}{4} = 2 + \frac{1}{4} = 2 + 0.25 = 2.25$: 2.25 is like a "mixed number" that contains a whole part and a fractional part.

Now that improper fractions can be converted to mixed numbers, mixed numbers can also be converted back to improper fractions. To do this, multiply the whole number part of the mixed number by the denominator of the fractional part of the mixed number, and then add the resulting product to the numerator of the fractional part of the mixed number. The resulting sum is a numerator of a fraction whose denominator is the same as used for the fractional part of the mixed number.

Ex. $3\frac{2}{4} = \frac{(3 \times 4) + 2}{4} = \frac{12 + 2}{4} = \frac{14}{4}$

The conversion process shown above is actually a "short-hand" method of adding fractions correctly of which could verify or check the method and example shown above. For the last example, the fractions to be added, and their sum, would be:

$$\frac{3}{1} + \frac{2}{4} = \frac{14}{4}$$

Hence, a mixed number represents an expression that is the sum of the number of whole (or entire) parts, and fractional parts. Note that 3/1=3. Any value can be divided by or "placed over" or divided by one, and the value will not be changed. But as mentioned previously, the fractions cannot be summed (added or "combined") until their denominators are equivalent. When the denominators of the fractions are the same, the fractions are said to have like or common denominators, and this is much like that which is necessary when adding things such as measurements that need to have the same units (of measurement or reference) so as to produce a result having those same units. Fractions with the same denominators can be said to be "like fractions". More on the addition of fractions will be shown later.

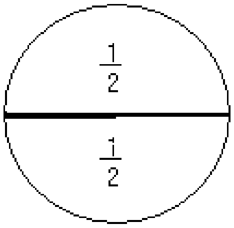
As another check to the above example, first consider that any value divided by itself it 1: (3/3) = 1

$$3 + \frac{2}{4} = (1 + 1 + 1) + \frac{2}{4} = \left(\frac{4}{4} + \frac{4}{4} + \frac{4}{4}\right) + \frac{2}{4} = \frac{12}{4} + \frac{2}{4} = \frac{12 + 2}{4} = \frac{14}{4} = 3.5$$

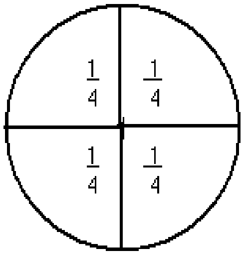
Note also, and previously discussed, that: $3 + \frac{2}{4} = \frac{(3 \times 4) + 2}{4} = \frac{14}{4} = 3.5$

EQUIVALENT FRACTIONS

If you divide a given circle into two equal parts that are the same size or portion, say an upper and lower half, each part is said to be one-half, or numerically as (1/2), of the entire 1 circle. Each part and fraction that numerically represents these parts are equal and therefore they are called equivalent fractions. Here, each part is numerically: (1/2). [FIG 5]



The 1 in the numerator position of the fraction represents one part in question or being considered, and the 2 in the denominator position indicates that the whole (here a circle) was divided into 2 equal parts. If you divide a whole (1) circle into 4 equal parts, each part is said to be one-fourth of that whole (1) circle. Numerically, each part is: (1/4). [FIG 6]



Clearly, by observation, two parts (one-fourth and one-fourth, or= two-fourths) of the circle that was divided into 4 equal parts is equivalent to the portion of one part (here, one-half) of the circle that was divided into 2 equal parts. Numerically, that is:

$\frac{2}{4} = \frac{1}{2}$: both fractions are equal in value, here it's 0.5 .
: "2 is to 4, as is 1 is to 2"

Each fraction has a value of 0.5 which means its portion is 50% of the (entire 100%) circle. Each part is half (= 1/2) of the circle, and even if the circles are of different sizes, because the portions of the circle(s) being referred to are mathematically the same fractional value of 1 circle, regardless of its actual size. A portion or percentage value is a basic generalization that is in reference to any whole or entirety regardless of its actual specific sizes or values involved. Equivalent fractions represent the same portion or fraction of something.

2/4 comes from the fact that there is 2 parts in question of the circle that was divided into 4 equal parts. Actually,
1/4 + 1/4 or (1/4) x 2 = 2/4 = 0.5 of 1 = (0.5)1 = 0.5 Also: (1/4) + (1/4) = 0.25 + 0.25 = 0.5

The fractions of 2/4 and 1/2 are said to be equivalent fractions since they represent the same quantity or value (here it's half or 0.5 of the circle, hence the same portion). The fraction of 2/4 has larger values for both the numerator and denominator, and it is said to be of "higher terms", that is, it has a higher numerator and denominator. Likewise, the fraction of 1/2 is said to be of "lower terms" since its numerator and denominator are lower in value than the other fraction. Still, the numerical values of both fractions represent an equal part of the circle. Actually, to make any equivalent fraction, simply multiply or divide both the numerator and denominator of a fraction by the same value. For example, a quick and simple way to find the next higher term equivalent fraction of 2/4 can be found by multiplying the numerator and denominator by the same value, such as for example, 2:

$$\frac{2}{4} = \frac{2 \times 2}{4 \times 2} = \frac{2(2)}{4(2)} = \frac{4}{8}$$

hence, $\frac{4}{8} = \frac{2}{4} = \frac{1}{2}$: = 0.5 , equivalent fractions, each represents 0.5 of the whole (1)

Given these numeric values, it can be said that 4 parts of a circle divided into 8 equal parts represents the same portion of a circle as 2 parts of a circle that was divided into 4 equal parts.

The fraction of 1/2 for the group of all possible equivalent fractions shown is said to be the fraction with the lowest terms. Also for this fraction of 1/2, since both the numerator and denominator cannot be evenly divided by any whole number greater than or equal to one, it is in lowest possible terms of all other equivalent fractions.

As a simple verification that they are equivalent fractions, consider that multiplying any value (including fractional values also) by 1 will not change that value. If any fraction is multiplied by say (2/2)=1, that is, the numerator and denominator are both multiplied by the same value, it is equivalent to multiplying by 1, and we know that multiplying any value by 1 does not change that value.

since $\frac{2}{2} = 1 = \frac{1}{1}$, multiplying this to any value, the value will not change:

$\frac{2}{4} = \frac{2\ (2)}{4\ (2)} = \frac{4}{8}$: the fractions look different (in the numerators and denominators), but they are numerically equivalent in value, here it's 0.5

Reversing this process, if we divide the same value from both the numerator (num.) and denominator (den.), the resulting fraction is still an equivalent fraction. For example:

$\frac{2}{4} = \frac{2/2}{4/2} = \dfrac{\frac{2}{2}}{\frac{4}{2}} = \frac{1}{2}$: after simplifying the num. and den. fractions

Again, a way to show or verify that these are equivalent (equal) fractions (of the whole) is to convert (represent) each to its decimal form by performing the indicated division.

$\frac{4}{8} = 0.5$, $\frac{2}{4} = 0.5$, $\frac{1}{2} = 0.5$:The fractions must be equivalent since each represents a value of (0.5).

Ex. Show that 2.00564 / 7 and 114.32148 / 399 are equivalent fractions or portions.

By using a calculator to perform the indicated division so as to find their quotient values:

$\frac{2.00564}{7} = 0.28652$ and $\frac{114.32148}{399} = 0.28652$: they are shown to be equivalent fractions numerically Each fraction represents a portion or total (sum of portions) that is about 28.7% of the whole (100%) or entirety.

There is another, less used method to create equivalent fractions described in the BASIC ALGEBRA section of this book.

Sometimes it could be helpful to express a given fraction as an equivalent part or fraction of 1, or as an equivalent fraction of 1 part out of a total number of parts. Doing this can give a basic grasp of the fraction when expressed as a single (1) portion of all the portions, or as a portion of 1.

Ex. 0.5 to 7 $= \frac{0.5}{7}$: 0.5 parts out of 7 parts $= 0.0714\underline{3}$ when expressed as a single decimal value

Equivalent fractions are usually solved by finding the multiplier needed to apply to both the num. and den., but since a value of 1 is used as a value in the equivalent traction being created, it become easier to complete that equivalent fraction.

0.5 is to 7, as 1 is to what? $\frac{0.5}{7} = \frac{1}{x}$: here, x is used in place of the word: "what"

Notice that if you divide the numerator here, by itself, that the result is 1. To keep the fraction the same value, this must also be done to the denominator:

$\frac{0.5}{7} = \frac{(0.5 / 0.5)}{(7 / 0.5)} = \frac{1}{14}$: 0.5 parts out of 7 parts can be numerically expressed as 1 part out of 14, or 1 part of 14

OR:

0.5 is to 7, as what is to 1? $\frac{0.5}{7} = \frac{x}{1}$

In a similar manner to the above, if we divide the denominator by itself, we will have a value of 1, and to keep the fraction as having the same value, we must do the same to the numerator:

$\frac{0.5}{7} = \frac{(0.5/7)}{(7/7)} = \frac{0.07143}{1}$: 0.5 parts out of 7 parts can be expressed as $0.0714\underline{3}$ parts to 1
: This is essentially the same result of simply dividing the num. by the den.

Ex. If a fast runner can run 1 mile in 4 minutes, how many miles an hour did they, or could they potentially run?

First, so as to have like units in the denominators, lets convert the units of hours to minutes:
1 hour = 1 hr = 60 min

$\frac{1\text{ mi}}{4\text{ min}} = \frac{x\text{ mi}}{60\text{ min}}$, since: 60 min / 4 min = 15, and also multiplying the numerator by this value:

$x\text{ mi} = (1\text{mi})(15) = 15\text{mi}$

1 mile per 4 minutes = 15 mi per 60 minutes = 15 mi / 60 min = 15 mi / 1 hour = 15 mi / hour

Another way is to mathematically solve for x mi:

$$x\text{ mi} = \frac{(1\text{mi})(60\text{ min})}{(4\text{ min})} = \frac{(1\text{mi})(\overset{15}{\cancel{60\text{ min}}})}{\underset{1}{\cancel{(4\text{ min})}}} = (1\text{mi})(15) = 15\text{ mi}$$

Ex. A basic and "generalized" (with non-specific units) recipe for hard candy is shown below. It also shows how to make an "equivalent proportions" recipe so as to make a bigger or smaller batch (amount, quantity) of the candy. Even though a batch can be a different size, weight or volume, the percentage, portion or fraction of each ingredient in the new batch will still be the same percentage, portion or fraction as that of each ingredient in the original recipe. It is sometimes noted that since the ingredient amounts used in a new sized batch are the same portion as that used in the original recipe, that the new batch and ingredients are said as being "proportional" (same portions, or "within proportion(s)") to the original recipe and-or batch. This ensures that the new sized batch will still taste the same as that of the original recipe and-or batch.

Main Ingredients: 2 units sugar : here "units" could be cups, or some other possible container
3/4 units corn syrup : 3/4 = 0.75 units used for the measurement(s)
2/3 units water
Other Ingredients: A few drops of flavor oil, and a few drops food color.

Mix the main ingredients in a bowl and then pour the mixed ingredients into a cooking pot. Cook (without stirring) till all the water is evaporated and to a temperature of 300°. Do not let the mixture turn dark yellow-brown and burn. Remove from heat, mix in flavor and color. Pour mixture onto a greased cookie sheet and let it cool. For the purpose of this mathematical example, the actual units of cups for the main ingredients is not explicitly indicated since you should use or expect any possible units for these measurements; perhaps you'll have some homemade units of and for your measurements such as: a jar, or spoon full, etc. Let's say you want to make a a different quantity (more or less) of candy. To do so, you need to adjust all the measurements (amounts of units used) for each ingredient equally by the same (magnification) factor value. Let's say you also want to make a more basic or general ("generalized") recipe so as to make batches of any quantity of candy that is based on a (1) unit of sugar, then for each additional unit of sugar added in, you will simply add in the new "general recipe's" measurement for all the other ingredients. Since there are 2 units of sugar used in the original recipe, you can divide these 2 units by 2 to have a recipe based on just using 1 unit of sugar. To keep the same ratio (ie. relative size amts.), or numerical proportions (consistent portions) of the amounts used for the ingredients in the recipe, you must then also divide all the other ingredient measurements by the same value, here, 2, and this will ensure that they are, and have, the same proportion (proper (same) and consistent fractional or portion value) as that of the original recipe, and that the ratios (essentially the quotient value of their division) of each two ingredients amounts is the same as that of the original Even though the specific quantity of an ingredient is now more or less, it is still numerically the same recipe. fractional or portion value as that of the original recipe. Expressing the basic concept of this mathematically:

$$\frac{\text{units of ingredient A}}{\text{units of ingredient B}} = \frac{\frac{\text{units of ingredient A}}{2}}{\frac{\text{units of ingredient B}}{2}}$$

: still has the same ratio value among , of, or
between these two amounts of ingredients.
Essentially created an equivalent fraction.
Divide the amount of all ingredients by 2.

The ratios, or relative (relational) sizes of one ingredient value to another, will still be the same as that in the original recipe. The total mixture or completed item being made, here candy, will also be divided in half since all of its parts (quantities) were divided in half, or vice-versa.

Dividing 3/4 by 2 we have 3/8 (division of fractions will be explained later), and dividing 2/3 by 2 we have 2/6 = 1/3, and the main ingredients and measurements of the new generalized recipe will become:

Main Ingredients: 1 units sugar For each 1 unit of sugar used, use:
3/8 units corn syrup : 3/8 = 0.375 units which is half of 0.75 = 3/4 units
1/3 units water

Since 1/2 = 0.50, you could have multiplied each ingredient amount by 0.50 instead of multiplying by 1/2 which is also equivalent to dividing by 2 as seen above. For some extra verification of all this, consider:

$$\frac{3}{4} \times \frac{1}{2} = \frac{(3)(1)}{(4)(2)} = \frac{3}{8}$$

: note that 3/4 and 3/8 are not equivalent fractions since the numerator and denominator were multiplied by different values.

$$0.75 \times 0.5 = 0.375$$ also:

If we divide a fraction, say 3/4, by 2 (same as 2/1), it is the same as multiplying both the entire new num. and den. by (1/2) as seen below. This procedure also shows why they are no longer equivalent fractions, since then num. (3), and den. (4) of 3/4 will not actually be multiplied by the same value. In short, dividing or multiplying a fraction by a value does not create an equivalent fraction, however, dividing both the num. and den. of a fraction by the same value does. For example if we have 4/8 = 0.5, and multiply this fraction by 2 or doubling (adding itself) it, we have (4/8)(2/1) = 8/8 = 1 which indicates that this is not an equivalent fraction (0.5 and 1 are not equal) but it is a magnification (ie. growth) of the fraction to where it does not represent the same part of the whole any longer, and is a completely new (different) fractional part or value.

same as multiplying the entire num. and den. by 0.5 = 1/2

$$\frac{\frac{3}{4}}{\frac{2}{1}} = \frac{\frac{3}{4}\;\frac{(1)}{(2)}}{\frac{2}{1}\;\frac{(1)}{(2)}} = \frac{\frac{3}{8}}{\frac{2}{2}} = \frac{\frac{3}{8}}{1} = \frac{3}{8} \qquad : \; = 0.375$$

Checking (note that 3/4 = 0.75):

$$\frac{0.75}{2} = 0.375$$

: as seen above, 3/4 = 0.75, and 3/8 = 0.375 are not equivalent fractions

We also see above, that a quick way to divide one fraction by another is to simply invert ("turn upside down") the denominator fraction and then simply multiply both the numerator and denominator by this value. Here, 2/1 inverted is 1/2. As another example, if you were to divide a fraction by 5/6, you could simply multiply both the num. and dem. of that fraction by 6/5 for the resulting quotient value. This process is also a good way to "clear" or "rid" the fractions, where possible, during a simplification (of an expression) process so as to have just one value (the quotient) to continue working with.

For completeness of the new recipe, note also that (2/3)unit / 2 = 2/6 unit. Dividing this num. and den. by 2, we have 1/3 unit , such as 1/3 of a cup, and which is usually easier to understand and measure in the kitchen, than 2/6 units or "two - sixths" of a cup.

When two or more things are said as being linear in value, they are also said as being proportional in value. That is, when one thing increase by some factor, the other thing will increase by the same rate or factor, and this is much like a magnification and-or a demagnification. This is also very much like an equivalent fraction concept, and can be solved as such. This book will sometimes mention that things such as this can be solved using a "proportional equation" or "equivalent fraction equation". Expressing all this in a pseudo-mathematical analysis and expression for when thing1 and thing2 are said as being proportional, or linear in value(s) and-or magnifications:

$$\frac{\text{thing1}}{\text{thing2}} = \mathbf{n} = \text{magnification}$$

, mathematically: thing1 = (n) thing2
and: thing1 / n = thing2

, $$\frac{\text{thing1}\ (\text{factor1})}{\text{thing2}\ (\text{factor1})} = \frac{\text{thing1magnified}}{\text{thing2magnified}} = \mathbf{n}$$

[This space for book edits.]

ADDING FRACTIONS

Adding fractions is not as difficult as you might think. Actually, we can think that we have always been working with fractions when we were just using whole values. For example, we know that 4+3=7, but we also know that we can make fractions by placing these values over one, which we know will not change their values.

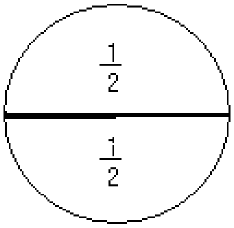
$4 + 3 = \frac{4}{1} + \frac{3}{1} = \frac{7}{1} = 7$: Add the numerators (the 4, and 3) of fractions with like denominators, and keep the denominator. The like denominators here are 1.

Checking:

$4 + 3 = \frac{(4 + 3)}{1} = \frac{7}{1} = 7$: checks

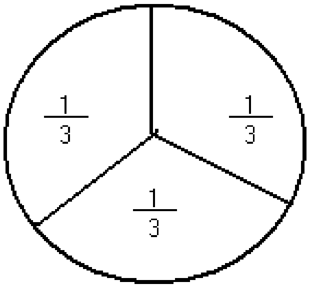
This leads to a general rule for combining (adding) fractions: Add the numerators of fractions with like, same or common denominators, and keep that same denominator. This is commonly known as the process of "adding like fractions".

If a circle (or 1 whole circle) is divided into two equal (ie. evenly divided) parts, each and every single part will numerically be (1/2), and we know that the sum of these parts (all the fractions or fractional parts) should equal to one (the whole circle) or the entire value of which they were taken out from and are in reference to. Since the fractions in question have like denominators (here, 2 or "halfs"), which makes them "like-fractions", simply add the numerators and keep the (same) denominator. [FIG 7]

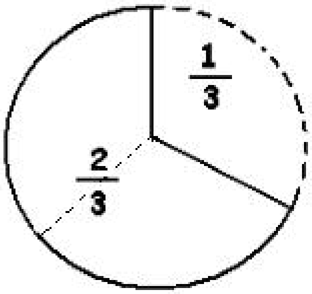


$\frac{1}{2} + \frac{1}{2} = \frac{(1 + 1)}{2} = \frac{2}{2} = 1$: A half (of a circle), plus another half, equals one (1) full circle.

If a circle or some quantity was evenly divided into 3 parts, each part is numerically (1/3). [FIG 8]



Summing up just two of those fractional parts or values, we have: [FIG 9]



$\frac{1}{3} + \frac{1}{3} = \frac{1 + 1}{3} = \frac{2}{3}$: "two thirds of a circle"

If we were to then add in one more of the parts, so as to have all 3 parts in the sum, we should then have one whole circle:

$\frac{2}{3} + \frac{1}{3} = \frac{2 + 1}{3} = \frac{3}{3} = 1$

As a check to this, expressing the sum of all three of the parts:

$\frac{1}{3} + \frac{1}{3} + \frac{1}{3} = \frac{1 + 1 + 1}{3} = \frac{3}{3} = 1$: checks

Also, expressing and performing the repeated addition above , with multiplication:

$\frac{1}{3} \times 3 = \left(\frac{1}{3}\right)\left(\frac{3}{1}\right) = \frac{(1)(3)}{(3)(1)} = \frac{3}{3} = 1$: checks

Ex. Add 4 tenths, 2 tenths, and 1 tenth

Notice that all the values have units of tenths. Hence, there is no "apples and oranges" problem with unlike units. Simply add the numerical values (or variables as in algebra) of quantities with like units for the sum, and keep the same units.

4 tenths + 2 tenths + 1 tenth = (4+2+1) tenths = 7 tenths

We can also do this problem using the addition of fractions method. Here, the fractions will be "like fractions" which have the common or like denominator of 10 or "tenths" (tenths of one) and therefore can be added.

First: 4 tenths = 1 tenth x 4 = 4 x 1 tenth = 4 (0.1) = 0.4

4 tenths $= \frac{1}{10} + \frac{1}{10} + \frac{1}{10} + \frac{1}{10} = 4\left(\frac{1}{(10)}\right) = \frac{4}{10} = 0.4$

And for the specific problem mentioned:

$\frac{4}{10} + \frac{2}{10} + \frac{1}{10} = \frac{(4+2+1)}{10} = \frac{7}{10}$: "seven tenths" , 7/10 = 0.7 as a basic decimal number.
A check by converting each fraction to its decimal value:

0.4 + 0.2 + 0.1 = 0.7 : "seven tenths of one (1)"

Ex. You have a certain recipe that you only want to make one-half of its resulting amount. How much of each ingredient or part must you then use to make that recipe?

Here is the original recipe:

amount_of_ingredient1 + amount_of_ingredient2 + amount_of_ingredient3 = resulting_recipe

If we divide the right hand side of the equation by 2, so as to make half of the resulting_recipe, the equation will be unbalanced. If we have done nothing to the amount of the ingredients used, surely the resulting_recipe will still be the same, and yet we would be expecting half the results. What we need to do is divide both side of this equation by the same value of 2 so as this equation, recipe or formula, is still correct and in balance or equivalence (equivalent, equal):

$$\frac{\text{amount\_of\_ingredient1} + \text{amount\_of\_ingredient2} + \text{amount\_of\_ingredient3}}{2} = \frac{\text{resulting\_recipe}}{2}$$

Now, what exactly is the sum of all the ingredients combined divided by 2? The sum, of all the ingredients or parts of the result, divided by 2 is equal to the sum of the amount of each ingredient or part divided by 2:

$$\frac{\text{amount\_of\_ingredient 1}}{2} + \frac{\text{amount\_of\_ingredient2}}{2} + \frac{\text{amount\_of\_ingredient3}}{2} = \text{resulting\_recipe}$$

Since $\frac{1}{2} = 0.5$, you can optionally multiply the amount of each ingredient by 0.5.

In simple words, the above can be described as: To make half the recipe, use half of all the ingredients, and therefore half of each individual ingredient. To make a certain or specific fraction of the recipe, use the same fraction of the amount of each ingredient.

Ex. If amount_of_ingredient1 is 1 cup: 1 cup , and to make half the amount of the original recipe, use:

$$\frac{1\text{cup}}{2} = \frac{1}{2}\text{ cup} = \text{"one-half cup"} = 0.5\text{ cups}$$

Ex. If amount_of_ingredient2 is 7oz, and to make half (50% = 0.5 = 1/2) the amount of the original recipe, use::

$$\frac{7\text{ oz}}{2} = 3.5\text{ oz}$$

ADDING MONEY AS FRACTIONS, AND A SHORT DISCUSSION ABOUT PERCENTS

When adding fractions which do not have a common denominator among them, one (or several) of them must be converted into an equivalent fraction so that all the fractions will then have the same (common) denominator. For example, fourths (ex. 1/4) cannot be added to thirds (ex. 2/3) unless there is some conversion of one of these fractions into an equivalent valued fraction and which will have the same denominator as the other fraction.

Here is a practical illustration of why the denominators must be the same for the addition (and subtraction) of fractions, and it is very similar to the concept of having like units or quantities for proper addition:

Given a number of pennies and nickels, you can't add the number of pennies (which is a certain fraction of a dollar, actually one-hundredth = 1/100 = 0.01 of a (1) dollar = "1 cent" = "1 percent") and the number of nickels (which is another certain fraction of a dollar, actually one-twentieth = 1/20 = 0.05 of a (1) dollar) together to find out how many total (or the total monetary value of) pennies you have, or to find out how many total nickels you have. A nickel is a different coin and monetary value than a penny. Before adding nickels and pennies, you must first convert the number or quantity of pennies to an equivalent number of nickels, so as to express the sum in terms of nickels, or convert the number of nickels to an equivalent number of pennies, so as to express the sum in terms of pennies or cents.

For the conversions: 1 nickel = 5 pennies :the known basic conversion reference, or, after switching sides:
5 pennies = 1 nickel :as an extra note, since 5 pennies is the same monetary value as a nickel, or 0.05. It is sometimes said that "there are 5 pennies in a nickel". A penny is also a fraction of a nickel:
1 penny =1 cent = 1/5 nickel = "one-fifth of a nickel". If you divide both sides of the conversion expression by 5 you can verify this.

If given a (1) nickel, you can multiply it by 5 to find the corresponding number of pennies. If given twice (2) as many nickels, the total quantity of pennies will also be twice (2 times) as much:

1 nickel = 5 pennies : basic conversion facts expressed as an equation
1 nickels + 1 nickel = 5 pennies + 5 pennies since multiplication is repeated addition :
2 (1 nickels) = 2 (5 pennies) multiplying or distributing the multiplying value:
2 x 1nickels = 2 x 5 pennies
2 nickels = 10 pennies

And in general, if given some quantity (Q) or number of nickels, the total quantity of pennies will also therefore increase by that times as much:
From: 1 nickel = 5 pennies expressing the multi. of both sides by the same value, here Q:
Q (1 nickel) = Q (5 pennies) or:
(Q x 1) nickel = (Q x 5) pennies after some simplification:
Q nickels = Q x 5 pennies

This might be spoken as: "multiply the quantity or number of nickels by 5 to find the equivalent number of pennies", or "The quantity of pennies is 5 times more than the quantity of nickels". In a reverse type of manner, we now know that if given a quantity of pennies, we can divide it by 5 to find the corresponding number of nickels.

Ex. 10 pennies + 2 nickels : converting nickels to pennies , first, it is known that: 1 nickel = 5 pennies
10 pennies + 2 x 5 pennies
10 pennies + 10 pennies performing the indicated addition of similar things, simply add their
(10 + 10) pennies numerical quantities and keep the same units, and this is much like
20 pennies adding the numerical coefficients (ie. factors) of variables as in algebra. Algebra is basically symbolic math where text letters represent, or are "placeholders", for (known or unknown) numeric values of mathematical expressions.

Ex. 10 pennies + 2 nickels converting the number of pennies to its equivalent quantity of nickels, by dividing the number of pennies by 5:

(10 pennies / 5 pennies per nickel) + 2 nickels or:
(10 pennies/1) / (5 pennies/1 nickel) + 2 nickels or:

$$\frac{\frac{10\ \text{pennies}}{1}}{\frac{5\ \text{pennies}}{1\ \text{nickel}}} = \frac{\frac{10\ \cancel{\text{pennies}}}{1}\left(\frac{1\ \text{nickel}}{5\ \cancel{\text{pennies}}}\right)}{\frac{\cancel{5\ \text{pennies}}}{\cancel{1\ \text{nickel}}}\left(\frac{\cancel{1\ \text{nickel}}}{\cancel{5\ \text{pennies}}}\right)} = \frac{10\ \text{nickels}}{5} = 2\ \text{nickels}$$

: or can use: 10 pennies/5pennies = 2

2 nickels + 2 nickels performing the indicated addition:
(2 + 2) nickels : or (2 x 2) nickels , since 2 was added to itself twice and
4 nickels that multiplication can represent repeated addition

By using the fractional values (of a dollar) that a penny and nickel represent, and using letter Q for the quantity of each coin, we have expressions for the total monetary (in dollar units) values of a quantity of either pennies or nickels. Remember, multiplication is repeated addition. First, since each penny has a value of 0.01 of a dollar, for each next penny, add 0.01 to the total sum or monetary value. This repeated addition, can be represented and expressed with multiplication; here by Q which is the number or quantity of pennies, or nickels, and times it was added into the total sum:

Pennies	Nickels
$Q\left(\frac{1}{100}\right) = Q(0.01)$	$Q\left(\frac{1}{20}\right) = Q(0.05)$

If P was used to represent the Quantity of pennies, and N was used to represent the Quantity of nickels, the above could be expressed as:

Total pennies monetary value = P(0.01) and Total nickels monetary value = N(0.05)

For converting the monetary value of a quantity of nickels to the corresponding monetary value of pennies, we will multiply the corresponding monetary value of pennies by 5 since a nickel is defined as equivalent to the monetary value of 5 pennies = (0.01 x 5 = 0.05). Note that the fractional value of 1/100, or "one cent", of 1 dollar assigned to a penny coin is also assigned as the pennies monetary value of 1 dollar. The monetary value of a penny is often called a "cent", meaning one-hundredth of. The word percent mathematically means "per hundredths of", or "parts per hundredth of", for example 5 percent means 5 equal parts of something (considered as 1 whole or entirety) that was divided into 100 equal parts (each being 1/100), hence 5 one-hundredths = 1/100 + 1/100 + 1/100 + 1/100 + 1/100 = (5/1)(1/100) = 5/100 = 0.05 = 5% = "five percent". More will be said about this later in the topic of percents. Since a nickel is (monetarily) equal to 5 pennies, it therefore also represents the monetary value of 5 pennies which is 5 cents = 0.05 = 5/100 = "five hundredths of 1 dollar" = 1/20 of a dollar when 5/100 is reduced to a lower termed equivalent fraction. A nickel is 5/100 = 1/20 = one-twentieth of a dollar. Coins less than a dollar in monetary value are fractions of a (1) dollar's monetary value.

Converting the monetary value of a quantity (Q) of nickels to that of pennies.

Pennies		Nickels	
$(Q \times 5)\left(\frac{1}{100}\right)$	=	$Q\left(\frac{1}{20}\right)$	: here, we let Q equal the quantity of nickels Perhaps you might use N instead of Q as mentioned previously. Remember that multiplication is essentially repeated addition.
$Q \times 5\,(0.01)$	=	$Q\ (0.05)$	: or

$Q \times 0.05 \quad = \quad Q \times 0.05$: checks

Ex. Find the total monetary value of 2 nickels and 4 pennies.

2 nickels + 4 pennies

$2\left(\frac{1}{20}\right) + 4\left(\frac{1}{100}\right)$: denominators and not identical, and "unlike fractions" cannot be added or "combined". Can use: 2 (0.05) + 4 (0.01) = 0.10 + 0.04 = 0.14

$\frac{2}{20} + \frac{4}{100}$: denominators are not identical, so we have unlike fractions that cannot be easily added or combined as currently expressed so as to have just one fraction

Converting the monetary value of nickels to its' equivalent monetary value in pennies so that an addition (of fractions with a common, similar (same) or "like" denominator of 100) can take place, we have:

$2 \times \frac{5\,(1)}{5\,(20)} + \frac{4}{100}$: the numerator and denominator in the first fraction were both multiplied by 5 to create an equivalent (valued) fraction of which has a denominator value of 100.

$\left(\frac{2}{1}\right)\left(\frac{5}{100}\right) + \frac{4}{100}$

$\frac{10}{100} + \frac{4}{100}$: "ten-hundredths plus 4-hundredths" equals:
: We now have "like fractions" with the same denominators that can be added.

$\frac{14}{100} = 0.14$: "fourteen-hundredths" or= 14 cents

If you wanted to express a quantity of coins in terms (ie. with similar variables or units) of dimes (which is a certain fraction of a dollar, actually one-tenth = 1/10 = 0.10 of a dollar), you would have to convert the number of pennies and nickels to their corresponding number of dimes. Again, this is a common "apples and oranges" type of problem, except here, it is possible to make numeric conversions. Since 1 dime = 2 nickels = 10 pennies, divide the number of pennies by 10 to find the corresponding number of dimes, and divide the number of nickels by 2 to find the corresponding number of dimes.

Ex. 10 pennies + 4 nickels after dividing the quantity or number pennies by 10, and nickels by 2 for the conversion to it's (monetary) equivalent quantity of dimes:
1 dime + 2 dimes : we now have "like units" that can be combined
(1 + 2) dimes : expressing the sum of the quantities of the like or similar units
3 dimes : 3 dimes = 3 (tenths of 1 dollar) = 3 (0.10) = 3/10 = 0.30
This value can be spoken as: "thirty-hundredths" or "thirty-cents".

Also note in the above discussions, that when converting a quantity with larger units (of measurement) to a quantity with smaller units, that a multiplication is performed on the quantity with larger units. This is because there will be a greater quantity of these smaller units per each larger unit. For example, when converting (a quantity of) nickels to a corresponding number (or quantity) of pennies, multiply by 5, and when converting (a quantity of) miles to feet, multiply by 5280. Likewise, in a inverse type of manner, when converting to a larger units, a division is performed on the quantity that has the smaller units (of measurement or reference) since there will be a fewer quantity of the larger units.

Here is an extra side note of some **fractions of a quantity** that are given a unit-like name, that you may occasionally encounter: First, here are some common **fractions of a unit**: sixteenth = one-sixteenth of 1 inch = (1/16) in. and 1 centimeter = one-hundredth of a meter (1/100) meter. Similar to fractions of a unit are **multiples of a unit** given a unit-like name. For example, 1 ft x 3 = 3 feet = 1 yard , and (1000) (1m) = 1000 meters = 1 kilometer = 1 km

A simple example of the concepts: If there are 10 balls in a bag, and 9 are blue in color, and 1 is yellow in color, it can be said that the number of yellow balls in this bag of balls is 1 part of 10 parts. Mathematically 1 out of 10 is: 1 / 10 = one-tenth = 0.1 = 10%. The number of blue balls in the bag is 9 parts in or of 10 total parts = 9 / 10 = 0.90 = 90%

Ex. What is ppm and ppb? **ppm** = **parts per million parts of something** = parts / 1,000,000 parts
1ppm is numerically: 1part / 1,000,000parts = 0.000,000,1
10,000 ppm = 10000 parts / 1000000 parts = 0.01 = 1%

For example, and a discussion of the example:

Seawater is about 10560 ppm sodium = ~ 1% , and about 19000 ppm chloride = ~ 2%
Seawater is often mentioned as being 3% salt. **(food or edible) Salt is sodium-chloride (NaCl) molecules** and is commonly known as table salt that we can put on foods to enhance their flavors if need be. The scientific and-or chemical formula for a water molecule is H201 = **H20** since it has 2 atoms of hydrogen and 1 atom of oxygen. Seawater or ocean water is sometimes said as being about 35 **parts per thousand (ppt)**, hence 35 parts / 1000 parts = 0.035 = 3.5% salt (sodium-chloride,table salt). Note that if the total parts was 1000 cc, this value is equivalent to 1 Liter = 1 L of volume, and 3.5% would correspond to 3.5cc of volume.
1000cc of water has a mass of 1000 grams = 1000g
A thin depth of seawater can be evaporated (ex., in the sunlight and heat) so as to obtain its dissolved minerals such as salt which is considered a necessary nutrient to the human body.

Salt, and here specifically as sodium-chloride, is also a vital nutrient for some body processes. The recommended daily amount of salt for a moderately active adult of average size and-or weight is about but about 2000 mg = 2g of sodium which can be obtained from 5 to 6 grams of table salt, about 1 level teaspoon (about 5 mL= 5cc in volume) , of table salt has about 2000 mg = 2g of sodium and 3000 mg = 3g of chloride.

Chloride (cl^- , a healthy ion form of the more dangerous chlorine atom) is also a vital nutrient for some body process. Sodium-chloride or common table salt is generally not found in plants, but chloride is due to that it is vital for the photosynthesis process so as to make food such as a carbohydrate [carbon and water, and water is hydrogen and oxygen] type of sugar. The sunlight energy will first splitting water molecules and releasing electrons for further chemical reactions to take place. An **ion** is a atom or molecule that is not neutral or balanced in charge, generally due to it loosing or gaining an electron(s).

Where does all the wood from a tree come from? Besides some minerals from the soil, its generally not much mass from the soil, but it comes from the carbon dioxide in the air being converted to carbon during photosynthesis. A living plant has about 65% of its mass and-or weight as water, and has abut 15% of its mass as carbon. As the plant dries due to water evaporation, such as when becoming dried wood, that percentage will increase to about 50% of the mass and-or corresponding weight of that wood.

A (photo-voltaic, light energy to electrical energy) solarcell (or solar cell) that creates free electrons from the light energy from the Sun is like an electrical analogy of photosynthesis which plants do.

ppb = parts of something per billion parts of something = parts / 1,000,000,000 parts
ppt = **parts of something per thousand total parts of something**
ppt, ppm, ppb, can be considered as the number of parts of a certain mass and-or weight, or volume.

COMMON DENOMINATOR FOR ADDING FRACTIONS

The common, same or "like" denominator found for the proper addition of fractions will be some multiple (including 1) of the largest denominator value of all the fractions in question. Hence, the common denominator will be greater than or equal to the highest denominator value. It will be shown that a common denominator of two or more fractions can simply be the product of all their denominators, and that it is therefore evenly divisible by each of those denominators since it will contain a multiple of each denominator.

Ex. Add 1/4 and 4/8 : "add one-fourth, and four-eighths"

First, notice that the highest denominator value of these two fractions is 8, and that the fraction of 1/4 can be converted to an equivalent fraction of 2/8 if we multiply both the numerator and denominator by 2. Both fractions will then have the same denominator value and can be added as fractions:

$$\frac{1(2)}{4(2)} = \frac{2}{8}$$

We now have "like fractions" (with a common denominator) which can be added.

$$\frac{2}{8} + \frac{4}{8} = \frac{6}{8}$$

Note that this example may have been stated as: How many eighths are 1/4 and 4/8? The answer is six eighths.

For the two fractions being summed in the last example, the common denominator derived at from the two given and "unlike" denominators is called the lowest common denominator (sometimes and simply indicated as LCD, as in this book). The name comes from the fact that it is the lowest possible value for the common denominator that can be evenly divided by each denominator of the fractions in question. Note, if all the fractions to be summed are first reduced to their lowest or "simplest terms" (ie. Made into equivalent fractions - with a lower numerator and denominator) before the LCD is sought, that this resulting LCD of those equivalent fractions may even be lower in value.

If the numerator and denominator, each being considered as a product value, have factors that are common to both, then the fraction can be reduced or changed to an equivalent fraction of lower terms by dividing out, or "canceling" (ie. removing) these common factors. If you divide both the numerator and denominator by the highest or greatest common factor of both the numerator and denominator, the fraction will be reduced to its lowest terms. Remember, this processes is allowed since the fractions will still be equivalent in value. The greatest common factor can be found as the product of the smallest power of each different prime factor of the two numbers; prime numbers will be discussed ahead. Whereas multiplying both the numerator and denominator creates a "magnified (increased)" equivalent fraction that is said to be of "higher terms (of both num. and den. values)", dividing both the numerator and denominator creates a "demagnified (decreased, reduced)" equivalent fraction of "lower terms (of both the num. and den. values").

Ex. For the fractions below, reduce each to an equivalent fraction of lowest terms before the addition.

$$\frac{2}{8} + \frac{4}{8} = \frac{6}{8}$$

The fraction of 2/8 can be reduced to lower terms by dividing both the numerator and denominator by 2. The value of 2 was chosen since it is the highest factor common to both the numerator and denominator. This is seen when the numerator and denominator of the fraction are first factored:

$\frac{2}{8} = \frac{(2)(1)}{(4)(2)}$: factored numerator and denominator, showing the common factor(s) of 2

Dividing both the numerator and denominator by the highest common factor of 2, or simply "cross canceling" (crossing out, to reduce and-or possibly eliminate to just a factor of 1) these factors with a line or hash mark. You can also write a small one near these values, indicating the result of a division, here by 2, and that the result was 1. After canceling common factors, the result in an equivalent fraction of lowest terms.

$$\frac{2}{8} = \frac{\frac{(2)}{(2)}}{\frac{(8)}{(2)}} = \frac{1}{4} \qquad : 2/2 = 1 \quad \text{and} \quad 8/2 = 4$$

or: $\frac{2}{8} = \frac{\cancel{(2)}(1)}{(4)\cancel{(2)}} = \frac{1}{4}$: showing the "cross canceling", "canceling out" or "dividing out". Also,
: remember that 2/2 = 1 and anything times 1 is that same value. A multiplier or factor of 1 need not be shown always, but it can always be implied and-or removed so as to simplify equations as much as possible.

Likewise, for the fraction of 4/8:

$\frac{4}{8} = \frac{\cancel{(4)}(1)}{\cancel{(4)}(2)}$: showing the factoring of both the numerator and denominator, and the highest common factor of 4

Note that both the numerator and denominator also have a common factor of 2, but this is not the highest common factor since 4 is, and this will help create a fraction of lowest terms.

$$\frac{4}{8} = \frac{\frac{4}{4}}{\frac{8}{4}} = \frac{1}{2}$$

hence, $\frac{2}{4} + \frac{4}{8} = \frac{1}{4} + \frac{1}{2}$: results in an equivalent expression, after we reduced each fraction to lower terms.

After converting all the fractions to their corresponding equivalent fractions (with lower terms), their sum should still be equivalent to the sum of 6/8 as shown above. First consider that we need "like fractions" (have the same denominator) for proper summing:

$\frac{6}{8} = \frac{\frac{6}{2}}{\frac{8}{2}} = \frac{3}{4}$: "six-eights" reduced or expressed as "three-fourths".

Now, a common denominator possible between the two fractions is 4, which is also the LCD. By multiplying both the numerator and denominator of the fraction (1/2) by 2, we can get "like fractions" which have a common denominator for their addition.

$\frac{1}{4} + \frac{1}{2} = \frac{1}{4} + \frac{1(2)}{2(2)} = \frac{1}{4} + \frac{2}{4} = \frac{3}{4}$: which checks

As mentioned previously, the easiest way to find a common denominator when adding or subtracting fractions is to use the product of all the denominators. This new and common denominator will then contain a factor of each single denominator. This denominator is usually larger than the LCD possible. The LCD is more desirable since reducing the result to lowest terms is already or more easily done. A common way to start finding the LCD of all the fractions is to factor the denominators into prime factors. Prime numbers are discussed next as a helpful part of this current topic.

PRIME NUMBERS

Prime or primary numbers are numbers that cannot be evenly divided by any other (whole, integer or counting) number except itself and 1, in other words, a prime number being considered as a product or not, cannot be factored into two other factors that are whole numbers. For example, 2 is a prime number since it is only divisible by 2 (itself) and 1. 4 is not a prime number since it is evenly divisible by 2. 5 is a prime number. 6 is not a prime number since it has factors of 2 and 3. A composite number, such as 6, is composed of factors that are either composite and-or prime. The first 10, and perhaps the most commonly used prime numbers are:

1, 2, 3, 5, 7, 11, 13, 17, 19, 23 , . . .

Note that 2 is the only even prime number. An even number will have its most rightward digit being either: 0, 2, 4, 6, or 8, and the entire number is therefore divisible by 2, that is, the number can be divided in half or evenly into two identical whole or integer numbers. An odd number cannot be divided in half evenly and expressed as two identical integers. Any even number will contain 2 as one of its factors, hence even numbers other than 2 cannot be a prime or "unfactorable number". In terms of a (algebra) formula, 2n is an even number, and 2n + 1 and-or 2n - 1 is an odd number.

To factor (factorization, factorize) is where you are given a product value (perhaps a numerator or denominator as is the case of working with fractions) and you are to find its factors (multiplicands and multipliers) that compose or construct that given product value. You could say that these factors are "unseen" or "hidden" because they are now effectively "contained within", "composing", "making up", or "part of" that product value.

Some numbers or product values may have more than one set of possible factors, for example:

18 = 6 x 3 = 9 x 2

Some of these factors are composite numbers that can be factored further to only prime numbers. After doing this, we see that the given value (here 18) has only one corresponding and specific set of prime number factors:

18 = 6 x 3 = 9 x 2
18 = (3 x 2) x 3 = (3 x 3) x 2 by rearranging or regrouping we can see that they are the same value(s):
18 = 3 x 3 x 2 = 3 x 3 x 2 :18 completely factored to prime number factors, or simply: "primes"
: The different prime factors of 18 are 2 and 3.

Factoring a factor further can be considered and expressed mathematically as:

product = (factor1)(factor2) If anyone of these factors is considered as a product that can be factored, such as (factor2) which can be factored into (factor3) and (factor4):
product = (factor1)(factor3)(factor4) . . .

When adding or subtracting fractions: Considering all the completely factored (to "primes") denominators, each different valued prime factor is chosen only once, and specifically the highest multiple or power it occurs in a given denominator in the entire group of denominators, and these selected values are then multiplied together, and this product is the LCD of all the fractions.

Ex. Given the denominators of 4, 8 and 3, what would be the LCD?

The factors of 4 are 2 and 2, and both are prime. The factors of 8 are 4 and 2. 4 is not prime since it has factors of 2 and 2. Hence, the prime factors of 8, when completely factored to prime factors, are 2, 2 and 2. The factors of 3 are 3 and 1, hence it is already a prime number. The different prime factors are 2 and 3. The prime factor of 1 is always understood. Since 2 appears a maximum of three times in a single denominator, and 3 appears only once, the LCD is:

(2 x 2 x 2) x (3)
8 x 3
24 : 24 is the lowest common denominator (LDC) that each denominator can wholly ("evenly", entirely, completely) divided into without a remainder left over.

Again, notice that the highest power or multiple of each prime factor must be chosen so that each denominator, more specifically, the largest of the group, can (evenly) divide into the LCD at least once, and hence the LCD must be at least equal to or greater than the largest of the denominators.

One might now ask: Given a fraction, how is the numerator of an equivalent fraction found once the denominator (such as a common denominator for adding or subtracting fractions) of the equivalent fraction is found? The answer is found by dividing the "new" denominator by the "old" denominator. This effectively finds the multiplier (factor of the product) value that the "old" denominator was multiplied by to get the "new" denominator of the equivalent fraction. This is the case when the equivalent fraction being created is of higher terms. It is possible that a multiplier value can be less than one, such as is the case if the equivalent fraction is of lower terms. Once the multiplier is found, the same value must also be multiplied to the numerator so as to make an equivalent fraction that still represents the same numeric value, part or portion, that the original fraction does.

Ex. $\frac{2}{3} + \frac{1}{4}$

A common denominator to add these fractions is simply the product of those denominators.

$(3)(4) = 12$ substituting 12 for all the denominators of the equivalent fractions being created:

$\frac{\_\_}{12} + \frac{\_\_}{12}$ Now we are to find the proper or correct numerators of these equivalent fractions being created:

Since the first fraction's denominator was multiplied by 4 (from 12/3 = 4), we must also multiply the numerator of that fraction by 4 to keep it an equivalent fraction. Likewise, since the second fraction's denominator was multiplied by 3 (from 12/4 = 3), we must also multiply the numerator of that fraction by 3 to keep the fraction equivalent in value:

$\frac{2\,(4)}{3\,(4)} + \frac{1\,(3)}{4\,(3)}$ performing the indicated multiplications:

$\frac{8}{12} + \frac{3}{12} = \frac{11}{12}$: we have "like fractions" (have the same denominator), and can therefore be added, and keeping that same or common denominator

Ex. $\frac{10}{5 + 2} + \frac{4}{7 + 1}$

This is an example of adding or combining fractions where the denominators are actual expressions themselves. Notice that each denominator can easily be simplified first, but here, the order of operations will not be strictly followed in order to show another method. Frequently, there are times in algebra (where letters are used to represent unknown values or numbers yet to be found) where simplification is not preferred or possible. The fractions can still be combined (added) by considering each entire denominator expression as just like one single or unique value to work with:

$\frac{\text{numerator1}}{\text{denominator1}} + \frac{\text{numerator2}}{\text{denominator2}}$: expressing a generalized or "formula" form, here, of adding fractions

A common denominator, and the lowest common denominator if a denominator is not evenly factorable (divisible) or composite is simply the product of those denominators. The fractions are combined in exactly the same manner as the last example:

Here, a common denominator, expressed in a factored form, is: common denominator = (denominator1)(denominator2).

$$\frac{\text{numerator1 (denominator2)}}{\text{denominator1 (denominator2)}} + \frac{\text{numerator 2 (denominator1)}}{\text{denominator 2 (denominator1)}}$$: expressed as the sum of the equivalent fractions

When combining (adding) like fractions, add the numerators over the same denominator:

$$\frac{(\text{numerator1})(\text{denominator2}) + (\text{numerator2})(\text{denominator1})}{(\text{denominator1})(\text{denominator2})}$$

Using the example given:

$$\frac{10}{(5+2)} + \frac{4}{(7+1)}$$ creating equivalent (to each fraction given) and like denominator fractions: Using the product of (5+2) and (7+1) as a common denominator:

$$\frac{10 \quad (7+1)}{(5+2)(7+1)} + \frac{4 \quad (5+2)}{(7+1)(5+2)}$$ combining (adding) these like fractions we have:

$$\frac{10(7+1) + 4(5+2)}{(5+2)(7+1)}$$: a sum of several fractions, expressed as one fraction

Checking: $$\frac{10}{(5+2)} + \frac{4}{(7+1)} = \frac{10}{7} + \frac{4}{8} = 1.42857 + 0.5 = 1.92857$$:approximately

$$\frac{10(7+1) + 4(5+2)}{(5+2)(7+1)} = \frac{80 + 28}{(7)(8)} = \frac{108}{56} = 1.92857$$: checks

Sometimes when working with fractions, an equivalent fraction of (expressed as) lower terms or values of the given numerator or denominator must be created. To find out what the common divisor to both the numerator and denominator is, divide the "old" numerator or denominator by the corresponding "new" numerator or denominator. Note that the method indicated above for finding an equivalent higher term fraction will still work as a method for finding an equivalent lower term fraction. If that method is continued to be utilized, the effective multiplier will always be less than one.

Ex. $\frac{2}{3} = \frac{\_\_\_\_}{12}$:Create an equivalent fraction of higher terms (because the denominator of 12 of the fraction being created is higher than 3) by finding the numerator that correctly corresponds to this denominator so as the fractions are equivalent in value.

The "new" numerator to be found will also be higher. By dividing 12 by 3 we get the value of 4. Since the "old" denominator was essentially multiplied by 4 to get this "new" denominator. The "old" numerator must then also be multiplied by 4 to create the "new" numerator of the equivalent fraction:

$\frac{2}{3} = \frac{2(4)}{3(4)} = \frac{8}{12}$: It may help in the understanding of this by remembering that (4/4) = 1, and multiplying anything, such as a fraction or quotient, by 1 will not change its value, and here, the quotient or value of both (equivalent) fractions is the same: 2/3 = 8/12 = 0.666666... = about 67% of the whole or entirety (= 100% = 1).

Ex. $\frac{8}{20} = \frac{2}{}$

Here, the equivalent fraction being found will be of lower terms since the "new" numerator is less than the "old" numerator. 8 divided by 2 is 4 (that is, 2 and 4 are two factors of 8). Therefore, a factor of 4 was divided out of 8. To make an equivalent fraction, the same must also be done to the denominator.

$$\frac{8}{20} = \frac{\frac{8}{4}}{\frac{20}{4}} = \frac{\frac{2}{1}}{\frac{5}{1}} = \frac{2}{5}$$

hence, $\frac{8}{20} = \frac{2}{5}$: checking, after dividing the numerators by the denominators, both fractions equal 0.4

Here is the same example as above, but the method for finding an equivalent higher term fraction is utilized:

$\frac{8}{20} = \frac{2}{\ }$

Finding the effective multiplier of the numerator 8 that equals a product of 2: $\frac{2}{8} = 0.25$

Checking: $(8)(0.25) = 2$

Now multiplying this same value to the denominator to create the equivalent fraction: $20 \times 0.25 = 5$

Hence: $\frac{8}{20} = \frac{2}{5}$

The example above, for creating an equivalent fraction, can also be solved by the basic facts about division and multiplication:

$\frac{8}{20} = \frac{2}{\ }$ simplifying by performing the indicated division on the left side of this equation:

$0.4 = \frac{2}{\text{denominator}}$ Here we can consider 2 as the dividend of a division operation, and the factors of that dividend are equal to the quotient (here 0.4), and denominator or divisor (to be found).

From: $\frac{\text{dividend}}{\text{divisor}} = \text{quotient}$ we have:

dividend = divisor x quotient : the dividend as a product. Dividing a product by either of it's factors (the divisor or quotient) will yield the other corresponding factor of that product:

$\frac{\text{dividend}}{\text{quotient}} = \text{divisor} = \frac{2}{0.4} = 5 =$ the denominator being found of the equivalent fraction

ADDITION OF MIXED NUMBERS

When adding mixed numbers, you can first change them to (improper) fractions and then add those fractions. You can also add the whole (integer) parts, and then add this sum to the sum of the fractional parts. This is the common method taught, and this method produces another mixed number.

Ex. $5\frac{2}{3} + 2\frac{1}{4}$, This can also be expressed as: $\frac{5}{1} + \frac{2}{3} + \frac{2}{1} + \frac{1}{4}$

Using the first method discussed:

$5\frac{2}{3} + 2\frac{1}{4} = \frac{17}{3} + \frac{9}{4} = \frac{68}{12} + \frac{27}{12} = \frac{95}{12}$ or $= 7 + \frac{11}{12}$ when you divided 95 by 12, the result is 7 with a dividend remainder of 11

Note that for example: $5\frac{2}{3} = 5 + \frac{2}{3}$: "five and (+) two-thirds". Expressing 5 as a sum of 1's:

$1 + 1 + 1 + 1 + 1 + \frac{2}{3}$ since any number divided by itself equals 1, this can be expressed as this when considering the denominator value of 3, so as to make "like fractions", that have "like" denominators, which can then be added:

$\frac{3}{3} + \frac{3}{3} + \frac{3}{3} + \frac{3}{3} + \frac{3}{3} + \frac{2}{3}$ combining or adding the first 5 fractions:

$\frac{15}{3} + \frac{2}{3} = \frac{17}{3}$: after combining these two fractions, and : this fraction was indicated above

Using the second method discussed:

$$\begin{array}{r} 5\ \frac{2}{3} \\ +\ 2\ \frac{1}{4} \\ \hline \end{array}$$

OR :

$$\begin{array}{rl} 5\ \frac{2}{3} & = \frac{8}{12} \\ +\ 2\ \frac{1}{4} & = \frac{3}{12} \\ \hline \end{array}$$

$(5+2) + \left(\frac{2}{3} + \frac{1}{4}\right)$: horizontally

$7 \quad \frac{11}{12}$: vertically

$7 + \left(\frac{8}{12} + \frac{3}{12}\right)$

$7 + \frac{11}{12}$ or simply : $7\frac{11}{12}$: checks

Another way to add (or subtract) improper fractions is to convert the fractional parts to their decimal equivalents. This was also mentioned previously.

Ex. $5\frac{2}{3} + 2\frac{1}{4}$

```
first,       0.66             0.25
          3| 2.00         4| 1.00
             18               8
              20             20
              18             20
               2              0
```

Note that 2/3 produces a repeating decimal. You may "round-off" (truncate or shorten) the quotient where needed.

$$5\frac{2}{3} + 2\frac{1}{4} = (5 + 0.66..) + (2 + 0.25) = 5.66 + 2.25$$

```
     1
   5.66              basic format is:       whole . fractional
+  2.25                                 +   whole . fractional
   7.91                                     whole . fractional
                                                 sum
```

Comparing this to the previous example: $7\frac{11}{12}$

```
           0.916
7  +  12| 11.000          ~  7.91 (not rounded)  ,   ~ means about or approximately equal to the following value.
          108              Note also that 11/12 also produces a repeating decimal as seen above.
             20
             12
              80
              72
               8
```

SUBTRACTION OF FRACTIONS

The rules and concepts regarding basic addition and subtraction, and for the addition of fractions, also hold true for the subtraction of fractions. The main issue is to have like denominators so the subtraction of fractions can take place.

Ex. You have 1 whole circle divided into 3 parts, hence each part is a fraction of that circle and has the numeric value or representation of (1/3). The sum of all of these 3 parts is therefore: (1/3) + (1/3) + (1/3) = 3 (1/3) = 3/3 = "three thirds" = 1. If you take away (ie. remove or subtract) one of these parts, what value will remain of the entire circle?

$\frac{3}{3} - \frac{1}{3} = \frac{(3-1)}{3} = \frac{2}{3}$: "two-thirds" of the circle remains

Below is an example using mixed numbers, and then a discussion about the procedure will follow.

Ex. Subtract 2 6/7 from 3 5/7

$$\begin{array}{r} 3\,\frac{5}{7} \\ -\ 2\,\frac{6}{7} \\ \hline \end{array} \quad = \quad \begin{array}{r} \overset{2}{\cancel{3}} + \left(\frac{7}{7} + \frac{5}{7}\right) \\ -\ 2 + \frac{6}{7} \qquad\quad \\ \hline \end{array} \quad = \quad \begin{array}{r} 2\,\frac{12}{7} \\ -\ 2\,\frac{6}{7} \\ \hline 0 + \frac{6}{7} = \frac{6}{7} \end{array}$$

Considering the fractional parts of the mixed numbers, 6 cannot be taken from 5, hence we need to borrow. One might ask: where did the 7/7 come from? The answer is that borrowing 1 from the 3 is essentially borrowing 7/7 since 7/7=1. The denominator of 7 was chosen since the other fraction used in the subtraction operation also has a denominator of 7. This makes subtracting (or adding) the fractions easy since they will all have common or "like" denominators.

Ex. $\frac{10}{3} - \frac{4}{7}$

We must first find a common denominator for the subtraction. It is usually best to find the LCD. Here, the LCD has a value of 21 since 3 and 7 are both prime and they can simply be multiplied together. Now convert each of the fractions to equivalent fractions that have the same denominator of 21 :

$\frac{10}{3} = \frac{70}{21}$ since 21/3 = 7 , and then $\frac{10(7)}{3(7)} = \frac{70}{21}$

$\frac{4}{7} = \frac{12}{21}$ since $\frac{4(3)}{7(3)} = \frac{12}{21}$

$\frac{70}{21} - \frac{12}{21} = \frac{58}{21}$: Since both of these operands were expressed in a fractional form, the result is arbitrarily expressed in a fractional form rather than as a mixed number.

As a mixed number:

$\frac{58}{21} = 2\,\frac{16}{21}$: after performing the indicated division of: 58/21 and expressing the result as a mixed number. Remember that you can check a subtraction problem by using addition.

DECIMAL VALUES AND FRACTIONS

The basic way to change a decimal value that is less than 1 to its equivalent fractional value is to first find the positional weight of the least significant digit, and then remove the decimal point and make a product of this value and weight. From the discussion of positional weights, this weight will be a power of 10 with a negative (basically, conceivable numbers that are less than 0) number as the exponent. More advanced mathematics (besides what has already been discussed in this book, and that which will be shown ahead) will show that multiplying by a value with a negative exponent is actually dividing by that value with a regular (positive, even if it's not explicitly indicated) exponent of the same value.

Ex. $0.5 = 5(10\text{^}{-1}) = \frac{5}{10\text{^}1} = \frac{5}{10}$: "five-tenths of one". Note that the last or "least significant" digit, the 5, is located in the "tenths" position.

Note that 0.5 was made larger to a value 5, so it should be clear, as seen above, that to equal the original value (here 0.5), a division would then be necessary to reduce it to it's original value. We also know that a division by 10 will essentially moves the decimal point one position to the left toward the more significant digits.

Checking by performing the indicated division:

```
      0.5_
 10 | 5.0
      5 0
        0
```

You may also consider the decimal point being moved leftward in any value without using division, for example:

$5 = 0.5\,(10^1) = 0.5\,(10)$: one place leftward , and the indicated exponent of 10 is 1, and 10 has 1 zero
$0.5 = 0.05\,(10^2) = 0.05\,(100)$: two places leftward, and the indicated exponent of 10 is 2, and 100 has 2 zeros

Note here that 5 was made smaller to 0.5, so it should be clear that for it to equal the original value (here 5), a multiplication applied to 0.5, to increase this value, would then be necessary.

Ex. Represent 0.47 as a fraction

$0.47 = 47(10\text{^}{-2}) = \frac{47}{10\text{^}2} = \frac{47}{100}$: "forty-seven hundredths". Note that the last or "least significant" digit, the 7, is located in the "hundredths" position.

Checking by using the concepts of positional notation, and the sum of positional products:

$$0.47 = 4(10\text{^}{-1}) + 7(10\text{^}{-2}) = \frac{4}{10\text{^}1} + \frac{7}{10\text{^}2} = \frac{4}{10} + \frac{7}{100} = \frac{40}{100} + \frac{7}{100} = \frac{47}{100}$$

The last fraction is "forty-seven hundredths".

Another question about decimals you might ask is: What is the reasoning of moving the decimal point during "long" division? In decimal division, to have the nice ability to work (divide) with an integer divisor (no fractional part) and to automatically adjust the decimal point of the result, the decimal point of the divisor is moved completely to the right of the least significant digit (note: include all trailing zero's in the whole portion) and then the decimal point of the dividend is moved to the right the same number of digit positions (including any possible new trailing zero's placed as least significant digits). This process is essentially creating an equivalent fraction by multiplying the divisor (denominator) and dividend (numerator) by a common (same) value such as when creating an equivalent fraction. Specifically, whenever the decimal point is moved rightward, this resulting value is, and was caused by, some multiple or power of 10. Some of these concepts have been previously mentioned, and in particular for "long" or manual division.

Ex. $1/0.5 = \frac{1}{0.5} = 0.5\overline{)\,1.0} = \begin{array}{r} 2.0 \\ 5\overline{)\,10.0} \\ \underline{10} \\ 0 \end{array} = 2.0$: 5/10 is where the decimal point is moved 1 position rightward in both the numerator and denominator

Here, since the decimal point was "shifted" right one digit position, in the divisor (or denominator), the common multiplier to both the dividend and divisor (or numerator and denominator) was essentially 10.

checking: $\frac{1}{0.5} = \frac{1\ (10)}{0.5(\ 10)} = \frac{10}{5} = 2$: checks

MULTIPLICATION OF FRACTIONS

As like with the addition of fractions, we can essentially say that we have always been multiplying fractions if we just place each whole (entire) value over 1, and the relatively simple process of multiplying fractions becomes apparent.

Ex. $5 \times 3 = \frac{5}{1} \times \frac{3}{1} = \frac{(5)}{(1)}\frac{(3)}{(1)} = \frac{15}{1} = 15$: division by 1 does not change any value

The basic rule for multiplying fractions is to simply multiply the numerators (N) together, and multiply the denominators (D) together. Unlike for the addition and subtraction of fractions, the denominators when multiplying fractions need not be the same. The product of all the numerators being multiplied is the resulting numerator of the product. The product of all the denominators being multiplied is the resulting denominator of the product.

Symbolically: $\frac{(N1)}{(D1)} \times \frac{(N2)}{(D2)} = \frac{(N1)(N2)}{(D1)(D2)} = \frac{(N3)}{(D3)}$: a symbolic form of the multiplication of fractions

Ex. If you had half a circle (1/2) and added this to the other half (1/2) of that circle, which is the same as multiplying the first half by 2 since multiplication is repeated addition, the result should be one (1) whole circle. This example also verifies the rules for multiplying fractions.

$\frac{1}{2} + \frac{1}{2} = \frac{2}{2} = 1$ Since this is repeated addition of the same value, we can express this with multiplication :

$\frac{1}{2} \times \frac{2}{1} = \frac{(1)(2)}{(2)(1)} = \frac{2}{2} = 1$

Consider if you have the fraction:

$\frac{3}{5}$ which, by factoring the numerator and denominator, can be expressed as:

$\frac{(3)(1)}{(1)(5)}$ by grouping fractions, this can be expressed as the multiplication of two fractions:

$\frac{(3)}{(1)}\frac{(1)}{(5)}$: with the understanding that these fractions can be multiplied.

Checking: $\left(\frac{3}{1}\right)\left(\frac{1}{5}\right) = 3 \times \left(\frac{1}{5}\right) = \left(\frac{1}{5}\right) \times 3 = \frac{1}{5} + \frac{1}{5} + \frac{1}{5} = \frac{1+1+1}{5} = \frac{3}{5}$

For more verification of this multiplication of fractions rule, first consider that there is nothing intuitive about this rule. Why should the following be true:

$\frac{2}{3} \times \frac{4}{5} = \frac{(2)(4)}{(3)(5)}$ or if this was (somewhat oddly) explicitly expressed in terms of "hand or long division":

$$3\overline{)\,2} \quad \times \quad 5\overline{)\,4} \quad = \quad (3)(5)\overline{)\,(2)(4)}$$

To make this mathematical discussion "less wordy", let's label the first numerator and denominator as N_1 and D_1, and the second numerator and denominator as N_2 and D_2 (Note, this does not mean Nx2, Dx2, etc, but these are unique or different (symbolic) identifiers or names assigned to a value that is either known, unknown, or being solved for).

First consider this where like fractions are combined, and the numerator (2) is repeatedly added (ie. multiplication):

$$\frac{2}{3} + \frac{2}{3} + \frac{2}{3} + \frac{2}{3} = \frac{2 + 2 + 2 + 2}{3} = \frac{2(4)}{3} = \frac{2\,(4)}{3\,(1)} = \frac{8}{3}$$

Or by repeatedly adding the same fraction 4 times, and expressing this with multiplication:

$$\frac{2}{3} \times 4 = \frac{2}{3} \times \frac{4}{1} = \frac{8}{3}$$

The two must therefore be equal, and expressing this we get: $\frac{2}{3} \times \frac{4}{1} = \frac{(2)(4)}{(3)(1)} = \frac{8}{3}$

In general, we have $\frac{N_1}{D_1}$ to be repeatedly added (ie. multiplication) to itself say N_2 times.

Then we have: $\frac{N_1}{D1} \times N_2 = \frac{N_1N_2}{D_1}$

If N_2 was shown as initially divided by some value (including 1 as shown above), say D_2, this can be expressed as:

$$\frac{N_1\left(\frac{N_2}{D_2}\right)}{D_1} = \frac{\frac{N_1\,N_2}{D_2}}{\frac{D_1}{1}}$$

: think of this numerator as the result of repeatedly adding (N_2/D_2) a total of N_1 times. Remember, in adding fractions, the like or common denominator is also expressed in the sum.

By multiplying both the numerator and denominator by D_2 (creating an equivalent fraction):

$$\frac{\frac{N_1\,N_2\,D_2}{D_2}}{D_1\,D_2} = \frac{N_1\,N_2}{D_1\,D_2}$$

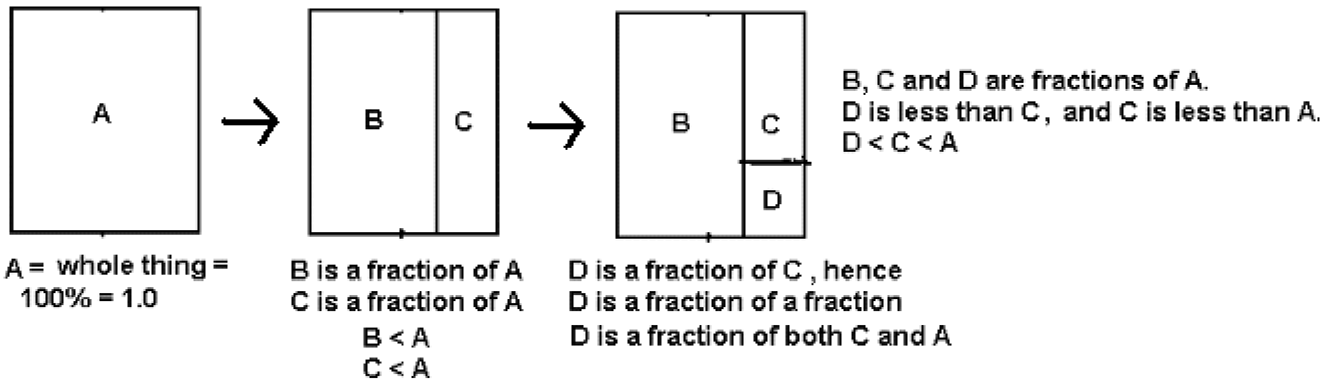
: after canceling, and therefore:

This same result could also be had by multiplying both the num. and den. by (1/D1). In conclusion we have:

$$\frac{N_1}{D_1} \times \frac{N_2}{D_2} = \frac{N_1\,N_2}{D_1\,D_2}$$

A FRACTION OF A FRACTION

Below is a visual or graphical example of having a fraction of a fraction, or having only a part of a part of something. As you might imagine, a part, of only part of something, is a smaller part and is represented by a smaller numeric value. The method to solve for the numerical result of a fraction of a fraction is to simply multiply the fractions together. The example below will demonstrate why, but first a graphical illustration of a fraction of a fraction. [FIG 9A]



C < B

Ex. What is one-fourth of one-half? This may also be mathematically expressed as:

1/4 of 1/2 = ? : 1/2 is a fraction, and 1/4 is a fraction, hence we are to find a fractional value of another fractional value.

The question in general is: "What is the value that represents this fraction of another fraction?" At first, you might be tempted to do something like divide, but then the question would have been stated as something like: "How many times can 1/4 go into (or divide into) 1/2?", or "How many times can 1/2 be divided by 1/4?" So solving the original question by division is not to be used. Can multiplication be the answer? Yes. A keyword to look for is the word "of". as indicated in 1/4 of 1/2. The word "of" is often associated with multiplication problems. You can also consider reading the word "of" used here as meaning: "of this", or "of this value".

Let's start at a basic example. If you have half of 10, you have 5 of the 10. Whenever you want to find half of some value, you divide that value by 2 to find out the numeric value.

$\frac{10}{2}$ half, or one-half of 10. This can be expressed as:

$\frac{10 \times 1}{2 \times 1}$ using the commutative rule in the denominator:

$\frac{10 \times 1}{1 \times 2}$ which can be expressed as:

$10 \times \frac{1}{2}$: a whole number times a fraction, which can be expressed as:

$\frac{10}{1} \times \frac{1}{2}$: clearly, a fraction times a fraction. Since this is "one-half of ten", the times symbol (x) is clearly associated with the word "of". For possible clarity and for how "one-half of ten" is spoken, this can also be mathematically expressed (with the commutative rule) as:

$\frac{1}{2} \times \frac{10}{1} = \frac{1}{2}$ of $\frac{10}{1} = \frac{10}{2}$: "one-half of ten"

If the whole number (10 as in this ex.) was divided by a number, say 4, we would then have a fraction times (multiplied by) another fraction:

$\frac{10}{4} \times \frac{1}{2}$: this could be expressed, read or spoken as: "one-half , of one-fourth of ten". Here is some more verification of this:

$\left(\frac{10}{1} \times \frac{1}{4}\right) \times \frac{1}{2}$: "one-half, of one-fourth of ten". For clarity, this could be expressed as:

$\frac{1}{2} \times \left(\frac{1}{4} \times \frac{10}{1}\right)$: "one-half, of one-fourth of ten".

So to solve for 1/4 of 1/2, "one-fourth, of one-half", simply multiply the two fractions:

$\frac{1}{2} \times \frac{1}{4} = \frac{1}{8}$: "one-fourth, of one-half is one-eighth" or "one-half, of one-fourth is one-eighth". If you know how to divide fractions, you can divide this product by either factor so as to find the other (associated or corresponding) factor as a check.

Here is a check using pure decimal numeric values one-fourth of one-half is:

one-fourth of one-half is = 1/4 of 1/2 = (0.25)(0.5) = 0.125 = 1/8

Note also that one-half of one-fourth has the same result, particularly because the factors are the same:

one-half of one-fourth is = 1/2 of 1/4 = (0.5)(0.25) = 0.125 = 1/8

Here are some other basic examples for more verification to this process:

Ex. What is one-half of one?

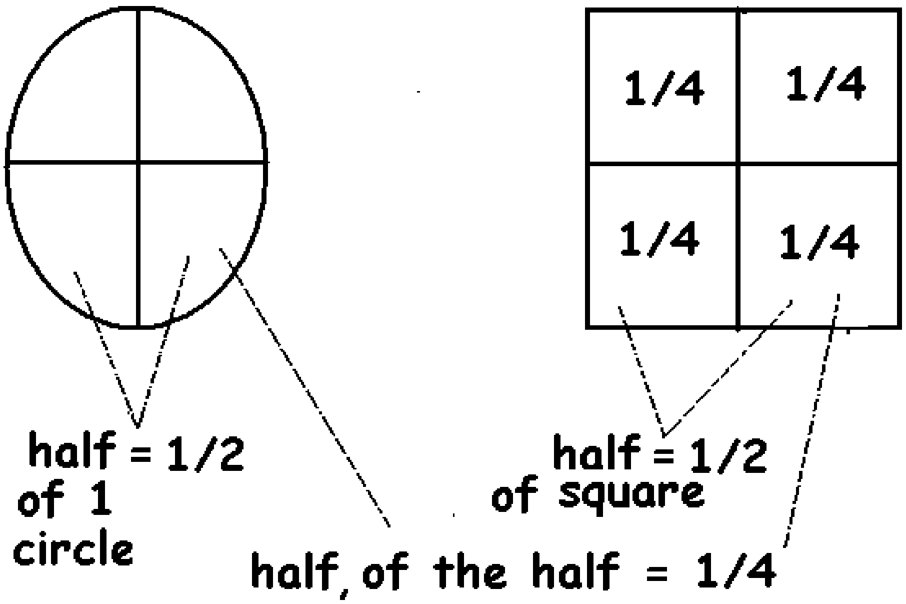
$\frac{1}{1} \times \frac{1}{2} = \frac{(1)(1)}{(1)(2)} = \frac{(1)(1)}{(1)(2)} = \frac{1}{2}$: "one-half", also you can divide any value, including a fraction, by 2 to find the half-value of it.

Ex. What is one-half, of one-half?

$\frac{1}{2} \times \frac{1}{2} = \frac{(1)(1)}{(2)(2)} = \frac{(1)(1)}{(2)(2)} = \frac{1}{4}$: "one-fourth". As mentioned above, this can also be solved by dividing the value by 2. (1 / 2) / 2 = (1 / 4)
Dividing by 2 is the same as multiplying by (1 / 2) = 0.5

Here is a graphical representation of this example (FIG 10): The circle or square was first divided into two equal parts (ie. in half), and then each of these parts was divided into two equal parts (ie. in half). The entire (1) square or circle has effectively been divided into 4 equal parts, and each part will therefore have a numeric value of (1/ 4).

[FIG 10]



If you were to then divide each quarter section (which are already existing fractions, of the entirety (=1)) into two equal parts, the square or circle would then contain a total of 8 equal parts or sections (fractions). Each of these new sections is a half (1 / 2) of any give quarter (1 / 4) section, hence mathematically: (1 / 2 of 1 / 4), and this new section only represents a smaller value, of (1 / 8) of the entire whole structure since it is a fraction (part) of another fractional (part less than 1 whole) value, and can therefore only be less in value:

$\frac{1}{2} \times \frac{1}{4} = \frac{1}{4} \times \frac{1}{2} = \frac{1}{8}$: one-half of one-fourth or = one-fourth of one-half = one-eighth

Before moving on to the next topic, the concept and wording of a fraction of a fraction may need to be stressed a little more carefully. Sometimes what is actually meant or being discussed can be subtle and different. Consider this:

"five-tenths of ten" and "five-tenths out of ten" : the key difference is the words "of" (= x), and "out of" (= /)

$\frac{5}{10} \times 10$!= $\frac{(5/10)}{10}$!= or $\neq$ or /=/ means: "is not equal to"

0.5×10 != $\frac{0.5}{10}$

5 != 0.05

DIVISION OF FRACTIONS

A fraction divided by another fractional or whole value is called a complex or compound fraction. That is, both the numerator and denominator of these fractions will also be fractions. A compound fraction is basically a "nested fraction" where the numerator and denominator fractions are the innermost fractions of the larger compound fraction. Some examples of compound fractions have already been seen in this book.

$$\text{A compound fraction:}\qquad \cfrac{\;\frac{2}{3}\;}{\frac{4}{8}} \qquad \begin{array}{l} :\text{ numerator} \\ \\ :\text{ denominator} \end{array}$$

Actually, you can think that you have always been working with compound fractions when working with just simple fractions by dividing both the numerator and denominator by the same value (as used when creating equivalent fractions) of 1:

$$\frac{2}{4} = \cfrac{\;\frac{2}{1}\;}{\frac{4}{1}}$$

Clearly, by simplifying both the numerator fraction and denominator fraction, of the compound fraction, the compound fraction is simplified to a simple fraction. Often, the simplified form of a compound fraction is expressed in terms of the numerators and denominators. Before a working example is shown, you should know more about canceling, or "to cancel", and what a reciprocal means.

Canceling is a process to possibly eliminate fractions to a single numeric value or number, essentially ridding the fraction completely. Remember, this was also stated in the order of operations second rule: clear/cancel grouping symbols. To cancel is to "divide out", "cancel out" or remove factors that are within and-or common to both the numerator and denominator. The result is either an equivalent fraction of lower or reduced terms, or a single numeric value or number. Canceling is basically like a "pre-division" and simplification step before the order of operations is followed more correctly where factors, if possible, are first multiplied together before the division. Sometimes a "hash mark" (/) type of symbol is shown when some division or canceling has been performed. A good approach for simplifying a compound fraction is to first try to rid the compound fraction of its denominator fraction. The method to do this will be shown below, and it is essentially done using the equivalent fraction concepts.

The reciprocal or "inverse" of a number is that number divided into one (1). Sometimes this is said as "one over the number (or value)". The word reciprocal is related to the word reciprocate which means "to move or change back and forth". The reciprocal of 5 or 5/1 is 1/5 as a fraction, or 0.2 when the indicated division is performed, which is its decimal equivalent. Likewise, the reciprocal of 0.2 is 1/0.2 = 5 which is the same value we started with. A reciprocal value of any integer (ie. counting) number is unique, that is, it can never be equal to the reciprocal of some other value. The product of two corresponding reciprocals is always 1. For example (1/4)(4/1) = 4/4 = 1 = (0.25)(4). One might ask: What is the reciprocal of a fraction? The answer is to simply "invert", or "turn upside down" the fraction. The numerator will become the denominator, and the denominator will become the numerator. As indicated in this discussion, the reciprocal of 5 or 5/1 is 1/5. The reciprocal of 2/3 is 3/2, and this is verified below:

The reciprocal of (2/3) is mathematically noted or expressed as: $\cfrac{1}{\frac{(2)}{(3)}} = \cfrac{\;\frac{1}{1}\;}{\frac{2}{3}}$: these are compound fraction expressions

Given this compound fraction, we note that if we multiply the denominator's fraction by its reciprocal value of 3/2, that we can effectively cancel it out.. The denominator will then be equal to one (1) after the canceling ("out", or "ridding") of each common factor of the entire numerator and entire denominator has been performed. Even though it has a value of 1, the denominator is still effectively eliminated since any value (here the numerator) divided by, or "placed over", 1 or not divided by any indicated value, is still equal to that value. Also, in order not to change the value of the (compound) fraction, that which is done to the denominator (fraction) must also be done to the numerator (fraction). This is necessary to create a (numerically) equivalent (compound) fraction.

$$\frac{\frac{1}{1}}{\frac{2}{3}} = \frac{\frac{1(3)}{1(2)}}{\frac{2(3)}{3(2)}} = \frac{\frac{3}{2}}{\frac{6}{6}} = \frac{\frac{3}{2}}{1} = \frac{3}{2}$$

: verification that 3/2 is the reciprocal of 2/3
The product of two corresponding reciprocals is always 1.

Note, it is best to attempt to cancel-out factors common to both the (entire) numerator and (entire) denominator before performing the indicated multiplication. This was also mentioned in step 2 of the order of operations.

$$\frac{\frac{1}{1}}{\frac{2}{3}} = \frac{\frac{1(3)}{1(2)}}{\frac{\cancel{2}(\cancel{3})}{\cancel{3}(\cancel{2})}} = \frac{\frac{3}{2}}{1} = \frac{3}{2}$$

: expressing the canceling with hash marks. If the values are not the same, such as for this example, a 2 in both the num. and den., you can reduce them both by dividing each by a common factor or value and indicate the quotients next to those factors that were reduced.

Hence, multiplying the denominator of a compound fraction by its reciprocal will easily cancel out or rid it of its denominator, leaving only a "simple" fraction in the numerator to work with. Here is a simple verification: How many times will one-half (1/2) of a circle divide into one (1=1/1) full circle? Clearly, the answer is 2, let's check:

$$\frac{\frac{1}{1}}{\frac{1}{2}} = \frac{\frac{1(2)}{1(1)}}{\frac{1(2)}{2(1)}} = \frac{\frac{2}{1}}{\frac{2}{2}} = \frac{\frac{2}{1}}{1} = \frac{2}{1} = 2$$

: note also: 1 / (1/2) = 1 / 0.5 = 2

Ex. $$\frac{\frac{1}{2}}{\frac{1}{4}} = \frac{\frac{1(\overset{2}{\cancel{4}})}{\cancel{2}(1)}}{\frac{1(4)}{4(1)}} = \frac{\frac{2}{1}}{1} = \frac{2}{1} = 2$$

: one-fourth will go into one-half, twice

Checking using the decimal equivalents of the fractions:

$$\frac{\frac{1}{2}}{\frac{1}{4}} = \frac{2\,|\overline{1.0}}{4\,|\,1.0} = \frac{0.5}{0.25} = 2$$

: checks

Ex. $$\frac{\frac{1}{4}}{\frac{5}{8}} = \frac{\frac{1(\overset{2}{\cancel{8}})}{\cancel{4}(5)}}{\frac{5(8)}{8(5)}} = \frac{2}{5}$$

Checking, by multiplying the denominator (divisor) by the resulting fraction (the quotient) to see if the product is equal to the numerator (dividend):

$$\frac{(5)(2)}{(8)(5)} = \frac{10}{40} = \frac{\overset{1}{\cancel{10}}}{\underset{4}{\cancel{40}}} = \frac{1}{4} \qquad \text{: checks}$$

Ex. A certain cooking recipe requires 1/3 of a cup of water, however you decide to only use enough of each ingredient to make half of the total quantity the recipe will make, how much water will you then need?

The answer is to use one-half (half = the whole or given part evenly divided by 2) of each ingredient.

$$\frac{\ \frac{1}{3}\text{ cup}\ }{\frac{2}{1}} = \frac{\ \frac{1(1)}{3(2)}\ }{\frac{\cancel{2}(1)}{1(\cancel{2})}} = \frac{1}{6}\text{ cup} \qquad \text{: one-sixth of a cup of water.}$$

As mentioned previously, product of a number and its corresponding reciprocal is always equal to 1. Reciprocals are also the reciprocals of each other.

$$5 \times \frac{1}{5} = \frac{(5)(1)}{(1)(5)} = \frac{5}{5} = 1 \qquad \text{or since } (1/5) = 0.2 :$$

$$5 \times 0.2 = 1.0$$

We see that in the above expressions for 1, that in one factor, the number is a multiplier, and in the other factor, that same number is a divisor. Since multiplication and division are inverse operations of each other, you may sometimes see reciprocals being mentioned as a "multiplicative inverse".

Most scientific calculators have a reciprocal-key or "calculator function" for the reciprocal operation. This key or button is usually labeled as: [1/x] . If your calculator does not have this convenient key, then simply divide 1 by the number in question that you want to find the reciprocal of.

Note: Canceling can only be done on one factor at a time of both the entire numerator or denominator. Once a value is reduced to 1, it is therefore essentially eliminated (canceled out) and what is left of its initial value cannot be used for any more possible canceling.

Ex. $\frac{(8)(4)}{2} = \frac{(\overset{4}{\cancel{8}})(4)}{\cancel{2}}$ or $= \frac{(8)(\overset{2}{\cancel{4}})}{\cancel{2}} = 16 \neq \frac{(\overset{4}{\cancel{8}})(\overset{2}{\cancel{4}})}{\cancel{2}} = 8$: once an initial factor is canceled or factored, it cannot be reused as that same initial factor value , but any factor remaining of an initial factor can be used for further canceling.

Checking: $\frac{(8)(4)}{2} = \frac{32}{2} = 16$

CANCELING ENTIRE EXPRESSIONS

Since an expression essentially, or eventually, represents one specific quantity or value in question, often indicated within a surrounding grouping symbol for clarity, it can be canceled-out just like one single numeric values if it's a (common) factor to both the entire numerator and denominator of the fraction.

Ex.

$$\frac{5(3+2)}{7(3+2)} = \frac{5\overset{1}{\cancel{(3+2)}}}{7\underset{1}{\cancel{(3+2)}}} = \frac{5}{7}$$

Checking by varying the order of operations, which can be performed wherever possible as long as the result is not caused to be made incorrect. Here, for some simplification of the expressions, addition is first performed within the grouping symbols as part of the effort to clear the grouping symbols in the numerator and denominator of the fraction. Canceling (division or dividing out) common factors is then chosen over multiplication, so as to first simplify the numerator and denominator) and help prevent the need to reduce the resulting fraction to lower terms:

$$\frac{5(3+2)}{7(3+2)} = \frac{5\overset{1}{\cancel{(5)}}}{7\underset{1}{\cancel{(5)}}} = \frac{5}{7}$$

: or = 25/35 when "unreduced" (to simpler terms), and if both the numerator and denominator are divided by 5, the equivalent fraction created is 5/7

PERCENTAGES

The word cent (or centi) in the word percentage means "one-hundredth of" which is 1/100 or 0.01 numerically. Therefore, percent means how many "(per) hundredths of something" or "parts per hundred of something, that was (physically, and-or mathematically, numerically) divided into one-hundred parts". The concept of percent was briefly mentioned in the topic of: A Short Discussion About Percentages.

A percentage, or more correctly, a percentage rate is simply a numerical measure of a part, fraction or portion of something, and is in reference and-or comparison to that whole or entire something. Symbolically:

$\frac{\text{Part}}{\text{Whole}}$ = numeric representation of how much Part and-or its numeric portion or representation is in reference to, or with respect to, the Whole thing. We see that this expression or mathematical representation of a percentage rate is the same as that of an expression for a fraction, and this is so since we are numerically finding out what is the relative size (ie., between 0 to 1, or 0% to 100% = "zero percent to one-hundred percent") that this portion or part is in reference to the entire or whole thing. The value of this expression is a rate or comparison of two values, and is called the portion rate or percentage rate, and the actual numeric value of Part is technically the actual percentage value (without the rate or comparison meaning) in question that was used to find the (percentage) rate:

Part / Whole = percentage value / total = percentage rate therefore, mathematically:
(Whole) (percentage rate) = percentage value = Part

Below are some examples to help demonstrate as to how we may use the concepts of percentages.

1. The monetary value of a common penny coin is one cent, or "one-hundredth" of a dollar, hence 1/100 = 0.01 of a dollar. To find a percentage is to find the total number of hundredths in question of any value or quantity that was divided (or imagined or conceived as divided) into 100 equal parts or fractions. The accepted symbol that indicates the amount of hundredths in question, or that hundredths are being considered, is %. It is called the percent symbol. Percent values are mostly used to easily generalize or indicate the basic comprehensible, relative value or size of a portion or fractional value of something, rather than use exact specific values, especially when the size or value of that something can change or vary, yet the (percentage) rate of the portion value in reference or respect to the whole value, remains constant, say for example, as being always 50% of any current value or total at hand or being considered. For some simplified examples of relative values and their percentages: "none" - such as 0 percent, "tiny" - such as 1 percent, "small" - such as 10 percent, "medium" - such as 50 percent, "big" - such as 70 percent, "large" - such as 90%, all, "entire" or "whole" - such as 100%.

2. When using a fixed or constant percentage value, the actual or specific result value automatically adjusts for any changes in the overall size of that something. For example, a store may indicate that the selling cost of any item(s) is 10% cheaper or less than its previous selling price rather than list the actual amount(s) reduced and-or the previous selling price of the item(s). A store may even have a "store-wide (all items) sale for a day", where everything in the store is 20% cheaper than the indicated price on the price-tag, rather than make many new and temporary price-tags for all of the store items.

3. By some contract or agreement, a person might own or be allotted a specific percentage, say 10%, of all (entire) the grain produced for the year at a farm. rather than say the allotment is to be specifically 500 pounds only, or 500 pounds maximum. In a good growing year, 10% of all the grain might be 600 pounds, and in a bad growing year, 10% of all the grain might only be 200 pounds. This way, all the people who were allotted or assigned to that grain produced at that farm will also share in the gains and losses in the actual total amount of grain produced during that growing season. Clearly, if the farm only produced 200 pounds of grain, and if a person was to be allotted a specific value of 500 pounds, it is no even possible for that person to receive that specific amount of grain.

4. Sales tax, often some low fixed percent, say 5 or 6 percent (5%, or 6%), at a store to purchase a specific item(s) will be

based on the selling price of the item(s). The higher the price of the item(s), the more the total sales tax money value will be, and yet the indicated percentage or sales tax rate is a constant or fixed value. At this point in this book, it could be obvious or intuitive that if the cost of the items doubles (2), or goes up by some factor, then the sales tax money needed for that item will also double or go up by that same exact factor (here 2), and yet the indicated percentage or sales tax rate is still the same constant or fixed value. When changes correspond in such a direct manner as this, the relationship of the resulting values, or the change values themselves, is said to be a direct, constant, straight, "one to one",or "linear" (line-like) mathematical relationship.

5. In a hospital, sometimes the amount or dosage of a certain medication to give a patient will be a specific (fixed, constant) percentage (ie. a fractional value or portion) of a persons weight. The more someone weighs, the more the specific amount of medicine they will need and receive, and yet the percentage value remains the same or "fixed" for patients that have various weights.

6. If a certain drink mixture is described as containing 10% fruit juice, regardless of the volume of that fruit juice, and hence for any specific volume (such as a spoonful, glassful, or a liter) of the mixture considered to be put into several glassfuls to drink, each glassful will contain 10% fruit juice. If you know the specific volume of the entire mixture used, and after solving for 10% of that volume, you have found the specific volume or amount of fruit juice in that specific volume of the mixture.

If you have 5% (commonly spoken as "five percent" or= a "five percent rate") of something, you have 5 one-hundredths of it:

$$\frac{1}{100} + \frac{1}{100} + \frac{1}{100} + \frac{1}{100} + \frac{1}{100} = \frac{5}{100}$$: "five one-hundredths" or simply: "five hundredths"

Or, since we have a repeated addition of adding the same value 5 times, we can express this with multiplication as:

$$\frac{(5)}{(1)} \times \frac{(1)}{(100)} = \frac{(5)(1)}{(1)(100)} = \frac{5}{100} = 0.05$$ in decimal form. or:

5(1/100) = 5(0.01) = 0.05

This is often indicated as: 5 hundredths = 5 percent = 5% when percents are considered. The percent symbol and the value preceding it are sometimes, and more formally, called the rate. The word rate is rooted in the words of: reason, rational (reasoning, logic), and ration (an allotment, fraction, or portion of something, and in the numerical sense, it similar to the word ratio). In this example, the (percent) rate is 5 percent = 5% = (5/100) = 0.05.

Ex. What is five percent of three hundred apples? This can be expressed as: 5% of 300 apples is how many apples? According to the definition of percent, 5% of 300 apples is = 5 hundredths of 300 apples = (5/100) of 300 apples. 300 represents the whole (entire, all = 100% = 1.0) lot, amount or quantity that is to be divided into 100 even (or equal, similar) parts when percents are being considered.

First of all, 1% (= one-hundredth = 1/100 = 0.01) of 300 apples is 300 apples divided into 100 equal parts:

$$\frac{300 \text{ apples}}{100} = 3 \text{ apples}$$: (a group of) 3 apples physically compose, and is mathematically, 1% of 300 apples. Checking by multiplying the quotient and divisor, the dividend is: (3 apples)(100) = 300 apples, and this expression also indicates that 300 apples is 100 times bigger or more than 3 apples. Likewise, it also expresses that if you have 3 apples, and increase, magnify (mathematically, a multiplication = multiples or many of) or multiply it by 100 (or 100 times, or multiples of), you will have 300 apples.

If we mathematically compare 3 apples to 300 apples, perhaps to find the "magnification size or factor", "how big one is compared to the other", or "how many times bigger one is to the other", we can get this expression below, which can also be mathematically derived from the above equation by dividing both sides by (300 apples).

$\frac{3 \text{ apples}}{300 \text{ apples}} = (1/100) = 0.01 = 1\%$:This shows why a percent is really a rate or plain unitless numeric ratio of two values. Extra: the reciprocal of this expressed fraction is: (300 apples) / (3 apples) = 100. This value of 100 indicates that 300 apples is 100 times more or bigger than 3 apples.

This indicates that three apples out of, or compared to 300 apples, is (only) 1% of them. Three apples is a portion (part, or fraction (less than all = the entirety = 100% = 1.0)) of the 300 apples. Mathematically, this portion is 0.01 = 1/100 = "one-hundredth" = 1%. The rate can be said as: "3 out of 300", or "3 per 300", or more commonly, basically or fundamentally (in terms of hundredths) as: "1 out of 100", or "1 per 100", and numerically, this is expressed as: 1/100 = 0.01 = 1%.

["Technically", the indicated rate is equal to the indicated percentage, and here, its 0.01 or 1%, and that the actual or specific value that this percentage rate represents (of the entirety) for this example is (3 apples). (3 apples) is therefore called the (actual or specific) percentage or percentage value. This may seem a bit confusing at first, but it is something to consider. It would help if the mathematical (rate) value (in terms of hundredths of the entirety) of a portion is called the percentage rate, or the indicated percentage, rather than simply and commonly as just the percentage. As we have seen, we can have a fixed percentage rate of say 6% sales tax, but the actual tax value or money needed, or the actual percentage value that this 6% rate indicates or is associated with, can vary widely since it depends on, and is mathematically in reference to, or based on, and calculated using the "total" (all, entire) cost or money required during a purchase or sale. Some more will be said about this further below. **]**

1% of anything or value is a hundredth of it, this can be mathematically expressed as: (value /100) or (total/100). 1% of 300 can therefore be expressed as (300/100) = 3 if we perform this indicated division. This leads to the conclusion that 3 apples is 1% of 300 apples . If we multiply this specific 1% value by 5, we will then know the number of apples equal to 5% of 300 apples, since 5 percent is obviously 5 times more than 1 percent. (5 percent/1 percent = 5). This could be stated in a question as something like: "If 3 apples = 1% of all the apples, how many apples are 5% of all the apples?".

(1% of apples) x 5 = (5 x 1%) of apples = 5% of apples :

$$\frac{300\text{ apples}}{100}\,\frac{(5)}{(1)} = \frac{\overset{3}{\cancel{300}}\text{ apples }(5)}{\underset{1}{\cancel{100}}\quad(1)} = 15\text{ apples}$$

or: 3 apples (5) = 3 apples x 5 = (3 x 5) apples = 15 apples

checking: $\frac{15\text{ apples}}{300\text{ apples}} = (15/300) = (5/100) = 0.05 = 5\%$

We showed that 5% = 5/100 = 0.05 = 5 (1/100) = 5 x 0.01 = 0.01 x 5 = 1% x 5 , and note that:

$\frac{300\text{ apples}}{100}\,\frac{(5)}{(1)}$ can be written or expressed as as:

$\frac{300\text{ apples}}{1}\,\frac{(\ 5\ )}{(100)}$: due to multiplication being commutative. This is equal to:

(300 apples)(0.05) = 15 apples = (300 apples)(5/100) = (300 apples)(5%) = 5% of 300 apples

Therefore, to simply get the actual (rather than the rate or indicated) percentage value (ie., the specific or actual quantity or value that this rate actually represents), multiply the total value or quantity given by the indicated rate expressed in decimal or fractional form. The general "formula" for finding percentages is usually written as:

(total)(rate) = percentage : the common and basic "percentage formula"

This percentage formula stems from (ie. is derived from) the basic form of any ratio. Here, rate is a ratio value (a mathematical representation of the comparison of two values which is essentially a numeric (and unitless) quotient) value of the actual percentage value (typically only some amount of the total amount) in question divided by the total or Whole value in question. Note the similarity of the word rate and ratio. Whereas two numbers can be mathematically compared by their resulting (linear) distance separation or difference (ie. a simple change, or mathematical measure of the separation), two numbers can also be mathematically compared by their resulting ratio value (ie. a multiplier or magnification change of one value [as a numerator] as compared to, or in reference to, the other value [such as a denominator]). Ratios will be given a more general discussion further ahead in this book.

Remember, to find the unknown factor in a product, you simply divide by the other given factor. Considering this using the formula above, this results to the following which is also equivalent to dividing both sides of the equation by (total), and then canceling out common factors in the entire numerators and denominators.

$$\frac{\text{percentage}}{\text{total}} = \frac{\text{Part}}{\text{Whole}} = \text{rate}$$

: Showing that the rate or "percentage rate" value is the mathematically or numerically "indicated percent" of the actual percentage value with respect to the total value. Likewise,the given formula can be expressed as:

$$\frac{\text{percentage}}{\text{rate}} = \text{total}$$

: total is sometimes called the base, base value, or working value being considered

From: (total) (rate) = percentage value

$$(300\text{ apples})(5\%) = (300\text{ apples})\left(\frac{5}{(100)}\right) = (300\text{ apples})(0.05) = 15\text{ apples}$$

The largest possible part or fraction of something is numerically: 100% = 100 parts out of, or of, 100 parts = 100/100 = 1 of something which is the entire, "all of it", or whole thing. It is possible to have percentages, or more correctly, rates, that are higher than 100% as when the that something is now larger than before, hence that higher than 100% value is in reference to a previous value, since the largest possible part or fraction of any value is still only 100%. If something is claimed to be 100% larger, or a 100% increase or bigger, it generally means that it has increased or been magnified (multiplied) by a factor of: (original value + increase) / original value = (100% + 100%) /100% = 200% / 100% = 2, and may be stated as being two times more or greater than the previous or original (reference) value, or now being twice as big.

Ex. What is 3.75% of $1530.35 to the nearest penny?

This can also be expressed as: What is 3.75% of $1530.35 rounded to the nearest penny.

"To the nearest" means **rounded** or mathematically adjusted and truncated (reduced or limited to) at that decimal position or "precision" to reflect if the next least significant digit (possibly rounded itself) was 5 or greater, and if so, it will be increased or "rounded up", by 1. Any and all digits having lesser numerical significance will be discarded as unneeded. Hence, the result, when rounding was used or considered, can only be assumed to be an approximation (not exact) or close value due to this process. **Rounding** is used to eliminate often unnecessary (lengthy. least significant or practically meaningless in value, that are of low effect or concern) digits in a number and to make further calculations shorter in length and easier to process, and to have nicer looking result values. The small error and effect of, and after discarding even some small (fractional) part of a value(s) can eventually "add up", or multiply in significance and therefore have growing influence on the results of further calculations, and in such a manner that the error or the difference from the actual or true result can be significant enough to consider and not ignore and the result should then be considered and explicitly stated as being an approximation.

To use a percentage value as an operand of an expression, first convert it to its equivalent decimal form. This can be done visually by moving the decimal point two digit positions leftward. For example:

5% = 0.05 : "five percent" equals 0.05 in decimal, or strict numeric form.

3.75% = 0.0375 : since 3.75% = 3.75/100 = 0.0375
The percent symbol, %, numerically means: (1/100).

Using a calculator: $1530.35 x 0.0375 = $57.388125

Rounding to the nearest penny (or hundredth of a dollar) we get: $\$57.3\underline{9}$ The underlined number, here for 9, is an expression or symbol to express that the actual, true or entire number given was rounded to and truncated this this position or precision ("precise", smallest part of).

Ex. In a coupon you received, a store claims that a certain items selling price of $7.99 will be reduced (decreased, discounted) by 10% (or "10% off") when you give them your coupon. What will be the new selling price?

From: (total)(rate) = percentage

($7.99)(10%) = percentage Often spoken as: "10 percent of $7.99" is:
($7.99)(0.10) = $0.799 : Which is $\$0.\underline{80}$ when rounded to the nearest penny. In rounding, as with addition, you must still consider carries. The cost of the item will be 80 cents less than the previous value.

New price = Old price - Reduction
New price = Old price - (10% of Old price)
New price = $7.99 - $0.80
New price = $7.19 : new selling price. Any sales tax should now be considered on this new and lesser value.

This problem may have been solved knowing that if 10% is removed, (100% - 10%) = 90% of the price remains, and 90% of $7.99 is:

($7.99)(90%) = $7.19

You can easily find 10% of a numeric decimal value if you move the decimal point one place to the left. This effectively multiplies that value by (1/10) = 0.10, or divides that value by 10.

Ex. 10% of 4.57 = 0.457

Just the same, to find 1% = 0.01 of a value, simply move the decimal point two places leftward, which is the same as multiplying that value by 0.01, or dividing it by 100.

Ex. 1% of 103 = (103)(0.01) = 103/100 = 1.03

Ex. 1% of 47 = 0.47

If you double this 1% value of 0.47, you then can find 2% of 47. Showing some helpful intermediate steps:

2% of 47 = (1% of 47) + (1% of 47) = 2 x (1% of 47) = 2 (0.47) = 0.47 + 0.47 = 0.94

The last equation was probably the easiest or quickest way to find the result, but it may not have been so (initially) obvious of just adding the 1% value twice so as to have the 2% value : 0.47 + 0.47 = 0.94

If you know 10% of a value, you can double that percentage value to find 20% of that same value.

Ex. If 10% of 100 is 10 , 20% of 100 = (10% of 100) + (10% of 100) = (10% of 100)(2) = 2(10) = 10 + 10 = 20

It is somewhat easy to find 50% of a value since 50% = 0.50 = 50/100 = 1/2, that is, you can simply divide a value by 2 to find 50% or "one half" (or simply: "half") of it.

Ex. 50% of 60 = (60/1)(1/2) = 60/2 = 30 : Likewise, if you divide a value by 2 or "in half", you have the 50% portion and value of it.

Ex. An item is on sale for \$5.20 and this value is indicated as being 30% cheaper. What was the original selling price?

There is a straight-forward algebraic approach to solving this, but since this book has not yet covered much of algebra yet, a simple mathematical method will be shown first:

If 30% was taken away (the reduction) from the 100% value (the original/starting or previous value), this leaves us with a value equivalent to:

100% - 30% = 70% of the original value (price). Hence, the ratio (fractional or percentage value if you will) of the current selling price (with respect) to the previous price is 70% or 0.70 in decimal form:

$$\frac{\text{current-price}}{\text{previous-price}} = 0.70$$

: "the current-price is 70 percent of the previous-price".
Also, 100% - 30% = 70% = 1.0 - 0.30 = 0.70

$$\frac{5.20}{\text{previous-price}} = 0.70$$

therefore, mathematically, as when checking a division problem we multiply the quotient and the divisor together to find the dividend, or an expression for it:

$$5.20 = \text{previous-price} \times 0.70$$

and therefore, dividing the product by one factor to find the other factor. as when solving or checking a multiplication problem:

$$\frac{5.20}{0.70} = \text{previous-price}$$

simplifying this,we find that:

previous-price = \$7.43 : original selling price

You may also consider this check:

current-price = previous-price - reduction in price
current-price = previous-price - 30% of the previous-price
current-price = 7.43 - (7.43)(0.30)
current-price = 7.43 - 2.23
current-price = 5.20

Since: previous or original price x percent reduced = reduction , we can get:

$$\frac{\text{reduction}}{\text{previous-price}} = \text{percent reduced}$$

$$\frac{2.23}{7.43} = 0.30 = 30\%$$

: "2.23 is 30% of 7.43" or: 2.23 = 30% x 7.43 or: 2.23 = (30%)(7.43)
In these above expressions, you may also use 0.30 for 30%, such as for actually doing or calculating those mathematical equations.

It could be stated, as indicated in the equations, that:

30% of the previous or original price is the reduction in price.

The current price is 70% of the previous or original price.

A similar, but a more algebraic approach, using the concepts of signed numbers that are yet to be discussed, to solve this problem would be:

previous-price - reduction = current-price   using the concept of substitution to substitute the values we know:
(1.0) previous-price - (0.30) previous-price = 5.20   Combining the like terms of: previous-price:
(0.70) previous-price = 5.20   After dividing both sides by 0.70 and canceling:

previous-price = $\frac{5.20}{0.70}$ = 7.43

The most straight-forward way to solve this problem above is to use the "percentage formula". Assigning \$5.20 as the actual or specific value of the percentage (left or remaining) of the Total value, and expressing that (100% - 30%) = 70% of the (unknown) Total is \$5.20:

Total x Rate = Percentage
? x 70% = \$5.20   Solving for Total = ? , dividing the product by one factor to find the other factor:

Total = $\frac{\$5.20}{0.70}$ = \$7.43

Ex. If you were to receive 50% of only 1/4 of something, how much of that something would you then receive?

First, note that what we are actually trying to find is a fractional value (here, expressed as a percentage; 50%) of another fraction (here 1/4), in short, we are to find a fraction of a fraction. This topic has been discussed previously in this book. (1/4) of something is 0.25 = 25 percent of something. You are to receive 50% of 25% of something.

Since 50% is 0.50 in decimal form, and we know that we can multiply this decimal form to the total value in question so as to find the actual percentage value:

$\frac{(0.50)(1)}{1(4)} = \frac{0.50}{4} = 0.125 = 12.5\%$ of something

Or, since 1/4 = 0.25 (or 25%) in decimal form:

(0.25 of something) (0.50) = (0.25)(0.50) of something = 0.125 of something , or = 12.5% of something

Note that since fractions and indicated percentages of a value are only relative to a specific value in question, "something", as in this example, can actually be any thing or value, and is considered as 100% = entirety or Whole.

50% of 25% = $\frac{(50)}{(100)}\frac{(25)}{(100)} = \left(\frac{1}{2}\right)$ of $\left(\frac{1}{4}\right). = \left(\frac{1}{2}\right)\left(\frac{1}{4}\right). = \frac{1}{8} = 0.125 = 12.5\%$

Ex. If 4 is 20% of something, (or same as: "if 20% of something is 4"), what number (ie. the actual percentage value) corresponds to 30% of that something?

We can easily solve this by setting up a proportion type of problem. Even though the concept of proportions has not been covered up to this point, let's first consider the common (formula) percentage type of equations that can be created with the information stated in the problem:

From: total x percentage rate = percentage

Equation 1: (total)(0.20) = 4
Equation 2: (total)(0.30) = (number)

Since the indicated percentage increases from 20% to 30%, the (number) to be found will be greater than 4.

Taking each equation and considering the two factors (that make the product) in each, and solving for (total):

$$\text{total} = \frac{4}{0.20}$$

: Note, this here could also be solved by division, and then substituting this quotient value into the following, derived from the second equation:

$$\text{total} = \frac{\text{number}}{0.30}$$

Since the right-hand side of both of these equations is equal to: total , they can both be equated as being equal. The resulting equation is an example of what is known as a proportion (same or equivalent portions, parts, or fraction of the whole) type of expression:

$$\frac{4}{0.20} = \frac{\text{number}}{0.30}$$

: a proportion type of problem, solving for number :
: This might be read or spoken as "4 is to 20%, as (equal to) number is to 30%".
: Note also that the left hand side could of been simplified here to: 4 / 0.20 = 20

If may not be apparent to you at this point, but notice that since each side is a fraction, and that both sides are equal, then the fractions can only be equivalent fractions and the problem could be solved as such. Much more will also be said about proportions later in this book. The two equations above for: total , are also known as a "system of equations" or as "simultaneous equations" since the value for "total" will solve both equations simultaneously (at the same time) or together, or "at once" when it is found just once, and since it has the same value for both equations.

Considering the entire left hand side of the equation as a quotient value of a division problem, such as on the right hand side, we know that to check a division problem, you multiply the quotient and divisor together and check if it equals the dividend. Indicating (expressing) this with the stated values:

$$\text{number} = (0.30) \times \left(\frac{4}{(0.20)}\right) = \frac{(0.30)(4)}{0.20}$$

after simplifying the right-hand side :

number = 6

Extra: Here is an example of how the value of: "total" can be found which could then be used to solve any of the original two equations:

From: $\frac{4}{\text{total}} = 0.20 = 20\%$: mathematically expressing that "four is (only) twenty percent of "total"

Multiplying the quotient and divisor together should yield the dividend:

4 = 0.20(total) : as was stated in the problem, and the equations: (Eq. 1)

Dividing 4 by one factor should yield the other factor, hence solving for "total", and this is also the result of dividing both sides of the equation by the same value of 0.20:

$$\text{total} = \frac{4}{0.20}$$

total = 20

Checking the value of number: (total) (0.30) = (number)
20 x 0.30 = 6.0 : checks

Here are some more examples of using percentages:

Ex. If 26% of something (perhaps an amount of money) is given to a person A, and then person A promises 35% of his share to person B, what percent of the original total (the 100% = 1, entire, all, full value, of the money) will person B actually receive?

First, note that this is a problem pertaining to a fractional value of another fraction. Person B will receive a fraction of Person A's fraction of the total.

Let's start by converting the percentages to decimal values:

26% = 0.26

and 35% of this is:

$$\begin{array}{r} 0.26 \\ \times\ \underline{0.35} \\ 130 \\ +\ \underline{780} \\ 0.0910 \end{array} = 9.1\%$$

: (0.26)(0.35) , a fraction, of another fraction

: Person B will receive 9.1% of the total money

Notice that the problem above is a relative or relative values (ie. with respect to one another, and not something else) type of problem and that the values are all relative (ie., not specific in actual values which could be any values conceivable) in the form of percentages. No actual amounts such as the total money value was used. The total money value could be any value, say from 1 dollar up to 1000 dollars, and the actual value does not matter for this type of problem, and the same (indicated) percentages (more specifically, the percentage rates) would result regardless of the actual values being considered.

Ex. If you are given $1.25 from a total of $7, what percent of this total did you receive?

First, consider that you received only a part or fraction of $7 since $1.25 is less than $7. This problem is solved by placing the part you received over the total, hence making a proper fraction:

$$\frac{1.25}{7.00} = 0.17857 = 17.857\%$$

: You received $1.25 which is 17.857% of $7.
Again, formally, $1.25 is the (resulting) percentage value
due to applying the percentage rate of 17.857%

CONVERTING A FRACTION TO A PERCENTAGE

If you have 5/10, or "five-tenths" of something, what percentage of that something do you have? Here, we have 5 parts of something divided into only 10 equal parts. Since a percentage is the result wanted, we really want to know how many parts we would have if we divided that something into 100 equal parts instead of 10. Considering both of these fractions, the denominator of 100 is ten times more than the other denominator of 10. Hence, we can make an equivalent fraction where the numerator and denominator are both ten times larger:

$\frac{5}{10} = \frac{\quad}{100}$ creating an equivalent fraction:

$$\frac{5}{10} = \frac{5(10)}{10(10)} = \frac{50}{100}$$

$\frac{50}{100}$ can be written as: $50\left(\frac{1}{100}\right) = 50\%$: If you have five-tenths of something, you have fifty-hundredths or 50% of something

If we perform the indicated division and multiplication, we get:

$$\frac{50(1)}{1(100)} = 50(0.01) = 0.50 = 50\%$$

If we perform the indicated division on the original fraction, we should also get this result without the need for creating the equivalent fraction. After all, equivalent fractions represent the same value, and if you find the value of one fraction, you have found the value of the other equivalent fraction:

$$\frac{5}{10} = \begin{array}{r} 0.5 \\ 10\,\overline{)\,5.0} \\ \underline{50} \\ 0 \end{array} = 0.50 = 50\%$$

This method can also be verified using factorization, and then canceling out common factors (to both the entire numerator and entire denominator):

$$\frac{50(1)}{1(100)} = \frac{5\overset{1}{\cancel{(10)}}(1)}{1\underset{10}{\cancel{(100)}}} = \frac{5}{10} = 0.50 = 50\% \qquad \text{or:} \quad (50/100) = (\overset{1}{\cancel{50}}/\underset{2}{\cancel{100}}) = 1/2 = 0.5 = 50\%$$

We see that the decimal equivalent of a fraction is equal to the fractional value or percentage (rate) that the numerator is (in reference, or respect) to the denominator, or it can be stated as the decimal equivalent of a fraction is equal to the rate that the numerator is to the denominator. The decimal equivalent of a fraction is also equal to the "magnification factor" or "multiplication, multiplier, or factor" of how many times bigger (or even smaller, if its less than 1, hence it's only a fractional part) that the numerator is in reference to the denominator. Consider:

numerator x magnification = denominator therefore: $\frac{\text{numerator}}{\text{denominator}} =$ magnification or fractional value

factor1 x factor2 = product therefore: $\frac{\text{factor1}}{\text{product}} = \text{factor2} = \frac{\text{dividend}}{\text{divisor}} = \text{quotient}$

Given: $\frac{5}{10} = 0.50 = 50\%$, we can then say:

"5 is 50% of 10" or = : "50% of 10 is 5" : If you substitute the equals symbol for "is", you will see that these two statements are the same, but the expressions on both sides of the equals sign were switched.

Ex. 7 is what percent of 8 ?

Assuming there are 7 parts in question of something divided up into 8 equal parts, and expressing this as a fraction, we get:

$\frac{7}{8} = 0.875$.

1

0.875 is the decimal equivalent of the percentage

Note, if we divide both the numerator and denominator by the denominator, we get: (7/8) / (8/8) = (7/8) / 1 = $\frac{0.875}{1}$ = 0.875

To show this value with the percent symbol, multiply it by 100 or simply move the decimal point 2 digit positions rightward:

0.875 = "eighty-seven point five, hundredths" = 87.5/100 = 87.5 (1/100) = 87.5%

We can then say that: "7 is 87.5% of 8" or=: "87.5% of 8 is 7"

To convert 87.5% back to its full decimal equivalent, show that 87.5% is 87.5 parts of 100 equal parts. This is easily done remembering that % = (1/100):

$$87.5\% = \frac{87.5}{1}\left(\frac{1}{100}\right) = \frac{87.5}{100} = 0.875$$

Hence, to convert an indicated percent to a strict, single numeric decimal value, divide it by 100 or simply move the decimal point 2 digit places leftward and remove the percent symbol.

Ex. A certain mixture contains 4 ingredients. The units of measurement for each ingredient could be ounces, teaspoons, tablespoons, cups, ounces, liters, milli-liters, and for this example, they will simply be indicated as (generic, generalization, unspecific) units so as to have a non-specific aspect. Regardless of the specific units (of measurement or reference) used, the percentage values would be the same. Here is the list of ingredients for the recipe (ingredients or substances, and instructions) of the mixture:

3 units of ingredient A : for example, all the same units of measurement might be cups, ounces or grams
2 units of ingredient B
1 unit of ingredient C
0.75 units of ingredient D

What percent of the entire mixture is ingredient B?

Summing up all the units included in the entire mixture:

3 units + 2 units + 1 unit + 0.75 unit = 6.75 units : total units of ingredients included in the entire mixture

$\frac{\text{amount of ingredient B}}{\text{total amount of all ingredients}} = \frac{2 \text{ units}}{6.75 \text{ units}} = 0.296\underline{3} = 29.63\%$: Ingredient B is about 30% of the entire mixture.

If you were to calculate each ingredients percentage of the total mixture, the sum of these percentages will be 100% = 1.0

Ex. An expected or ideal value of 10.0 is typical for a certain thing, but its measurement is found to be slightly over at 10.81. Express this difference in values as a percentage.

Difference = measured value - ideal value = 10.81 - 10.0 = +0.81

Expressing the difference as a percentage from the ideal value: $\frac{+0.81}{10.0} = 0.081 = 8.1\%$ over or increased

Note also for relative values: $\frac{10.81}{10.0} = 1.081 = 1.0 + 0.081 = 100\% + 8.1\%$ and $1.081 - 1.0 = 0.081 = 8.1\%$

Ex. Given 5, and if it is increased by 1, what percent, and multiplying factor (n) did 5 increase by:

$\frac{1}{5} = 0.2 = \mathbf{20\%}$, 1 is 20% of 5 , adding 1 to 5 is adding 20% of 5, increase to 5 , : Checking: $5\,(0.2) = 1$

$5 + 1 = 5 + (5)(0.20) = 5\,(1 + 0.20) = 5\,(\mathbf{1.20}) = 6$

$\frac{(5+1)}{5} = \frac{6}{5} = 1.2 = 1.00 + 0.20 = 100\% + 20\% = 120\%$, : Checking: $5\,(1.2) = 6$

We found that 1 is 20% of 5, and the multiplying factor to 5 is then 1.2 , and we can also find that:

1 out of the total of 6 = $\frac{1}{6} = 0.1667 = 16.6\underline{7}\%$ of the total, and $\frac{5}{6} = 0.8333 = 83.33\%$ of the total

$5/6 + 1/6 = 6/6$
$0.8333 + 0.1667 = 1.0$
$83.33\% + 15.67\% = 100\%$

FINDING A VALUE OR ITS' PERCENTAGE BETWEEN A RANGE OF VALUES

Given a range of values from 7 to 15, what percentage (%) from 7 (ie., seven will be considered as the start, or 0% value within the range specified) is 10, in other words, 10 is what percent of the "total numeric distance = 100% range of values" between 7 and 15? Also, if given a certain percentage (rate) between a range of values, what value between that range corresponds to that percentage (rate)?

Expressing some of this in number form, we are NOT finding this: $\frac{10}{15} = 66.\underline{7} = 66.\underline{7}\%$:Though this is mathematically right, this is not what we are solving for.

This last concept was mentioned because the denominator would then actually represents a range of 0 to 15, that is 15 is in reference to, and is the distance from, 0 and not some other value such as 10 as first mentioned.

We can use line segments (a small portion of a line that extends to infinity) an-or a number (ie., numbered, indicated) line as a graphic aid for analyzing these types of problems since a length value is essentially the difference between the start and end values on a line.

Line Segment 1: _____
Line Segment 2: ____________________

Line segment 1 is obviously less in length than line segment 2, and is therefore only a certain fraction or percentage of line segment 2.

Given two values, say 2 and 4, 2 is 0.50 = 50% of 4 since: 2/4=0.5 and 4 x 0.5 = 2 or:

$\% = \frac{\text{number1}}{\text{number2}}$: percentage that number 1 is with respect, or in reference to, number 2

$\frac{2}{4} = 0.5 = 50\%$: number1 is equivalent to a 0.50=50% portion of number2

These values can be thought of as the lengths of line segments:

```
----------------          : length1
       2

--------------------------------     : length2
               4
```

$\% = \frac{\text{length1}}{\text{length2}}$: percentage that length1 is with respect to length2

Each line segment can also be considered as a part of the same or different number lines where the difference between the maximum and minimum values is the length of that line segment.

Since: max. = min. + length : You can also think of length as distance. Algebraically:
length = max. - min.

```
     ----|----------------|----          : length = max. - min. = 10 - 8 = 2
 . . .   8               10    . . .      max. = maximum, here the maximum value
                                          min. = minimum, here the minimum value
```

We see that length and-or the difference or change between two lengths or values is actually calculated as a difference of the two value or locations. This difference or length between two values is sometimes called their "range" or "extent".

```
         ----|--------------------------------|---
. . .        3                                7    . . .
```

: length = max. - min. = 7 - 3 = 4
We also see that length is actually a "difference" which is a measure of separation. This difference could also be called the "change" from one value (here the min. value) to another (here, the max. value).

Below, a smaller line segment (line1) with a length of 0.5 is superimposed (placed on or over) on a larger line segment (line2) with a length of 2.0 that is within (bounded by) the range from 3 to 5.

```
        ----|----------|-----------------------------|---      : numbered line
. . .       3         3.5                            5    . . .
            |— 0.5 —|                                |
            |———————————————— 2 —————————————————————|
```

Using the above drawing, 3.5 is what percent (%) of this range from 3 to 5? This is very similar to the original problem stated above. Again, considering the numbers as line segments is a good method for such problems.

$$\% = \frac{\text{length1}}{\text{length2}} = \frac{(\text{max.1} - \text{min.1})}{(\text{max.2} - \text{min 2})} = \frac{\text{distance in question}}{\text{total distance}}$$: CORRESPONDING PERCENTAGE A VALUE IS WITHIN TWO OTHER VALUES

Note that here in this specific example, that min.1 of line1, and min.2 of line2 are actually the same value of 3.

$$\% = \frac{3.5 - 3.0}{5.0 - 3.0} = \frac{0.5}{2.0}$$

% = 25% : It could be said that 3.5 is 25% of and-or along the way of the distance or length from 3.5 to 5.

Now solving the original problem stated:

$$\frac{(10 - 7)}{(15 - 7)} = \frac{3}{8} = 0.375 \quad \text{or} \quad 37.5\%$$: This could be stated as "10 is at the 37.5% point in the range from 7 to 15". Or, "37.5% of the range from 7 to 15, is 10".

Likewise, given a certain indicated percentage (ie. the percentage rate or simply the rate) between some range of values, the corresponding value to that percentage can be found:

Solving for max.1 that is in the above formula:

max.1 = min.1 + (%) (max.2 - min.2) : CORRESPONDING VALUE TO A PERCENTAGE RATE WITHIN TWO VALUES (The minimum values are also the same.)

You can think of max. 1 as the number that is somewhere between the range of values of min. 2 and max. 2.

```
             0%                                                100%
        --------|--------------|--------------------------------------------|--------
. . .         min.2                                                       max.2      . . .
              min.1          max.1
```

Ex. Using values from the above example, what value corresponds to 25% (0.25 = 1/4 = "one-fourth") of the range from 3 to 5?

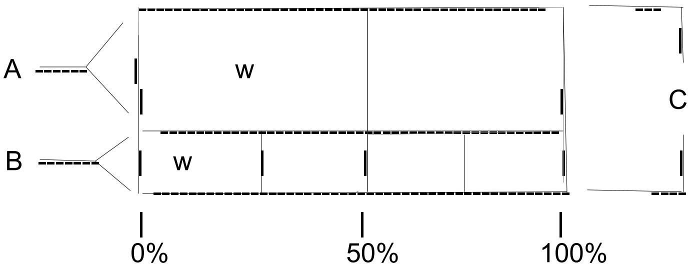
$\text{value} = \text{max.1} = 3 + (0.25)(5 - 3)$
$\text{value} = \text{max.1} = 3 + (0.25)\ 2$
$\text{value} = 3 + 0.5$
$\text{value} = 3.5$

Note also that if the min. values, or the "starting points", were at 0, then the equation simply reduces to:

$\text{max.1} = \text{min.1} + (\%)(\text{max.2} - \text{min.2})$
$\text{max 1} = 0 + (\%)\ (\text{max. 2} - 0)$
$\text{max 1} = (\%)\ (\text{max.2})$

A NOTE ON COMBINING PERCENTAGES

The ingredients for some manufactured products identified as Product A and Product B are to be combined to produce Product C. If 50% of Product A is water, and 25% of Product B is water, what percent of Product C is water (w)? [FIG 11]



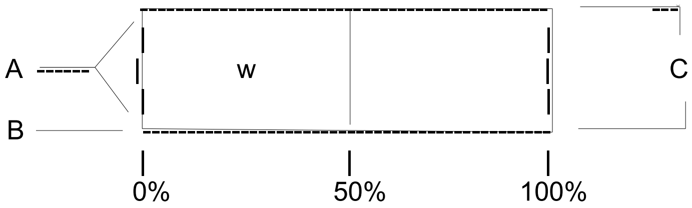
To begin with, the answer is **not** the sum of the percentages: 50% + 25% = 75% : a wrong method and solution

In general, the answer is also **not** the average percentage: $\frac{50\% + 25\%}{2} = \frac{75\%}{2} = 37.5\%$

This is so since the percent values are in reference, or with respect to, two different things, here Product A, and Product B, rather than just one thing in question.

That is, in general, relative values (ie. percentage values such as 50% and 25% here) cannot be combined by addition or averaging to produce another relative value. The only exception is when the units (perhaps weight or volume) of both (or more) products being combined have the same actual value or measurement.

Now consider product B getting smaller and smaller in weight, but still, 25% of it is water, even if its an negligible amount. The entire amount of units of Product C, including the amount of water, will also get smaller and smaller due to Product B getting smaller and smaller. As the actual units or amount of water in Product B becomes very small and meaningless, the percent of water in Product C will approach nearer and nearer to that of Product A. Hence, Product C will then contain only the water from Product A which is 50% water during that condition, and it is obvious that the percentage values cannot be simply combined to find the total percentage value for this kind of problem: [FIG 12]



: If Product B was very small negligible amount, it would still consist of 25% water.

The following is correct, but it is unsolvable given just the values mentioned:

Product C = product A + product B

This is also correct, but it is unsolvable given just the values mentioned, because we need their specific amounts.

Product C water /=/ 50% of product A + 25% of product B

To find the actual percentage of water in Product C, you must first know the actual amount (not just a relative value(s)) of water in both Product A and Product B. If Product A weighs 200grams, then 50%, or 200g x 0.50 = 100g is water. If Product B weighs 60grams, then 25% or 60g x 0.25 = 15g is water. When combined, Product C will contain:

Amount of water in Product C = Amt. of water in Product A + Amt. of water in Product B
Amount of water in Product C = 100g + 15g
Amount of water in Product C = 115g

The total weight of Product C is:

Weight of Product C = Weight of Product A + Weight of Product B
Weight of Product C = 200g + 60g
Weight of Product C = 260g

Technically, grams is a measurement of the mass (ie. a measurement of the amount of physical matter, atoms) of a substance and not the weight (a force due to gravity) of that substance. However, mass and weight are physically directly related, and mathematically proportional to each other. The ratios of two values with units of mass (such as grams), will be equal in numeric value to their corresponding ratio of their weights (such as units called Newtons).

If 115g of Product C is water, then 115g is: $\frac{115\text{g}}{260\text{g}} = 0.4423 = 44.23\%$ of the total weight of Product C is water.

If it was initially indicated that the amount of water in Product B is equivalent to 30% of the water in Product A, an equation for the relative amount of water in Product C in relation to only Product A, can be derived without knowing any specific values (amount of water, or weight) for either Product A or Product B. The amount of water in Product B is now indicated in reference to the amount of water in Product A, hence the amount of water in Product B is a fraction (here 30% = 0.30) of the amount of water in Product A and which is a fraction (0.50 = 50%) of Product A. Hence, the amount of water in Product B is a fraction of another fraction. The basic solution here is to substitute the mathematical equivalent of the amount of water in Product B with a value mathematically expressed in relation or respect to, or in reference of (ie. "in terms of") Product A. This will help create a simpler and-or a solvable equation:

water in Product C = water in Product A + water in Product B
water in Product C = (50% of Product A) + (30% of the water in Product A)
water in Product C = 50% Product A + 30% of (50% of Product A)
water in Product C = 0.50 Product A + (0.30 x 0.50) of Product A
water in Product C = 0.50 Product A + 0.15 Product A combining like values with the same units or "terms":
water in Product C = (0.50 + 0.15) Product A
water in Product C = 65% Product A : note, Product C still contains the amount of water in Product B, even though Product B is not included in this last expression. Also, the original description, only 50% of Product A is water, but in this expression here, the amount of water in Product C is expressed as being 65% of the water in Product A since this value includes, or takes account of, the percentage of water in Product B.

Ex. A mixture of 8 ounces weight (rather than volume or space measurement) contains 10% sugar by weight. If 1 more ounce of sugar is added into the mixture, what total percent of the mixture is now sugar? Let's first find out the number of ounces of sugar that were originally in the mixture, and then add 1 more ounce to that so as to find the total weight of sugar in the new or modified mixture:

total amount of sugar in the original mixture = (8 ounces)(10%) = (0.10) 8oz = 0.8oz

total amount of sugar in the new mixture = original amount + added in amount = 0.8oz + 1oz = 1.8oz

$$\text{percent of sugar in the new mixture} = \frac{\text{total amount of sugar}}{\text{total amount of mixture}} = \frac{1.8\text{oz}}{8\text{oz} + 1\text{ oz}} = \frac{1.8\text{oz}}{9\text{oz}} = 0.2 = 20\%$$

PERFORMING OR EXPRESSING DIVISION WITH MULTIPLICATION

The concept and process can be useful for re-expressing or simplifying expressions, and is as follows:

$\frac{\text{dividend}}{\text{divisor}}$ or = $\frac{\text{numerator}}{\text{denominator}}$ equals these expressions:

$$\left(\frac{\text{dividend}}{1}\right)\left(\frac{1}{\text{divisor}}\right) = \text{(dividend) (reciprocal of the divisor)}$$

Hence an alternative to division is to multiply by the reciprocal value of the divisor.

The process of finding the reciprocal is somewhat defeating to the entire process since it in itself normally requires division. However, the concept is important since it shows how to express or convert a division problem to one of a multiplication problem. Most people also find it easier to see and-or to perform multiplication than division, hence it is helpful to express an equation that uses some multiplication rather than division.

Ex. $\frac{1234}{5} = \frac{1235}{1}\left(\frac{1}{5}\right) = 1234\,(0.2)$: = 246.8

If you make a table of the reciprocals of the prime numbers, you can then solve for (non-prime) composite number reciprocals (which may or may not contain a fractional portion) by factoring the number into prime factors whose reciprocals are already known. Solving a reciprocal is therefore converted to a problem of multiplication. For example:

number	reciprocal of number = 1/number	
1	1	
2	0.5	
3	0.333333333	
5	0.2	
7	0.142857142	: clearly, the larger the number, the smaller it's corresponding reciprocal is

Ex. Find $\frac{5}{6}$

$$\frac{5}{6} = \frac{5}{1}\left(\frac{1}{6}\right) = \frac{5\,(1)(1)}{(2)(3)} = \frac{5}{1}\left(\frac{1}{2}\right)\left(\frac{1}{3}\right) = 5\,(0.5)\,(0.333333333) = 0.833333333$$

Note above, that the prime factors of 6 are 2 and 3. If you multiply the reciprocals of 2 and 3, you will have the reciprocal of 6:

$$\frac{1}{6} = \frac{1}{(2)(3)} = \frac{(1)(1)}{(2)(3)} = \frac{1}{2} \times \frac{1}{3} = 0.5 \times 0.333333.. = 0.166666666\underline{7}$$

Ex. Find $\frac{1}{0.6}$

First using an equivalent fraction method:

$$\frac{1}{0.6} = \frac{1\,(10)}{0.6(10)} = \left(\frac{1}{6}\right)10 = \left(\frac{1}{3}\right)\left(\frac{1}{2}\right)10 = (0.333333333)\,(0.5)\,(10) = 1.666666666$$

Now using the concepts of "scientific" and exponential notation:

$$\frac{1}{0.6} = \frac{1}{(6)(10^{-1})} = \left(\frac{1}{6}\right)(10^{+1}) = \left(\frac{1}{3}\right)\left(\frac{1}{2}\right)(10) = (0.333333333)(0.5)(10) = 1.666666666$$

AVERAGE

An average is a single numerical value that can be used to represent an entire set of group numerical values. The average will always be a value between the minimum and maximum values of the specific set of data values given or used, and may, or may not, be equal to any member of that set of values. The mathematical definition of average is (initially, or loosely) based upon the "half-way" or "center-point" point between two values of which you can imagine as the "end-points" on a line-segment (a small part or section of an infinite line) which bound that half-way or "middle" point:

```
<-------------------|-----------------------------------------|-----------------------------------------|--------------->
                min. value                               mid. value                                  max. value
                                                       "half-way" value
```

$$\text{"half-way" value} = \frac{\text{sum of two values}}{2}$$

:Halfway (or "mid-point" between two values) Value Formula
The two values in question can be called the extreme
values or "end points".

The value or distance from both of the two end points (ie. the minimum and maximum extreme values) to the "half-way" point is exactly the same. The total distance or value between those defining, bounding, or end points is equal to the length or difference between those two points or values:

difference = maximum value - minimum value : a (numeric) difference is the amount of (numeric) separation, and is also known as the change in one value with respect to, or in reference to, another value.

The halfway-value formula is only slightly intuitive and may need some further explanation. First, the formula is based on the half (or half-value) of any given number, and that half of a value is equal to the given value divided by 2:

$$\text{half-value of a number} = \frac{\text{number}}{2}$$

: here number is actually equal to the max. value, and 0 is equal to the min. value in relation to the "half-way" value formula. This could be expressed as:

half-value of a number
or "halfway" from 0 to number

$$= \frac{0 + \text{number}}{2} = \frac{0}{2} + \frac{\text{number}}{2} = 0 + \frac{\text{number}}{2} = \frac{\text{number}}{2}$$

The value of half of a number, is also (equivalent to) the "halfway-value" between 0 and that given number. This "halfway-value" is half of the "distance" or amount from 0 to number. This value is exactly between those two given values, and is therefore said as being "equidistant" (equal, or equivalent, in distance) from them. Here, 0 can be considered as the starting or minimum value of this distance (or range of values), and number can be considered as the ending or maximum value of the distance (or range of values).

Note, for ex., if given 6 things, it is incorrect to consider the average as being a value between the third and fourth thing:

```
                        Between 3 and 4 , is  3.5 , =  the value between  3 and 4, and is not the average of 6.
                                                  3.5 is actually the average value of 3 and 4 = (3 + 4)/7 = 7/2 = 3.5
      ( 6 things)                       ↓

```

The average (point or location, the "halfway-point") is a numerical value (formally defined as) between two values or numbers is considered as being between a min. value, and a max. value, and for here, it is: 0 and 6. That is, 0 is actually the (unspecified) min., or "start value" (to consider, or include in the calculation, so as to consider the distance or values between 0 and 1), and it is actually the reference value of what 6 is in reference to, and therefore, 0 must also be considered for the average. (6 + 0) / 2 = (6/2) = 3 (and not 3.5) . 3 is technically the equidistant value from 0 and the max value 6. Consider that length or distance values start at 0, and not 1, that is, there is still some distance to consider between 0 and 1 which cannot be ignored. This will also account for the average of fractional values (ie. less than 1). A single value, such as 6, technically, does not have an average among several values to consider. Still, you can divided any number or value into two equal valued parts by dividing it by 2. Consider that If you had some data values all being near (about, close to), or even the same value of 8, and therefore, the average, common or typical value would be said as being about 8, and not (8+0)/2 = 8/2=4. In short, the average value of a set of data or values, may not even be the "half-way" or "mid value" as when 0 is considered, and therefore, it is generally incorrect to consider an average or representative value as the same thing as the "half-way" value.

Sometimes the word "range" or "range of values" is used as a generalized indication of the distance or separation (difference) between the min. and max. values. This may be spoken as something like, for example: "the range of the data values or numbers start at 300, and end at 400", or "the (range of) values go from 300 to 400". The specific size of this specific range (of data values) is the difference between the maximum and minimum values, and here, it is:
(400 - 300) = 100. If you had several various data values, of say having values that are between or within 500 and 600 in value, the (entire) range of values is still 100 since (600-500 = 100). It could also be said that the rage of values extends from, and-or, are within the values of, or from, 500 to 600.

Don't confuse the actual "half-way" point value with half of the distance or physical length (ie., a difference) between the two points. For example: Given values of 103 and 105, the half-way point or value is 104, and the difference or length between these defining, bounding, or extreme points is only 105 - 103 = 2, and half of this distance is just 1. Clearly, the "half-way" point or (data) value (of all the data values), and the half-length (ie., half of the difference or (range)) distance between the max. and min. extreme values, or "end points", is not the same concept and-or value.

Given 0 and 10, what is the "half-way" or "middle" value?

$$\frac{10 + 0}{2} = \frac{10}{2} = 5.0$$

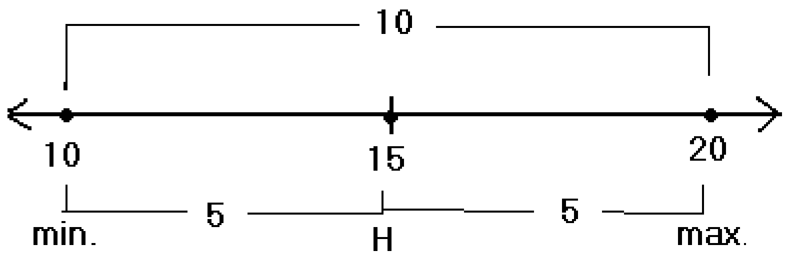
In the example.

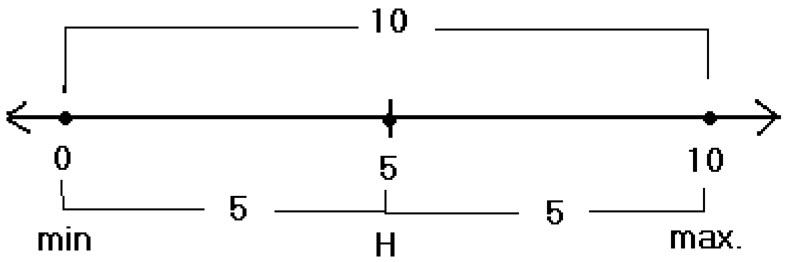
difference = max. - min = 10 - 0 = 10. This also verifies the "halfway-point", or "point-halfway", value formula above. 5 is both the halfway value (between 0 and 10) and is also equal to the difference (here, 5) that this halfway values is from both of the extreme or end values, here 0 and 10. Clearly, as expressed, 5 equal to just half of the difference (here indicated as: max - min. = 10 - 0 = 10) in the two given values, as seen expressed as: 10/2 = 5. The distance from 5 to the two "end points" is the same, so therefore, twice (2) of the "halfway" value" (here 5) that is between the two given extreme or end values is equal to the sum of those two values (here, 0 and 10 = 10).

(halfway-value) x 2 = sum of the two values. Therefore, mathematically:

halfway-value = sum of the two values / 2 :as expressed in the initial formula.

At this point in the discussion, we can consider this illustration given these two sets containing just two numbers:
(10 and 20), and (0 and 10): [FIG 13]





In both cases, the difference (D) from, or between, the minimum value to the maximum value is (max. - min) = 10, and half of this difference is 5. H is the halfway point and value between the minimum and maximum values. Also:

H - min. = max - H : = D/2 = (max. - min.)/2
Adding min. to both sides of this equation:

H - min + min = max - H + min since a value added (here, min), and then subtracted is equal to adding 0:
H - 0 = max. + min - H : adding H to both sides:
H + H = max. + min = - H + H combining 1H + 1H, we get (1 + 1)H = 2H
2H = max. + min. expressing the division of both sides by 2, and canceling common factors:

$H = \frac{\text{max + min.}}{2}$: formula for the halfway point or value between two values

Also: H = min. + (D/2) = max. - (D/2) : since (H-min) = (D/2) and (max-H) = (D/2)

However, even with all that has been mentioned, an average value is only based on the "half-way" value concept, and it is incorrect to use this as a general way or formula to find the average of any set of values, especially where there is more than two values in the set to consider. An average is only equal to the half-way value if there are only two values involved. When more than two values are involved, another more generalized formula for an average must be used, and this will be derived (developed) in the discussion that follows.

Given a set that contains (data) values which are identical, it is common sense that the representative or average value of those values is equal to any one member of that set.

Ex. A set contains 100 and 100, what is the average?

average = 100 : since a value of 100 is said to, or can represent this set (all the values) very well.
You could say something also like: "The typical or representative value is 100".

Considering the last example, if one or more of the values is only slightly different, it is fair to say that the average will still be about the same value of 100. For example, if this new set contains values of 100 and 101, what is the average? You can make an estimate of the average here at being slightly higher than 100. The actual average is 100.5

Ex. A set contains 5, 5, and 5, what is the average?

average = 5 :5 is said to represent this set very well.

Even though the average of the above sets is quite obvious, what is a numerical formula for this average given any set which contains all the same values? Notice that the sum of the values ("elements", "members", or "data") of the set (list or group of things related) divided by the number of individual values or members (of that set) is equal to the average value of that set of values:

$$\frac{100 + 100}{2} = \frac{200}{2} = 100$$

$$\frac{5 + 5 + 5}{3} = \frac{15}{3} = 5$$ now expressing this into a general formula:

$$\text{average} = \frac{\text{sum of values}}{\text{number of values}}$$: AVERAGE FORMULA (when all the data values are the same)

Given values that are not identical, say 2 and 4, what is their average? Does the formula above hold true for different values? It should be obvious that the average should not be either 2 or 4, since the values are not the same and are different to each other. As you may have guessed, after viewing the previous discussions, that the average is somewhere or a value between those two values.

Here is a representation of all the values from 0 up to any value that we can call or indicate as B. Letter (or mathematical variable) A represents the half-way point and average (A) of these two values:

0--------------------A--------------------B

Here, the value of $A = \frac{B+0}{2} = \frac{B}{2}$ since there is only two values involved and one value is 0.

If we assign the variable of C to represent the value of 0 above, we get:

C--------------------A--------------------B

$A = \frac{B + C}{2}$: formula for average of any two values

If we let both C and B increase by 1, you would expect their half-way point and-or average to increase by 1 also, and so that it is still "centered" or "midway" between them.

The average of 0 and 2 is 1. If the members of this set are increase by 1, the average (ie, the "center" of the two values) of this set would naturally be expected to also increase by 1. If the values increased by (1), such as values (0) and (2) increased by (1): (0+1) and (2+1), or= the new values of (1) and (3), their average is now equal in value to the average of (0) and (2), and also increased by (1). The new average value is: (old average + 1) = (1 + 1) = 2.

Let's verify this concept a bit more mathematically in equation forms:

Let's see if this equation is correct: $(A + 1) = \frac{(B+1) + (C+1)}{2}$ simplifying the right side:

$A + 1 = = \frac{B + C + 2}{2}$

Since we know that $A = \frac{B + C}{2}$ we can substitute this value for A into the previous equation:

$\frac{B + C}{2} + \frac{1}{1} = \frac{B + C + 2}{2}$ creating like fractions, as needed for their addition, on the left side:
(: note 1 = 1/1 = 2/2, and then combining fractions of the left side:)

$\frac{B + C}{2} + \frac{2}{2} = \frac{B + C + 2}{2}$ combining fractions on the left side:

$\frac{B + C + 2}{2} = \frac{B + C + 2}{2}$:checks

Ex. The average of 2 and 4 is: $\frac{2 + 4}{2} = \frac{6}{2} = 3$, now consider:

If one member increased by 1, and the other member decreased by 1, you would expect the average to remain the same in order to still remain "centered" between the two. This is verified below, where C is decreased by 1, and B is increased by 1:

$A = \frac{(C - 1) + (B + 1)}{2} = \frac{C - 1 + B + 1}{2}$ simplifying using the commutative law of addition:
Also note that: $-1 + 1 = +1 - 1 = 0$

$A = \frac{B + C}{2}$: checks , the average remained the same

Ex. Using the last examples values: $\frac{2 + 4}{2}$

$$\frac{(2 - 1) + (4 + 1)}{2} = \frac{1 + 5}{2} = \frac{6}{2} = 3$$

Now, let's give some verification to general average formula when the average of more than two different values is to be found:

Average 100 and 100. According the above discussions:

$\frac{100 + 100}{2} = \frac{200}{2} = 100$

If we average 99 and 101, the average should be, and somewhat obviously a value between those two values: = 100

$\frac{99 + 101}{2} = \frac{200}{2} = 100$

Likewise, now average 98 and 102, and we should expect the result to be the same:

$$\frac{98 + 102}{2} = \frac{200}{2} = 100$$

Now with three values: 100, 100, and 100:

$$\frac{100 + 100 + 100}{3} = \frac{300}{3} = 100$$ which can be mathematically written or expressed as:

$$\frac{100}{3} + \frac{100}{3} + \frac{100}{3} = 33.333... + 33.333... + 33.333... = 100$$ combining (adding) the first two fractions we get:

$$\frac{200}{3} + \frac{100}{3} = \frac{300}{3} = 100$$

Now with other values: 99, 100, and 100:

$$\frac{99 + 100 + 101}{3}$$ which can be mathematically written as:

$$\frac{99}{3} + \frac{101}{3} + \frac{100}{3}$$ by combining (adding) the first and second fractions:

$$\frac{200}{3} + \frac{100}{3} = \frac{300}{3} = 100$$: and this is the same equation expressed above

Now, perhaps when it's less obvious:

Average 1, 2 and 297

$$\frac{1 + 2 + 297}{3} = \frac{300}{3} = 100$$ which can be written as:

$$\frac{1}{3} + \frac{2}{3} + \frac{297}{3}$$ which can be written or expressed as:

$$\frac{1}{3} + \frac{2}{3} + \frac{(200 + 97)}{3} = \frac{1}{3} + \frac{2}{3} + \frac{200}{3} + \frac{97}{3}$$ combining some terms:

$$\frac{200}{3} + \frac{100}{3}$$: same fractions as in the previous examples above, and this can even be expressed as:

$$\frac{100}{3} + \frac{100}{3} + \frac{100}{3} = \frac{300}{3} = 100$$ Giving verification to the general average formula, for when the values are not the same.

When finding the average, a data value of extreme value, either large or small, can effect the value of the average in such a manner that this average, if used, does not fairly represent most of the data values. For example:

The average of: 1, 3, 3, 5, 6, 7, 8 is = (1 + 3 + 3 + 5 + 6 + 7 + 8) / 7 = 33/7 = 4.71

Now here is the same set of data, but instead of a data item with a value of 8, there is a value of 300:

The average of: 1, 3, 3, 5, 6, 7, 300 is 46.43 : this new average is not even close in value to most of the values in this set.

Often, "extreme" values, when not to be expected and/or considered, are not to be used when finding the average. These "abnormal" values could be an indication of some type of measurement and-or communication error. Where the average value is concerned, they would be discarded (removed, ignored) and not considered (here added) in the sum of the set members, and in the number of the total members in the set.

The word average is sometimes referred to as the arithmetic mean ("in common with", or "about") or simply "mean". An average value of a set of data values, say a data set represented or identified as x, is frequently shown as an x with a bar-line over it:

$\bar{x}$: expresses and represents the average value a the set of values, here identified as set x

A common use for average is in finding a single value that can represent several values such as test scores or measurements. Average has widespread use in the branch of mathematics called **statistics**. In brief, a statistical value is a single and a particular representative value of many data values of a group ("ie., set) of data. A statistic provides a quick numeric grasp or understanding of a situation and can be used for estimates, expectations and-or predictions. Average will be discussed again further ahead in this book during the topics of average deviation and standard deviation, and due to that the topics of square roots and signed numbers need to be discussed first.

COMMON MONEY PROBLEMS

Money can be described as a medium of exchange or trade, and-or a storage of wealth. The concept of **bartering** is about negotiating the exchange or trade of products between two parties or people. For example, the products might be that one person has wheat, and the other person has pottery. Often one or both people do not have or need what the other party wants or has, and so a concept called "**money**" was created as a standardized exchange medium of which both people would be happy to and-or mandated to exchange and-or accept in place of the actual desired product that is unavailable, and then use that money later and elsewhere so as to purchase the product(s) they need.

Typical monetary (money) problems involve finding the total money value when given some whole dollars and coins (which essentially are fractions of a dollar or dollar unit), and how much change there is after a purchase. Here, change is the difference between the total amount given to pay for a product and the actual price of that product. When a product is purchased, often some extra money, such as paying with an even amount of dollars, is used to pay for the item(s), hence some value (ie., "change" or the difference) needs to be given back to you. Change in the monetary sense is often spoken as something like: "What you will get, or be given back, after a purchase". Some of the concepts of money and fractions, particularly with coins, has been previously discussed in this book during the topic of: adding money as fractions.

amount given - price = change : change essentially means the difference in, or of, values, hence it is mathematically equal to the amount of separation. When a value has increased or decreased, it is said to have changed since it is now a different value. The amount that is different is called the change value. The difference between any two values is also then called the change value, even if none of the values actually changed in value.

A good method to understanding money (particularly coins) problems is to understand the penny. For instance, someone might ask, "How many pennies are in a dime"? In the physical sense, the answer is none, since a penny is a coin, not a monetary value, and a dime is a separate coin unto itself. There is however the equivalent of 10 cents, not pennies, in a dime since a dime's 10 cent monetary value is equivalent to, or can represent, the monetary value of 10 pennies which is also 10 cents. Even though this question is probably "understood" by most, it may of been better to say, "How many pennies are equivalent (in monetary value) to a dime"?

The basic unit in our monetary system is the dollar. A penny's monetary value is defined as one-hundredth (= 1/100) of 1 dollar, and this value or "derived" (and fractional) unit is commonly called a cent. A cent is often symbolized as letter c, or c with a vertical line through it. The numerical representation of 1 cent is therefore:

$1 \text{ cent} = \frac{1 \text{ dollar}}{100} = 0.01 \text{ dollar}$: a cent is one-hundredth of a dollar ($1). Again, dollar is a unit of measurement here, and not a specific numeric value or variable. Cent is the name of a (smaller, fractional) unit of measurement derived from the (base of the monetary system) units of dollars.

A dollars' monetary value is therefore equivalent to 100 cents. Since (0.01)(100)=1.00, or (cent)(number of cents) = (total dollars), given some total number of cents, simply move the decimal point 2 places leftward (the same as dividing by 100) to find the decimal equivalent in dollars.

Ex. 365cents is equivalent to: $\frac{365}{100} = 3.65$dollars.

Likewise, given a total dollar value, simply move the decimal point two places rightward to find the equivalent number of cents.

Ex. $1.79 is equivalent to: 1.79 x 100cents = 179 cents : $ means dollars, and an indicated value is therefore in reference to, and has units called **dollars**
$ is called the "dollar symbol".

The monetary value of a nickel coin is equivalent to that of 5 pennies:

1 cent + 1 cent + 1 cent + 1 cent + 1cent = 1 cent x 5 = 0.01 x 5 = 0.05 : "five cents"

Here are the monetary values of the common coins:

COIN	CENTS (c)	DECIMAL EQUIVALENT (in dollars, $)	FRACTIONAL EQUIVALENT (of a dollar, $)
PENNY	1	0.01	1/100 = "one-hundredth of a dollar"
NICKEL	5	0.05	5/100 = 1/20 = "one-twentieth of a dollar"
DIME	10	0.10	10/100 = 1/10 = "one-tenth of a dollar"
QUARTER	25	0.25	25/100 = 1/4 = "one-quarter of a dollar"

Given several coins, to find the total monetary value, simply sum up the corresponding cent values for all the coins. If some coins are the same, multiplication can be used instead of repeated addition.

Ex. How much money is 1 quarter, 3 dimes, 4 nickels and 2 pennies?

COINS	MONETARY VALUE ($)	CENTS (c)	
1 quarter	0.25	25	: 0.25 x 1 = 0.25 = 25 cents x 1 = 25 cents
3 dimes	0.30	30	: 0.10 x 3 = 0.30 = 10 cents x 3 = 30 cents = 0.30
4 nickels	0.20	20	: 0.05 x 4 = 0.20 = 5 cents x 4 = 20 cents = 0.20
2 pennies	0.02	2	: 0.01 x 2 = 0.02 = 1 cents x 2 = 2 cents = 0.02
	+ ---------	+ ----------	
	$ 0.77 =	77c	

If you were to give 77c to someone, you could use the coins mentioned in the last example, however, to give the least number of coins, first find the highest number (multiple) of the larger (in monetary value) coins first and of which the total monetary value of those coins does not exceed the required change. As a simple example, rather than give 25 pennies for 25c, you could simply give 1 quarter for 25c. For the 77c example above, 25 cents (from 1 quarter) can go into (divide into) or be subtracted from 77 cents a total of 3 times with a 2 cent remainder:

$$\begin{array}{r@{\,}l} & 3 \\ 25 & \overline{)77} \\ & \underline{75} \\ & 2 \end{array}$$

: 3 quarters is (equivalent to) 75 cents = 0.25 x 3 = $0.75 = 75c

Since both dimes and nickels have monetary values larger than 2 cents, the only coin left to consider is the penny, and it takes two pennies to account for two cents monetary value. For this example, we find that the minimum number of coins to give is only 5 coins consisting of 3 quarters, and 2 pennies, instead of the 10 total coins listed above.

Ex. If you gave a 5 dollar bill to purchase an item that cost only $1.99, how much change should you receive?

amount given - price = change
$5.00 - $1.99 = $3.01

At the time of writing this book, pennies, and other coins, are still in widespread use, but they may be obsolete in the future, and hence this topic could then be considered a historical review of the times when they were available. At the time of this writing, a basic loaf of sliced sandwich bread, about 1 pound in weight, can be purchased at a thrift (low item cost, bargain) grocery (foods) store for about the price of: $1.25 . As of the year 2025, about half of the people are still using cash (ie., money) to purchase products, and the other half is using a debit or credit card associated with their bank savings and-or bank account.

Some Currency Exchange Rates

At the time of writing this book edit and edition at May 7, 2020, know that these values can vary by a few percent in just 1 day, and with a average tenancy to rather increase in value. Even if these values change, you can still use it for practical and historic comparison purposes.

1 English or Great Britain Pound (GBP) = $1.24 USD : **USD = United States Dollars , 1 cent = 1 penny = $0.01 USD**
$1 USD = 0.81 GBP or "sterling" = 106.26 Japanese Yen = 0.93 Euro (EU Union) = 7.10 Yuan (Chinese)
$1 USD = C$1.41CAD (Canadian Dollar) = 24.33 Peso (Mexico) = 74.43 Ruble (Russian) = 0.98 Franc (Swiss)
$1 USD = 50.56 Philippine Peso = 5.72 Brazilian Real = 15.73 Egyptian Pound = 7.75 Hong Kong Dollar
$1 USD = 3.52 Israel New Shekel = 1.66 New Zealand Dollar = 4.22 Zloty (Poland) = 18.74 Rand (South Africa)
$1 USD = 1225.54 Won (South Korea) = 6.70 Trinidad And Tobago Dollar = 23445.50 Dong (Vietnam)
$1 USD = 607.69 CFA franc (West Africa) = 33.09 Birr (Ethiopia) = 76.05 Rupee (India) = 42105.00 Rial (Iran)
$1 USD = 1.55 AUD (Australian Dollar) = 4.47 Leu (Romania) = 7.21 Lira (Turkey) = 55.30 Sudanese pound
$1 USD = 582.0 Somali (Somalia) Shilling = 931.79 Rwandan (Rwanda) franc = 159.01 Pakistani Rupee
$1 USD = 12 Cedi (Ghana) = 1 Panamanian Balboa (PAB, Panama and some other countries, often islands)

The unit of money in the United States of America is the dollar. 1 dollar = $1 , A fraction of a dollar is usually expressed in the number of cents (ie., from the word percent) of a dollar. 1 cent is 1percent of a dollar. 1 dollar = $1 = 100 cents = 100c. A price of an item expressed as: $dollars.cents = dollars + cents of a dollar = dollar + cents
Ex. $1.75 = 1 dollar and 75 cents = $1 + 75c

Common United States Coins: quarter = a quarter of 1 dollar = $1/4 = $0.25 = 100c / 4 = 25c
dime = a tenth of 1 dollar = $1/10 = $0.10 = 100c / 10 = 10c
nickel = one-twentieth of 1 dollar = $1 / 20 = $0.05 = 100c / 20 = 5c
penny = one-hundredth of 1 dollar = $1 / 100 = $0.01 = 100c / 100 = 1c = "1 cent"

The **Euro** dollar became available in Europe on January 1, 2022

Before the "decimalization" of the British monetary system on February 15, 1971:
The unit of money in the England is the **pound** (L), and is sometimes called a (slang) "**quid**" meaning "an exchange of".
1**L** = 20 **shillings** = 20**s** , hence 1s = (1/20) L = 0.05 L , A shilling is sometimes called a "**bob**".
1 shilling = 12 pennies (or "pence")= 12**d** , 2 shillings = 1 florin , 5 shillings = 1 crown
1 penny = 2 half-pennys = 4 farthings , hence 1 farthing = (1/4) of a penny
1L = 20 shillings = (20s)(12d / 1s) = 240d
Ex. L5.3s.2d = L5 , 3s , 2d = 5 pounds + 3 shillings + 2 pennies

After the "decimalization" of the British monetary system on February 15, 1971:
1 penny = 1p , 1 shilling = 5p , 1 florin = 10p , 1 crown = 25p , 1 pound = 1L = 100p

Some Metal Prices Per Ounce (On May 7, 2020, silver and gold also show the USD price at February 20, 2023) ,
Note: 1 oz of weight = 1 dry ounce = 1 oz = 28.35 g , 1g = 0.035274 oz. A "dry ounce" means for solids, and not "wet" or fluid or liquid ounces. (General for plain bullion (bulk) and-or scrap (waste, recycled) metals, and not for specific manufactured products):

Gold = $1684 USD / 1 oz and $1845 / 1 oz on February 20, 2023, In terms of bartering and receiving change when
using gold or silver, it is perhaps best to get small weights of it, such as 1/10 oz, 1/20 oz , and-or 1 to 5 gram
sizes.

Silver = $14.81 USD / 1 oz and $21.84 / 1 oz on February 20, 2023 and this is an increase of,
(new / old) = $21.84 / $14.81 = 1.47$\underline{5}$ or about 0.47 = 47% more than 1.0 = 100% , or calculated as:
change or difference = (new - old) = (21.84 - 14.81) = 7.03 and
(change from old / old) = (change from reference value / reference value) = 7.03 / 14.81 = 0.47$\underline{5}$

A 90% = 0.90 silver USD quarter weighs 0.22 oz, and therefore has (0.22 oz)(0.90) = 0.198 oz of silver , and has (price per ounce)(number of ounces) = ($21.84 / 1 oz)(0.198 oz) = $4.32 worth of silver as of Feb., 20, 2023. 5 of these old and worn-out "junk silver" quarters will weigh about: (5 coins) (0.198 oz / coin) =
= 0.99 oz =~ 1 oz.

Platinum = $752 USD / 1 oz , Palladium = $ 1712 USD / 1oz
Copper = $ 0.14 / 1 oz , Brass = $0.13 / 1 oz , Bronze = $0.07 / 1 oz , Aluminum = 0.04\underline{5}$ / 1oz , Lead = $0.05/oz
Nickel = $0.38 / 1 oz , Tin = $0.47 / 1 oz , Cobalt = $0.90 / 1 oz , Zinc = $0.06 / 1 oz
Steel = $0.028 av / 1 oz , Stainless Steel = steel with about 11% chromium or more = $0.038 / 1 oz

It is of note that although an object may weight say 1 ounce due to be constructed of a certain metal(s) for example, that product is usually many times that value due to manufacturing and many other associated costs to produce that product.

A **blacksmith** can take a piece of pre-made steel from a steel factory or scrap (left over, unused, to be recycled) metal, and cut and hammer (ie., "forge") it to produce a product. Before doing this, he may soften or "**anneal**" the steel by heating it hot and then allowed to slowly cool so that it is slightly softer to work with and less brittle, and this allows it to be more easily shaped and is less prone to breaking in the process. Once the steel has been worked into the desired shape, it is usually "**heat-treated**" so as to have a better, more uniform and stronger (atomic, atom) crystal structure that is more resistance to wear, that is, its harder. This process is usually done by heating the steel to a high temperature and then quickly quenching or dipping it in water or oil. Making the steel harder also makes it more brittle, This process may also be followed by what is called "**tempering**" the steel so as to help reduce its brittleness slightly and yet still maintain a fairly hard steel, and this process is to heat it up to a lower temperature, and then let the steel cool slowly.

One helpful tool a blacksmith can use for bending metal, either heated to be softer, more pliable, or even cold thin metal, is called a **flypress**. This heavy machine made of metal, has a large upper wheel where an input force is applied and then amplified to be a very large torque force of which then causes a large screw and its tip to make contact with the metal being worked, and so as to easily bend it, punch holes in it, etc. Pre-shaped metal forms can also be used to help make a consistent product by bending the metal upon its surface.

It is of note that a blacksmith may routinely, mechanically force some extra air (ie., containing oxygen) into the fire and-or coals that are combusting and releasing heat or thermal energy. Extra oxygen helps improve the combustion efficiency and-or rate of burning or combustion. When wind blows onto a hot coal and-or fire it will burn (ie., combust) more and get hotter. A fire-pit dug into the ground and-or surrounding a fire or any other open flame helps prevent unwanted fires. A **fire** can be considered a slow and-or moderate (ie., not an explosion) form of **combustion** which is a (fast) chemical reaction which utilizes oxygen, and in which heat and light are produced as long as there is fuel (ie., source of the energy) which includes and-or requires oxygen to do so. To start or ignite a fire usually requires a hot, heat source applied to the fuel (ex., wood, gasoline, oil, all of which are hydro-carbon, life based, but fuels such methane or natural gas is also made in the Earth). Once ignited, a fire will continue like a self-sustaining chain-reaction without an outside heat source since the fuel being combusted itself is now the heat source.

Metal parts such as screws, nuts, bolts, springs, gears, and washers are often standardized. The main types of screws are wood screes for wood, and machine screws for metal. A typical machine screw will have a length and a thread count per inch (tpi) or centimeter. The type of "head" and-or tool needed to set a screw in place is also important such as the cross-head, straight head or hex-head. Metal parts and tools such as sockets and wrenches are made to either an

English size or Metric size. Metric sized parts and tools are becoming more widespread and common in the U.S.A.

Metals such as gold, silver, platinum, palladium are relatively rare and are known as "precious metals" and which mostly means that they are valuable in some way(s). These metals (except silver which can tarnish easily) are often needed for some modern technology such as plating steel electrical contacts so as to reduce rust (Iron-oxide caused by oxygen and water on iron or steel) corrosion (here, slowly dissolving, like in an acid) and maintain good electrical contact for power and signal conduction. Gold has been used for plating metals(s) to make them look impressive and to prevent rusting and-or corrosion. The "platinum group" of metals consists of: platinum, palladium, iridium, osmium, ruthenium and rhodium. A common use for thee metals is in the medical field since they are not easily reactive (such as oxidation or rust, corrosion) to their environment. Some of these metals are used in catalytic converters that reduce the amount of the pollutants in the exhaust of combustion engines, and this is done by a chemical reaction of the exhaust gasses upon the surface of the metal.

WERE THINGS REALLY CHEAPER "BACK THEN"?

Consider this example so as to find out if things were really cheaper (less expensive) in the "old days" (previously, in the past, years ago, decades ago). This method of analysis will compare, in a relative manner (by using percentages; %), the price of the same product to the minimum labor wage (income) per hour. This method of analysis can also be used for the current situation of one or more locations (cities, states, countries, etc), and which depends upon the current local (supply, demand, etc) economy there.

Price of a product as a % of Minimum Wage = (Price of product / Minimum Wage) x 100

Year	Price	Minimum Wage	Price of a product, as a % of Minimum Wage	
1930	$0.15	$0.75 per hour	20.00%	: 15 cents or hundredths of a dollar or 100 cents = 15/100
2017	$1.25	$6.50 per hour	19.23%	: 125 cents or pennies

This analysis shows that the price of a certain product in the year 1930 was about the same percentage, and in fact, it was slightly higher "back then", and hence, it was slightly cheaper in 2017. 15c is certainly cheaper than $1.50 or 150 cents, but the percentage and-or actual cost of that item for the consumer is about the same as it was "back then". Often, modern production methods and the greater availability (distribution, transportation, selling price, fair competition) of some resources have, or can, effectively reduce the average selling price of an item(s) for consumers (people purchasing the product). This analysis does not mean that all items were effectively cheaper "back then", and the analysis must be considered for each specific item in question.

Associated with the above concept is the topic called **value shopping.** For example given two similar quality products for sale that may have a different quantity and-or different price, how can we value shop so as to find the best value in terms of having the lowest cost? To do this we can find the cost per ounce or pound of each item and then compare them:

$\frac{\text{total cost of item 1}}{\text{total ounces of item 1}}$, and compare this to: $\frac{\text{total cost of item 2}}{\text{total ounces of item 2}}$: both fractions will find the cost per ounce of the associated item, when the division, "reduction" (to lowest terms) or cancellation takes place.

POWERS

Whereas on a fundamental level, multiplication is the sum of the repeated addition of the same number, the **power** of a number is the product of the repeated multiplication of the same number. The number (ie. the factor) used for the repeated multiplication is formally known as the **base** of the power or resulting value of it. You could say that the base of a power is what the power value to be found is based upon, sourced, rooted upon, or derived from. A power of a number is the result of the repeated multiplication of the base value.

The "shorthand" notation used to represent this repeated multiplication is called exponential notation. You can basically view and think of it as the "power operation". This notation or expression of a power uses the base (effectively the multiplicand) value, and the number of times (ie. the multiplier) the repeated multiplication of it by itself is to occur is indicated by a value formally called the **exponent** (or the exponent of the base, and-or indicated (expressed) power). For example, 10 x 10, or = 10^1 x 10^1, can be represented or expressed using an exponential or power form as 10^2. 10 is the base, and 2 is the exponent of the base. 10 x 10 = 10^2 = 100. Sometimes an exponent is called the power indicated or the indicated power of a number. In a more technical definition, the exponent indicates the number of times that the base is to be multiplied to an initial value of 1. Every value has a factor of 1, and multiplying any value by 1 will not affect it.

Also note this similarity to addition:

Since multiplication = repeated addition, and powers = repeated multiplication (a multiple, of a multiplication), in a logical kind of way, powers could be considered as (multiples of) repeated addition. This concept, or the link to addition, is generally not considered much in applied or everyday mathematics, but it is a deeper understanding if you need it.

Here is the formal or general expression and equation for a power value:

$\text{power} = \text{base}^{\text{exponent}}$: GENERAL POWER EXPRESSION OR "FORMULA"
or:

power = base^exponent : GENERAL POWER FORMULA
This book mostly uses the carat symbol = ^
to indicate an exponent, rather than use
superscript values (numbers or letters).

If you were to call the power value as "number", and use N as a shorthand or symbolic identifier for it, and likewise, use (b) for base, and (e) for exponent, we have this:

N = b^e : GENERAL POWER FORMULA
An common alternate notation is to use (x) for (e):
N = b^x

10 = 10^1 : "plain 10" without any exponent indicated is actually "ten to the first power"
10 x 10 = 10^1 x 10^1 = 10^(1+1) = 10^2 : "ten to the second power" = "the second power of 10"
10 x 10 x 10 = 10^1 x 10^1 x 10^1 = 10^(1+1+1) = 10^3 : "ten to the third power" = "the third power of 10"

Due to the associative law, this can be expressed or checked as:

10 x 10 x 10 : an "expanded" form of the expressed power of 10^3
(10^1 x 10^1)(10^1)
(10^2)(10^1) = 100 x 10
10^(2+1) = 10^3 = 1000

Clearly, when the base value (or variable as used in algebra) of the powers are the same, and are being multiplied, you can simply add their exponents and keep that same base for the simplified expression:

10 x 10 x 10 x 10 = 10^(1+1+1+1) = 10^4
10 x 10 x 10 x 10 = 10^(1+1+1) (10^1) = 10^3 10^1 = 10^(3+1) = 10^4

Ex. What is the third, and fourth power of 2 ?

2^3 = 2 x 2 x 2 = 8
2^4 = 2 x 2 x 2 x 2 = 16

Note that the last answer could also be found by multiplying the preceding power of 2 that was 2^3, by 2 = 2^1:

2^4 = 2 x 2 x 2 x 2 = (2 x 2 x 2) x 2 = 2^3 x 2^1 = 8 x 2 = 16

Note, frequently the words "exponents" and "powers" are exchanged for each other. For example, "ten to the second power", or "the second power of 10", really means a base of 10 with an exponent of 2. 2 is not the power, but the exponent or indicated power. (10^2) or 100 is the actual power (value, result) of 10 in question. Some older texts may use the word "index" (meaning the indicated power) instead of the word "exponent".

Given a number raised to a (integer or basic number) power, how many times greater is the next power? The answer is that the next power of a number is that number times greater:

Ex. 10^3 / 10^2 = 1000 / 100 = 10 = 10^1 : "one-thousand is ten times greater than one-hundred"

Ex. How many times greater is 4^3 = 64, than 4^2 = 16: 64/16 = 4 : "sixty-four is four times greater than sixteen"

Later in this book, all this can be generalized, or generally expressed as:
(Number^(n+1)) / Number^n = Number^(n+1 -n) = Number^1 = Number = N , and
N^(n+1) = N^1 N^n
Also, the difference between two successive integer powers of a number can be simply expressed as:
(N^(n+1) - N^n , Ex. 10^3 - 10^2 = 1000 - 100 = 900
A more formal formula for the difference between successive (ie., N^n and N^(n+1)) integer powers of a number is:
(N-1) (N^n) , Ex: With N=base=10, and n=exponent=2, difference = (9)(10^2) = (9)(100) = 900

Powers with any base, and an exponent of 2 are often called "squares". It gets this name from the fact that area is defined and measured (with its units) in reference or with respect to a basic square shape and unit of measurement for areas, which is a two-dimensional (ie., planar (plane) or "flat, level shape", having. a length and width dimension only, with no height or thickness), four sided enclosed figure, where each of those two dimensions is equivalent in length and having the same units of measurement. This is true even if the area being measured is triangular, rectangular, circular or any other possible bounded, limited or defined region of a (infinite) plane. The area of these shapes will be measured with respect to their equivalent number (ie. a multiple or repeated sum) of square units. A "square unit" is one unit long and (by) one unit wide. The units of any particular area shape are therefore that of the units of the two dimensions of a square (or "unit square") of which it (the area) is to be measured in reference (or compared to) to. Hence, an area value will have units of: units x units = units^2 or "square units". For example, an area might be stated simply as one value of 10 square feet, or 10 sq. ft., rather than say something like the area is 5 feet (units) long, by 2 feet (units) wide. Though the values of 5 feet and 2 feet are important measurements for something like a rug or piece of metal that you may need, the store may sell the rug or metal as priced per "square foot", rather than in the particular or specific sections or sizes that only you may need for a certain project.

Note: 10^2 is often referred to as "ten square" : here the (base) value of 10 is squared , 10^2=100 , but

10ft^2 is "ten, square feet" where only the unit of feet is squared, and not the base value of 10, that is, it is not equal to 10^2 ft = 100 feet or 100 square-feet

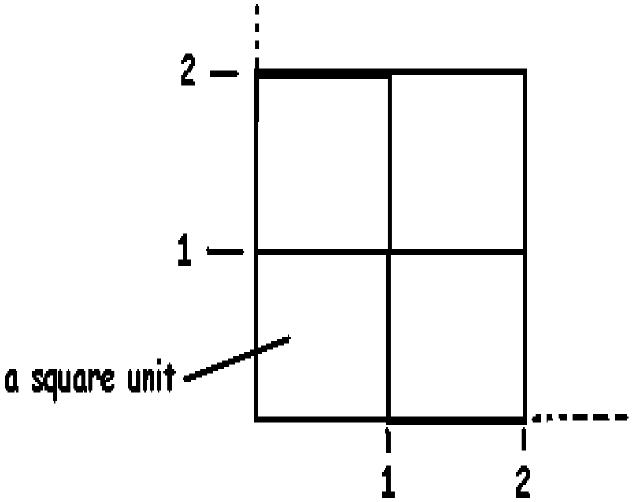
Ex. If you had a rectangular area that was 2 units long, and 2 units wide, the total area is:

square units in row 1 + square units in row 2

2 square units + 2 square units Since multiplication is repeated addition:

2 (2 square units) = 4 square units = 4 units square = 4 units x units = 4 units^2

[FIG 14]



Clearly, the area is 4 square units

Ex. If you had a rectangular area that was 2 units long, and 3 units wide, the total area is:

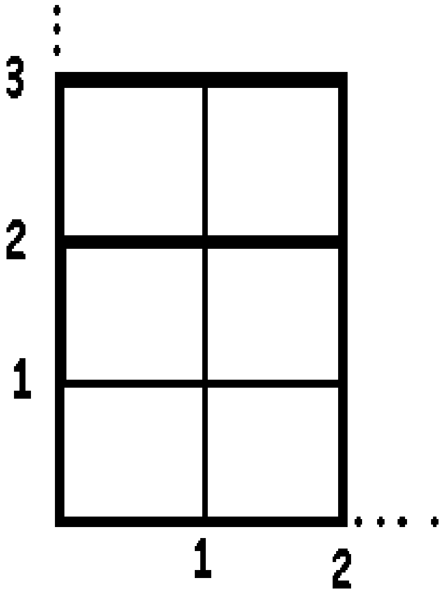
2 square units + 2 square units + 2 square units

3 (2 square units) = 6 square units = 6 units square = 6 units^2

Note also that: 3 units x 2 units = (3) (2) (1 units) (1 units) = 6 (1 units^2) = 6 units^2

We also see that the area of a rectangular shape is simply the product of the size (or measured length if you will) of each dimension (length and width) of the rectangle. This is so since multiplication (ie. for a product) essentially represents repeated addition. Here, the repeated addition is of similar squares or "square units" since each dimension of these squares have the same length and same units of measurement for that length.

[FIG 15]



Clearly, the area is 6 sq. units or 6 units^2

Ex. 5^2 can be called "five to the second power" or "five square" and equal 25.

The third power of a number is often called the "cube" of that number. This is from the fact that a certain (reference of measurement) volume called a cube (ie. a cube of space or volume) has three dimensions, each having the same basic units of measurement The dimensions are called the length, width, and height. A cube is very similar to a square area with its length and width units, but the cube also places a height of 1 unit above that flat planar square, and creates a (3-dimensional) "space" or volume. All possible volumes are measured in reference to a "cube unit" or "cubic unit" of volume where the (sides) dimensions are all 1 unit of length in value.

Note: number^3 = a number raised to the third power is sometimes called the cube of that number.
Ex.: 10^3 is sometimes called "ten cubed" , 10^3 = 10 x 10 x 10 = 1,000

If a value doubles (multiplied by 2), such as the side length of a square shape, it's square (ie. square area) will increase by four times. This is an example of a non-proportional or non-linear relationship of two values, where as when one value increases or changes by a factor, the other value increases or changes by some other constant factor. For the example shown below, the side lengths of a square change in a linear manner, but the corresponding area changes in an exponential manner, and the values of the area increase or change rapidly due to the squared value of its side length.

Ex. 1^2 = 1 if 1 is doubled to 2, its square is:
2^2 = 4 an increase of a factor of (4/1) = 4. If 2 is doubled to 4, its square is:
4^2 = 16 an increase of a factor of (16/4) = 4, if 4 is doubled to 8, its square is:
8^2 = 64 an increase of a factor of (64/16) = 4

Here is a mathematical verification of this increase, or magnification, factor, of 4:

4^2 = (1 x 4)^2 = 4^2 = 4 x 4 = 16
8^2 = (2 x 4)^2 = (2 x 4)(2 x 4) = 4 x 4 x 2 x 2 : this factor of 2 x 2 = 2^2 = 4 will always be present
= 4^2 x 4

If a value doubles (multiplied by 2), such as the length of a cube shape, it's cube (ie. volume space) will increase by a factor of 8.

Ex. 1^3 = 1 : a cube with a side length of 1 = a cube or volume of 1 cubic unit
2^3 = 8 : a cube with a side length of 2 = a cube or volume of 8 cubic units = 8 units^3.
8 is 8 times more than 1
4^3 = 64 : 64 is 8 times more than 8

Here is a mathematical verification of this increase or magnification factor of 8:

2^3 = (1 x 2)^3 = 2^3 = 2 x 2 x 2 = 8

4^3 = (2 x 2)^3 = (2 x 2)(2 x 2)(2 x 2) = (2 x 2 x 2)(2 x 2 x 2) : this factor of 2^3 = 8 will always be present
= 2^3 x 8 when the side length doubles, consider:

Given : area1 = side^3 , if side length doubles:
area2 = (2 side)^3 = (2^3)(side^3) = 8 side^3 = 8 area1

NOTE: It is incorrect to think that a cube is the second power (or numeric square) of an area such as that of a square. Give the side length (s) of a square area, its area is: Areas of the square = As = (s)(s) = s^2 . If this area was the side of a cube, its volume is NOT equal to Vc /=/ (As)^2 = (s^2)^2 = s^4, but is rather equal to Vc = (Vs)(s) = (s)(s)(s) = s^3. The reason for this is that given a square or square area with two dimensions, a three-dimensional cube only has one more physical or real dimension to be considered into the equation for an area.

8 cubic-feet = **8 ft^3** = 8 (1 ft^3) = (3$\sqrt{8}$)^3 (1 ft^3) = (2^3) (1 ft^3) = ((2)(1 ft))^3 = **(2 ft)^3** = **(cube root 8 ft^3)^3**

Be aware of what value is actually being raised to a power, and-or to properly express it as so, perhaps by using parenthesis to clarify the expression:

(0.5 in)^3 does not equal (0.5) in^3 = 0.5 in^3

(0.5 inches) cubed does not equal (0.5) cubic inches.

(0.5 in)^3 = (0.5 in)(0.5 in)(0.5 in) or= (0.5^3)(1 in)^3) = (0.5 in)^3 (1 in^3) = 0.125 in^3

AN OBSERVATION ON SQUARING VALUES

When a value (such as a base of a power) greater than 1 is squared or "raised" to any indicated power (ie. the exponent) greater than 1, the result is always a greater value than the value (the base) that was "raised" or increased to that power value.

Ex. $2^2 = 4$
$2^3 = 8$
$3.5^2 = 12.25$
$1^{1.01} = 1$
$1^{73} = 1$
$1.1^3 = 1.331$
$4^{1.0001} = 4.000554556$

Now note that when a value less than one is squared or "raised" to any other indicated power greater than 1, the result is smaller than the number itself. The greater the indicated power (ie. the exponent that the number is raised to), the smaller the resulting power value. Actually, multiplying any value by a (proper, less than 1) fractional value always results in a lower value. This is similar to the concept to having "a fraction, of a fraction", and the result is smaller than the original fraction.

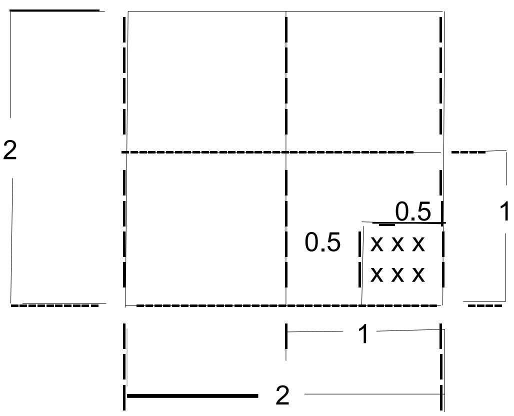
Ex. First, $0.5 = \frac{5}{10} = \frac{1}{2}$: "one-half. or one-half of one (whole)" , squaring this value we have:

$(0.5)^2 = (0.5)(0.5) = \left(\frac{1}{2}\right)\left(\frac{1}{2}\right) = \frac{1}{4} = 0.25$ and:

$0.25 = \frac{25}{100} = \frac{1}{4}$: "one-fourth or one-quarter of one (whole, all or entirely)". 0.25 is less than 0.5 , and sometimes this is indicated or mathematically expressed as: $0.25 < 0.5$, $<$ is the mathematical notation symbol for "less than", or "not equal to, but less than the following number".

Even though 0.5 is half of the length (1st dimension) on 1 unit, this value will only represent one-fourth of the area (a two dimensional concept) of one square, as indicated above when the value is squared.

A geometric representation of this is shown below. The largest square shape represents $2^2 = 4$. The shaded square represents $(0.5)^2 = 0.25 = 1/4$ (= one-fourth of one square. One square $= 1^2 = 1$). A unit square (or a squared unit) is the basic unit of measurement for measuring (2 dimensional) surface or planar (ie.,flat) areas. [FIG 16]



: consider this a square shape, if not displayed as so

0.5 is half (ie., 1/2) of 1, but when 0.5 is squared (ie., 0.5^2), it becomes smaller and is only one-quarter (ie., 1/4) of 1.

The third or cubed power of the value of 0.5 will be considered below. As mentioned previously, a unit cubed is the basic unit of measurement for (3 dimensional) volumes. You can consider a volume as moving a flat area (a plane, or planar area, having a length and width dimension only) through a height distance. Area and volume will be discussed to a greater depth further ahead in this book.

(0.5)^3 = 0.125 = 1/8 : One-eighth of one cube. One cube = 1^3 = 1.
It will take 8 of these cubes, each having a side
length of 0.5, to fill a single cube of 1 unit length.

Even though 0.5 is half of the length (1st dimension) of 1, this value will only represent one-eighth of the volume (a 3 dimensional concept) of one cube. In a reverse type of manner, it could also be said that if a length value (such as 0.5 here) doubles, the volume (or cubed value) will increase by eight times. If the length values is halved (divided by 2), the volume will decrease (a demagnification) by eight times.

Ex. 0.5^3 = 0.125 : 0.5 is half of 1, and its cube or volume is 8 times less than that of 1
1^3 = 1 : 1 is double or twice that of 0.5, and its cube is 8 times more than that of 0.5
2^3 = 8 : 2 is double or twice that of 1, and its cube is 8 times more than that of 1
4^3 = 64 : 4 is double or twice that of 2, and its cube is 8 times more than that of 2

These kind of relationships of the length to the areas and volume is not a constant or linear (mathematical, or numerical) relationship. For example, if the length doubles, the area and volume will increase, but they more than double. Area will increase by 4, and volume will increase by 8. This kind of non-linear (non-corresponding or the same growth or magnification [ie. multiplication of]) relationship is called an exponential relationship. Things that are said to be linear, are linearly related, that is, their mathematical relationship of their values is a linear or "line-like" relationship. Specifically, a mathematical relationship of or between two values is linear when the ratio (or rate) of the change of one variable with respect to the change of another variable is a constant value. Although this is of a topic to be discussed further ahead in this book, this can be mathematically expressing as: (change in variable1) / (change in variable2) = the rate of the changes, or simply the rate of change. For a linear relationship, the rate of changes between the two values or variables is a constant value. It can also be said that In a linear relationship, as one value, the independent variable changes in value by 1, the other corresponding or dependent value or variable will always change by the same constant value that is called the slope or "steepness" of the line. On a graph, a linear mathematical relationship between two variables can be shown as a line. In a non-linear relationship of values or variables, when one values changes by some factor, that the other does not change by some constant factor, but by a factor that is non-constant and is also changing, such as increasing or decreasing in value. The rate of changes between the two values or variables is then not a constant value. On a graph, their relationship can be shown to be some type of curve.

Special note on dividing expressed powers: If given an expressed power value of a number that contains the base (b) and the exponent (e), and if that power value is divided by a value (d), it is incorrect to divide either or both the base and the exponent by that divider. The true result is found only by dividing the actual total or number value of that indicated power by that denominator.

Ex. $$\frac{10\hat{}3}{2} \;/\!=\!/\; \left(\frac{10}{2}\right)\hat{}3 = 5\hat{}3 = 125, \quad \text{or } /\!=\!/ \;\; 10\hat{}(3/2) = 10\hat{}1.5 = 31.62 \;\;, \quad \text{the true result is: } \frac{(10\hat{}3)}{2} = \frac{1000}{2} = 500$$

A CHART OF THE VALUES OF A POWER WITH RESPECT TO THE BASE AND EXPONENT

First, N = 1^exponent = 1 : base is 1, and exponent is any value

N = base^1 = base : N=number=actual resulting (power) value , and base is any value

Considering only positive (greater than zero , > 0) valued exponents:

When the base is greater than 1: (base > 1): Examples:

base^(exponent < 1) 3^(0.5) = 1.7321 : (N < base)
base^(exponent = 1) 3^1 = 3 : (N = base)
base^(exponent > 1) 3^2 = 9 : (N > base)

When the base is less than 1: (base < 1): Examples:

base^(exponent < 1) 0.5^0.5 = 0.70711 : (N > base)
base^(exponent = 1) 0.5^1 = 0.5 : (N = base)
base^(exponent > 1) 0.5^2 = 0.25 : (N < base) , and here due to a fractional value times a fractional value results in a smaller fractional value.
A fraction of a another fraction =
(fraction2) (fraction1) = fraction3
Ex: 0.5^2 = (0.5)(0.5) = 0.25

MULTIPLYING LIKE VALUES

When multiplying like or similar values, variables (which can represent any value) or terms as in algebra, the result can be expressed as a power of that value; where the value becomes a base and whose exponent is the sum of the exponents of that value.

Note that a value without an exponent is considered or understood to have an exponent of one (1) For example: 3 = 3^1. The explanation of this is that a value to the first power is the first multiple by itself to an initial product of 1, and this is shown directly below, but may be skipped over if appears somewhat complicated for now:

For 3^1: 1 x 3 = 3 x 1 = 3 = 3^1 , : the first power of a number is equal to the first multiple or instance of that number which is the same as multiplying that number by 1. The first power of a number is equal to itself.

Note that 1 x 3 is technically equal to 1 repeatedly added to itself 3 times: 1 + 1 + 1 = (1)(3) = 3 = (3)(1) = 3 added to itself 1 time. It could be said that the first multiple of a number is equal to itself.

For 3^2: 1 x 3 x 3 = (1 x 3)(3) = (3^1)(3) = (3^1)(3^1) = 3 x 3 = 9 = 3^2 = 3^(1+1)

Ex. 5 x 5 = 5^1 x 5^1 = 5^(1+1) = 5^2 : Note: 5^1 x 5^1 /=/ 2(5^1) = 5^1 + 5^1 = 10
That is, you do not add the numerical coefficients of the same or like values when multiplying, but rather add their exponents.

5^1 + 5^1 = ((1)(5^1)) + ((1)(5^1) = ((1+1)(5^1) = 2 (5^1)
This is repeated addition of the like values. Add their numerical coefficients or factors for the resulting coefficient or factor of that value.

Remember that multiplication is associated with repeated addition, and powers are associated with repeated multiplication.

Ex. (4^1)(4^2) = 4^(1+2) = 4^3

checking: (4^1) (4^2) Or: (4^1)(4^2)
(4^1) (4^1)(4^1) (4)(16)
4^(1+1+1) 64
4^3 = 64 : 4 x 4 = 16, and 16 x 4 = 64

Ex . 2^2 + 2^2

Since this is repeated addition of a value (here, 2^2) twice, we can express this with multiplication:

2^2 + 2^2 = 2 x 2^2 = (2^1)(2^2) = 2^(1+2) = 2^3 : add the exponents of like factors to simplify

Checking: 2^2 + 2^2 = 4 + 4 = 8 = 2^3

As previously mentioned, try not to confuse the concept of adding like values with the concept of multiplying like values. When adding like values, their numerical coefficients are added and the variable is kept the same. When multiplying like values, their numerical coefficients are multiplied, and their exponents are added.

Ex. First add, and then multiply these two values: $5x$ and $2x$

Note, variables, such as x, are used here. If you are somewhat worried or unfamiliar with using variables, you can replace (or substitute) it with a (constant, unchanging, known, fixed or solid) numeric value. For example, if we let $x=3$, we would have: $5x = 5(3)$ and $2x = 2(3)$. Their sum would be:

$5(3) + 2(3) = (5+2)(3) = 7(3)$: adding the values. Checking:

$3(5) + 3(2) = (3+3+3+3+3)+(3+3) = 3+3+3+3+3+3+3$

Using the concepts and expression for repeated multiplication, the result is: $3(7) = 7(3) = 21$

$5x + 2x = (5 + 2)x = 7x$: adding the like terms.
Here, you can see (x) is a common factor to all the terms (here 5x and 2x), hence they are called "like-terms".

Checking: $5x + 2x$ Expressing the terms using repeated addition:
$(1x + 1x + 1x + 1x + 1x) + (1x + 1x)$ Which can be expressed simply as:
$(x + x + x + x + x) + (x + x)$ Now using the associative law of addition:
$(x + x + x + x + x + x + x)$ Expressing this repeated addition, of x, using multiplication:
$7x$

Note that for x and x^2, although being the same variable, they are not like terms since their exponents are different and therefore these (powers of the variable) represent two entirely different values. For example: $5x + 2x^2$!=, does not equal: $(5 + 2)x$, or $(5 + 2)x^2$, or $(5+2)(x + x^2)$

$(5x)(2x) = (5)(2)(x\,x) = 10x^2$: multiplying the like terms. Everything, both the numerical coefficients, and variables are to be multiplied together. This example is verified by the concepts of the associative law of multiplication that states that grouping (ie. associating) does not matter when multiplying, and the result will be the same.

Before moving on to another topic, another good point must be made. If given an (indicated) power value, that value can essentially be factored by using the same base with exponents values that sum up to that given exponent of the power. Using an example previously given:

Ex. Since: $(4^1)(4^2) = 4^{(1+2)} = 4^3$ we see that (4^1) and (4^2) are factors of the product 4^3, hence 4^3 can be factored to:

$4^3 = (4^1)(4^2)$: the factors of 4^3 can be any indicated (with an exponent) power of that base of 4, just as long as the sum of the exponents of all the "like factors" sum up to 3

$4^3 = 4^{(1.5 + 1.5)} = (4^{1.5})(4^{1.5})$

A POWER TO A POWER

If an indicated power of a value (base), or variable as in algebra, is itself raised to an indicated power, simply multiply the exponents for the resulting exponent (of that base) to simplify this type of expression. A simple verification of this is shown below:

First note: (5)^2 = (5^1)(5^1) = (5^1)^2 = 5^(1x2) = 5^2

Ex. (5^2)^2 = 5^(2x2) = 5^4

checking: (5^2)^2 = (5^2)(5^2) = 5^(2+2) = 5^4 : this check uses "extending" or "expanding" the indicated expression to a fuller form

or: (5^2)^2 = (5^2)(5^2) = (5^1)(5^1)(5^1)(5^1) = 5^(1+1+1+1) = 5^4

or: (5^2)^2 = (25)^2 = 625 = 5^4

To help understand this, we can remember that multiplication is a "shorthand" expression for a repeated addition expression.

Ex. (4^2)^3 = (4^2) (4^2) (4^2) = 4^(2+2+2) = 4^6 : showing the repeated addition of the exponents

(4^2)^3 = 4^(2x3) = 4^6 : showing using multiplication, instead of repeated addition, of the exponents

Ex. (0.7^2)^3 (0.7^2)^2 = (0.7^2)^(3+2) = (0.7^2)^5 = 0.7^10

checking: (0.7^2)^3 (0.7^2)^2
(0.7^6)(0.7^4)
0.7^(6+4)
0.7^10

A PRODUCT TO A POWER

This is very similar to a "power to a power" mentioned above, but the power that this product is being raised to will be "distributed" (shared or applied among, essentially multiplied) to the exponent of each factor of the indicated product when simplifying the expression.

Ex. (4 x 2)^2 = ((4^1)(2^1))^2 = (4^(1x2))(2^(1x2)) : Here, showing that the exponent was "distributed" (or applied) to each factor and its corresponding exponent..
= (4^2)(2^2)
= (16) (4) = 64

checking: (4 x 2)^2 = (8)^2 = 64 : Here, the expression in the grouping symbols was simplified first.

Ex. (2^2 x 3^2)^2 = (2^(2x2)) (3^(2x2)) = (2^4)(3^4) = 16 x 81 = 1296

checking: (2^2 x 3^2)^2 = (4 x 9)^2 = (36)^2 = 1296

We also see a rule can be developed here due to the above example. First, given a product of two (expressed) powers, and if the exponent is not indicated, it is understood as 1. The product of two numbers having the same exponent is the product of those numbers and whose exponent is that exponent. For example:

(2^2 x 3^2) = (2 x 3)^2 here is a verification using the above discussion, distributing the exponent:
(2^2 x 3^2) = (2^(1x2))(3^(1x2))
(2^2 x 3^2) = (2^2 x 3^2) : the result is the original expression on the left side, hence they are equivalent

Checking:

(2^2 x 3^2) = (2 x 3)^2
(2^2 x 3^2) = 6^2 : another, somewhat obvious, rule to observe here is that you can factor a product (here 6) to where each factor (here, 2 and 3) has the same indicated power
4 x 9 = 6^2
36 = 36

Ex. (9^0.5)(4^0.5) = [(9)(4)]^0.5 = [36]^0.5 = 36^0.5 : doing the reverse, you can factor the base of an indicated power, and each factor will have the same exponent

A SIMPLE EXPRESSION TO A POWER

The word simple in the title refers to addition and subtraction. First, a very important word of caution: You cannot simply distribute the power to the values being added or subtracted in an expression that is raised to a power.

Ex. (5 + 2)^2 /=/ (does not equal) ((5^2) + (2^2)) = 25 + 4 = 29

The correct result can only be found (when not using the order of operations directly) by performing the indicated operation. This is sometimes referred to as "extending" or "fully expressing" (the given expression) to the indicated power.

(5 + 2)^2 = (5 + 2) (5 +2)

To simplify this, especially when algebraic variables are used, requires you knowing about the distributive law of multiplication which will be shown later. Since only numeric values are used here, by using the order of operations, we can get the correct answer by simplifying the original expression which represents a value that could be simplified and-or expressed as a single number that is contained within the grouping symbols.

(5 + 2)^2 = (7)^2 = 7^2 = (7)(7) = 49 : basic simplification within the grouping symbols first, or by:

(5 + 2)^2 = (5+2)^1 (5+2)^1 = (5 + 2)(5 +2) = (7)(7) = 49 : "extended method", then simplifying

DIVIDING LIKE VALUES THAT HAVE EXPONENTS

When dividing indicated or expressed powers that have the same base value, or variables as in algebra, simply subtract their exponents so as to have the exponent of the resulting quotient and which will also have that same base value.

Ex. $\frac{5^3}{5^1} = \frac{5^{(3-1)}}{1} = 5^2 = 25$:here, the same base value is 5

checking: $\frac{5^3}{5^1} = \frac{125}{5} = 25$ or: $\frac{5^3}{5^1} = \frac{\overset{1}{\cancel{(5)}}(5)(5)}{\underset{1}{\cancel{(5)}}} = 5^2 = 25$

Hence, subtracting (to reduce, make less) exponents is essentially equal to canceling some factors common to both the entire numerator and denominator. As another check, the product of the quotient and the divisor (or "divider") should equal the dividend. Using the example above:

$(5^2)(5^1) = 5^{(2+1)} = 5^3$: checks

Ex. $\frac{7^9}{7^3} = \frac{7^{(9-3)}}{1} = 7^6$: $7^9 = 7^3 \times 7^{(9-3)} = 7^3 \times 7^6 = 7^{(6+3)}$

Checking: Here, the numerator is factored by using the inverse of the rule (add the exponents) when multiplying like values, or variables as in algebra. It is factored to create like values in both the numerator and denominator which can then be canceled. Since 7^3 is the smallest power of the value, or variable as in algebra, in question, there is no reason in this example to factor it. 7^9 will be factored so that there will be a highest common factor (HCF) of 7^3 for both the numerator and denominator which can then be canceled out:

$\frac{7^9}{7^3} = \frac{\overset{1}{\cancel{(7^3)}}(7^6)}{\underset{1}{\cancel{7^3}}} = \frac{7^6}{1} = 7^6$: A way to factor 7^9 is: $7^9 = 7^3 \times 7^{(9-3)} = 7^3 \times 7^{(6)}$

What if the exponent of the same base in the denominator is larger? One answer is to subtract the least value exponent from the largest exponent of the like or similar base values, and this ensures a result with a positive valued exponent rather than a negative valued exponent (which requires you knowing about signed values or numbers that will be shown further in this book).

Ex. $\frac{5^1}{5^2} = \frac{1}{5^{(2-1)}} = \frac{1}{5^1}$

checking: $\frac{5^1}{5^2} = \frac{\cancel{(5^1)}}{\cancel{(5^1)}(5^1)} = \frac{1}{5^1}$: after canceling a common factor of (5^1).

also: $\frac{5^1}{5^2} = \frac{\overset{1}{\cancel{5}}}{\underset{5}{\cancel{25}}} = \frac{1}{5} = \frac{1}{5^1}$: equivalent fractions, and both equal 0.2

AN EXPONENT OF 0?

Any value, or variable as in algebra, with an exponent of zero (0) is equal to one (1). Besides being logically or mathematically correct, using 0 as an exponent is sometimes (explicitly) expressed or used to help clarify a simplification or a derivation process.

Ex. 10^0 = 1 : This is easily verified when the exponent in the numerator and denominator are equal. Also, any value divided by itself is equal to 1:

$$\frac{10}{10} = \frac{10^1}{10^1} = \frac{10^{(1-1)}}{1} = 10^0 = 1$$

In general, or symbolically expressed: number^0 = 1

(0) indicates that the given base is to be repeatedly multiplied to a value of 1, a total of 0 (ie. none) times. Since there won't be any multiplication performed on this value of 1, the result is that this 1 will remain unchanged. Also note that 10^0 is the weight of the "ones" digit position (in the decimal number system) expressed with exponential notation.

10^0 = 1 = 1 : weight of the "ones" digit position in the decimal number system
10^1 = 1 x 10 = 10
10^2 = 1 x 10 x 10 = 100 : with 10 as the base, each new value is 10 times more, and therefore, each preceding value is 10 times less (ie. a division by 10)

Also note:

3^0 = 1 and this is also the same value as for example:

5^0 = 1

Hence: 3^0 = 5^0 = 1

4.7^0 + 3.2^0 = 1 + 1 = 2

If you had 3^2 / 3^2 , the result is 1 since any value divided by itself it 1. Hence both the base (here it's 3) and the exponent (here it's 2) is essentially eliminated and the result is just 1 as it would be for any other base and exponent (including 1 also) divided by itself. Mathematically, shown in an expression form, you can eliminate (set to 0) the exponent by subtracting the exponents. Subtracting exponents is a common form for simplification of the division of like values (or variables) that have the same base:

3^2 / 3^2 = 1 = 3^(2-2) = 3^0 = 1 = n^0 : n = any other number

A FRACTION TO A POWER

A fraction to an indicated power is equal to both the numerator and denominator "raised" to that indicated power. The exponent (ie. the indicated power) of the fraction is essentially "distributed" (applied to, and essentially multiplied) to the numerator and denominator exponents.

Ex. $\left[\frac{(5)}{(1)}\right]^2 = \left[\frac{(5^1)}{(1^1)}\right]^2 = \frac{(5^1)^2}{(1^1)^2} = \frac{5^{(1\text{x}2)}}{1^{(1\text{x}2)}} = \frac{5^2}{1^2} = \frac{25}{1} = 25$: for this book, large brackets will be utilized, but large parentheses can also be used

Checking this by performing the indicated operation:

$\left[\frac{(5)}{(1)}\right]^2 = \frac{(5)(5)}{(1)(1)} = \frac{25}{1} = 25$: this expressed the extending (showing multiplication) of the indicated power

Ex. $\left[\frac{(2)}{(3^2)}\right]^3 = \frac{(2)^3}{(3^2)^3} = \frac{2^3}{3^6}$

Likewise, in a reverse-like manner, the division of two values, or variables as in algebra, having the same exponent or raised to the same indicated power is equal to the fraction (division) of those variables raised to that indicated power.

Ex. $\frac{2^2}{3^2} = \left[\frac{(2)}{(3)}\right]^2$

checking: $\frac{2^2}{3^2} = \frac{4}{9}$ and $\left[\frac{(2)}{(3)}\right]^2 = \frac{(2)}{(3)}\frac{(2)}{(3)} = \frac{4}{9}$

Ex. $\frac{5^3}{7^3} = \left[\frac{(5)}{(7)}\right]^3$

Ex. $\frac{(3^4)(3^3)}{5^7} = \frac{3^{(4+3)}}{5^7} = \frac{3^7}{5^7} = \left[\frac{(3)}{(5)}\right]^7$

Ex. $\frac{3^{10}}{5^7} = \frac{3^{(3+7)}}{5^7} = \frac{(3^3)(3^7)}{5^7} = (3^3)\frac{(3^7)}{(5^7)} = (3^3)\left[\frac{(3)}{(5)}\right]^7$

ROOTS AND RADICALS

Finding the root of a number is mathematically the opposite or "inverse" of finding a power of a number. The following description may seem complex to the new student, however, after viewing a few examples below, the concept becomes an understandable and necessary part of mathematics.

Here, you are essentially given the power of some number (ie. a base), and the indicated power (the base's exponent), and the base (now called a root for this type of mathematical operation) of that power value is to be found. The symbol for a root operation is the radical symbol ($\sqrt{\quad}$). The value, essentially the power value, underneath the radical symbol is now formally called the radicand. The root to be found is indicated by a value correspondingly called an index. This index means "take or find this specific indicated root of the radicand". The index is essentially the exponent that the root (when considered as a base) will need to be raised to equal that radicand (when considered as a power value or number). Some older ways would refer to a radical as a "surd", and an index as the "root extraction number".

Here is the general "root" expression and formula:

root = $\sqrt[\text{index}]{\text{radicand}}$: GENERAL ROOT EXPRESSION OR "FORMULA"

This can be rearranged mathematically, to solve for the radicand as:

root ^index = radicand this is mathematically equivalent to a power expression:

base^exponent = power hence, comparing this to the general root expression above:

base = $\sqrt[\text{exponent}]{\text{power}}$: showing that the base of a power is found using the root of a power, and therefore base=root

Mathematical operation or expression to solve for the index (the indicated root of a radical, or the indicated (as an exponent number) power of a base value) value is called a logarithm, and it will be discussed more further ahead in this book. A logarithm is basically equivalent to the index of a root and-or exponent value of a base. As expressed above, to solve for a value of these root and power expressions that have, contain or include these three values will require having or knowing the other two values used. Likewise, to solve for the specific value of the logarithm equation will require the two other specific values (the radicand and corresponding root value, or the base and corresponding power value) of which it is in reference to.

The radical symbol may look somewhat like a division symbol, and the only casual relationship among theses operations and the symbol used is that the result, either a quotient or a root, is usually a smaller value. When the index or "indicated root to be taken" is not explicitly given, it is to be understood as being 2 or the second or "square-root".

It is easy to imagine any of the various or different possible factors of a number, for example:

36 = (12)(3) = (4)(3)(3) = (2)(2)(3)(3) = (18)(2) = (9)(4) = (6)(6)

Here, the only factors of the number that are all identical, and have a product of 36, are 6. 6 is the only factor that the product of itself (here twice, or 2) several times equals the given value of 36. The repeated product of 6, twice, is mathematically expressed as 6 x 6 = 6^2 = 36 . The expression 6^2 is called the square (or second (2) indicated power) of 6. This single factor value of 6 is therefore called the square (or second = 2) root of 36. A very common root of a number to "take" (solve for) is a square root. Squared = second = 2 as a mathematical value. When solving for the square root of a number, power or product value, you are effectively solving for a single factor (or base) that when it is squared or "raised" (increased in value) to the second (2) indicated power, that it will equal that given value.

For special note of a roots similarity and-or its relationship to division: A root can be thought of as a special instance of division where if we divide (and sometimes repeatedly) a value by a certain or specific dividend value (called the root), we will have a final result or quotient that is equal to that same dividend or root value used. For example, the square root of 25 is 5. If you were to divide 25 by 5, the result is 5 which is the same value as the divisor. Checking 5^2 = 25. 5/5=1 shows a complete and pure division (after 2 divisions) with no remainder. For example, the cube root of 8 is 2. If you were to repeatedly (here 3 times) divide 8, and all the following results by 2 repeatedly, you would have: 8/2 = 4, 4/2 = 2 and 2/2=1. Checking 2^3 = 8. For example, the fourth root of 16 is 2. 2^4=16. 16/2 = 8, and 8/2 = 4, 4/2 = 2, and 2/2=1. Mathematically, since: radicand = root^index , we then have: radicand / (root^index) = 1. Checking: 16 / 2^4 = 16/16 = 1

base^exponent = power = 6^2 = 36 = radicand = root^index

root = $\sqrt[\text{index}]{\text{radicand}}$ = 6 = $\sqrt[2]{36}$ = base = $\sqrt[\text{exponent}]{\text{power}}$

Given a number or value of 9. The two identical factors of 9 are 3 and 3. 9 = (3)(3) = 3^2. We see that this has a form of the expression: base^exponent Here the base is 3, and the exponent is 2. The expression also has the form of: root^index , 3 is the root, and 2 is the index. 3 is equivalent to the second (2) root of the radicand of 9. The first root of a value it itself.

3^2 = 9 and 3 = $\sqrt[2]{9}$: "the square root of 9 is 3" and "3 squared is 9"
: "the second root of 9 is 3" and "3 raised to the second power is 9"
or "the second power of 3 is 9"

Ex. What is the square root of 16 ?

$\sqrt[2]{16}$: 16 is the radicand, the index is 2 and is common and understood as the (indicated) root value if it is not explicitly expressed or indicated:

$\sqrt[2]{16}$ = $\sqrt{16}$ = 4 : since 4 x 4 = 4^2 = 16

Ex. 10 = $\sqrt{100}$: since 10^2 = 10 x 10 = 100

Ex. What is the third (3) or "cube" root of 75 ?

$\sqrt[3]{75}$ = 5 : since 5^3 = 75

checking: 5^3 = 5 x 5 x 5 = 25 x 5 = 75

Extra: $\log_5 75 = 3$, since 5^3=75 : "log" is an abbreviation of the word "logarithm" which is essentially the inverse (or reverse) mathematical operation to that of a power.
"The log or exponent of, or for a base of 5 necessary to produce or be equal to its power value of 75 is 3".

The word cube comes from concepts of the measurement of volume. Volume is a 3-dimensional (length, width, height) measurement of spacial (ie., space area). A planar area is measured with units based on only 2 dimension (length and width). The units of measurement of volume have 3-dimensions (length, width, and height) and the reference unit of volume also has the same unit of length for each dimension, and is therefore a ("geometric") cube shaped unit of reference or measurement. A cube shape is essentially the shape of a square box with equal side lengths. Here is how cube or "cubic" units of measurement are expressed:

units x units x units or simply: unit^3 : a cubic unit , ex. a cubic inch = in^3 , a cubic centimeter = cm^3 = cc

For general mathematical expressions and purposes, such as here for powers and roots, that are not necessarily related to the specific topic of cubic volumes, the value of 3 , instead of the word cube, should be utilized.

Frequently, calculators are utilized for finding roots since they have preprogrammed **algorithms** (steps and procedures to solve a problem) that operate or function very fast. Most basic "home" or "4- function calculators" now also include a generous square root function. These calculators and others are as inexpensive as $1USD as of 2020, and are very important due to their helpfulness. There are also calculator programs and "apps" (application = programs) available for computers and-or phones.

Ex. $2\sqrt{2}$ ~ (about) 1.414213562 : using a 10 digit calculator. Any least significant digits which cannot be be entered, processed and-or displayed are truncated (removed), and are therefore not available for further (and more exact) calculation. What is displayed is sufficient for 99% of all types of people and professions. Some values have an endless number of digits, and only a limited number can be processed either by man and-or machine.

The actual value is often expressed as: 1.414213562**. . .** **: . . .** indicates further, and possibly, endless digits

Several methods will be presented in this book for calculating any indicated root. The appendix section of this book includes a method for calculating integer (basically a number without any fractional part) roots. Many methods for calculating roots, particularly square roots, have been developed and the one shown in the appendix is perhaps the most straight-forward and simplest to remember. The appendix also contains many pre-calculated tables.

Probably the oldest method to calculate a square-root of a number is by using an initial good guess at the square-root. If the guess is correct, the product of the root and the root (ie. root^2) as two factors should equal that number (radicand) of which the corresponding square-root is to be found. If the product or "square" of the guessed or assumed root is not equal to the radicand, the guess is typically adjusted by increasing or decreasing a specific digit of it and trying again. Here, a specific digit usually means the current digit in question or the next least significant digit when you are getting "closer" to the true root.

Ex. What is the square-root of 9.61?

Since 3 squared equals 9, and 4 squared equals 16, the square root of 9.61 is somewhere between 3 and 4, and that the square-root of 9.61 appears to be much closer to 3 than 4. Since 9.61 is slightly more than 9, we will adjust the root estimate value of 3 to a slightly larger value:

Trying 3.1 as the new root estimate and then checking it, we get 3.1 x 3.1 = 9.61, hence 3.1 is the square-root of 9.61:

$$3.1 = \sqrt{9.61}$$

Occasionally, the root of a number is exact. Sometimes this root would be called a rational, or rationalized, root. For example, the square root of 9 is 3, the square root of 64 is 8. Often, the square root of values, such as 2, and even though it is a constant value (always the same, and never changing) it is irrational or not-resolvable to an exact, specific or completed value since it will have non-ending and non-repeating decimal digits. Only "in theory" or possibly "conceivable in the mind" can a number like the square root of 2 have an exact or specific value, and rather than express or write the approximate answer out to a certain number of decimal places, it is simply expressed or given as just $\sqrt{2}$.

Irrational numbers cannot be expressed as the division of two integers (ie. plain rational numbers). Just because a calculator displays 8, 9 or 10 digits, don't automatically assume that this is the exact square root, it is however a very close approximation for nearly all practical purposes. If your calculator can display 9 digits and if the displayed result is less than 9 digits, only then can you assume this is the exact square root.

Ex. An area of land is said as being 100 square feet, how long is a side (assuming the land is square shaped, or if it could be represented as simple to conceive square shape)?

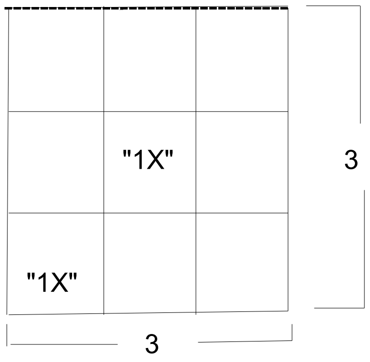
$\sqrt{100}$ = 10 :since 10 x 10 = 100 , and "technically correct" by using the given units:

$\sqrt{100\text{ ft}^2}$ = 10ft^1 :since 10ft x 10ft = (10)(10)(1ft)(1ft) = 100 square feet = 100ft^2

Ex. A small hand-held telescope is noted by the manufacturer as being 9X ("nine times" or "9 power") magnification, that is, the eye with the aid of the telescope will appear (ie., apparent) to see an object, or its area, as 9 times larger than the object as seen (ie. 1x or 1 time, no magnification, true size seen) without the telescope. How many times will the length and width of an object appear to be magnified through this telescope? Since area can be thought of and measured as a two dimensional "square" concept, calculated by multiplying the length and width dimensions which have the same numeric values and units of measurement, then doing the inverse by taking the square root of the given area (of the object as seen magnified) will yield the length (= width for that area, =side) dimension of that apparent area magnification.

$\sqrt{9}$ = 3 since: 3 x 3 = 9

Therefore, an object as viewed through the telescope will appear about 3 times longer and wider (not 9). The total (magnified) area appears as (3 x 3) = 9 times more or bigger. Below is a graphical representation of this example , the "1x" = "1 times" = "1 power" indicated square is a representation of what the unaided eye without a telescope will see. [FIG 17]



: 9X = "nine times" = "nine power"
Nine of one area. An area of one increased, magnified, or spread out over to the same size as an area of nine.
The "**linear magnification**" of 9 power is $\sqrt{9}$ = 3

You might have a thought that for an 18 power, "18x", telescope that the length and width, or linear (basically means straight), dimensions seen should double (from 3 to 6) since 18 is twice , or double of 9. Let's check:

$\sqrt{18}$ = 4.243 : $\sqrt{\text{"power"}}$ = $\sqrt{\text{apparent, area magnification}}$ = (apparent) linear magnification = (apparent) increases in length and width

The result is less than predicted due to the non-linear nature of powers and roots as mentioned previously in this book. For a "100 power" telescope, the length and width will only appear to be this many times longer;

$\sqrt{100}$ = 10

That is, as the "power of the telescope" (shown as a radicand here), increases or "grows" very large, the dimensions of the object now seen (ie, the root) does not increase or "grow" as fast, but appears to grow less and less. Technically, the rate of change between the linear magnification and the power or area magnification is decreasing or slowing. A large telescope with a large lens or mirror may not have as much magnification as most would think it would. Today, digital image sensors with a very higher density of individual elements (ie. basically pixels) per unit area are helping to effectively increase the **resolution** (ie., "resolve", "fineness", "smallest amount", "precision", "detail") of the image, and which can then even be "digitally magnified", hence effectively magnifying the initial image that the telescope itself can produce. The smallest resolution of a digital image is 1 pixel, and if it represent 1 foot of the actual subject of that image, and the combination of image and subject resolutions can be stated as 1 pixel per foot.

If an already magnified image of an object or area is then magnified again, the resulting magnification,"power" or "times" = "X", is simply the product of those two magnifications. Ex. If an object is magnified by 100 power, and if that magnified image (perhaps even considered as an initial, 1x, image) is then magnified by a power of 4, the resulting magnification of the object is: (100)(4)power = 400 power.

In a telescope or microscope, the image is linear magnified equally in both the horizontal and vertical (or width) directions. If the linear dimensions of an image or area (A1) are both or equally magnified, say by (n) times longer, the area is magnified or increased by a (magnification or "power") factor of n^2, and results in A2.

A1 = (horizontal length) x (vertical length) or = (length) x (width) = LW

A2 = (n) horizontal length x (n) vertical length = n^2 (LW) = n^2 A1

The magnification ratio, factor or "power" is: A2/ A1 = n^2, and the linear magnification is: $\sqrt{n^2} = n$

As an extra note, you can make a crude, low-power telescope using two magnifying glasses separated by a foot or two, but the image will be "upside down". For the larger objective (initial) lens, a low power lens is preferred because a longer focus distance (ie., focal length) actually increases the magnification. For the eyepiece lens which is used to view the image from the objective lens, the shorter the focal length of it, the greater the magnification of the entire telescope lens system. **Do not look at the Sun with your eyes, or with a telescope, because the concentrated and-or focused light it is too "bright" and can burn and damage your eyes. Remind people.**

When a value less than 1 is raised to a higher power, such as squared, the result is a smaller value since a fraction of a fraction is a smaller fraction. Now, in a reverse type of manner, if an indicated root larger than 1, such as a square root, is then taken on this smaller value, the result is a larger value.

Ex. 0.5^2 = (0.5)(0.5) = 0.25 : A fraction of a value (here, another fraction) is a smaller value.
Ex. A fraction squared is a smaller value

$\sqrt{0.25} = 0.5$: here, the root is larger than the radicand itself.
The square root of a fraction (a proper fraction, less than 1) will be greater than that given fraction.

NEGATIVE POWERS OF 10

10^0 = 1
10^-1 = 1/10^1 = 0.1 : 10^0 / 10^1 = 1/10^1 = 1(10^0) / 10^1 = 10^(0-1) = 10^-1 = 0.1 = "a (1) tenth" = "a tenth"

10^-2 = 1/10^2 = 1/100 = 0.01 : 1/100 = "1/one-hundred" = "one/one-hundred" = "one-hundredth"
1/100 = 1 / (10)(10) = (1/10)(1/10) = a tenth of a tenth = one-hundredth
= (0.1)(0.1) = 0.01
= (1/10^-1)(1/10^-1) = 1/10^-2
10^-3 = 1/10^3 = 1/1,000 = 0.001 : one-thousandth , extra: 0.123 = 123 thousandths of a (1) unit
10^-4 = 1/10^4 = 1/10,000 = 0.000,1 : one-tenth of one thousandth = 100 millionths
10^-5 = 1/10^5 = 1/100,000 = 0.000,01 : one-hundredth of one thousandth
10^-6 = 1/10^6 = 1/1,000,000 = 0.000,001 : one-millionth = one-thousandth of one thousandth

The square roots of negative powers of 10 will be shown further ahead.

CHART EXAMPLE THAT SHOWS THE SIMILARITIES BETWEEN POWER AND RADICAL EXPRESSIONS

Except for the names used, the operands and results of a given power expression and corresponding root expression are identical in value due to that powers are roots are mathematically the inverse operations of one another.

Operands of a power operation:

Base	Exponent	Power	Power Expression (mathematical notation)	
2	1	2	2^1	: two to the first power
2	2	4	2^2	: two to the second power
2	3	8	2^3	: two to the third power
2	4	16	2^4	: two to the fourth power
2	5	32	2^5	: two to the fifth power
etc.				

Operands of a radical operation:

Root	Index	Radicand	Radical Expression (notation)	
2	1	2	$\sqrt[1]{2}$	: the first root of two
2	2	4	$\sqrt[2]{4}$	: the second root of four
2	3	8	$\sqrt[3]{8}$	: the third root of eight
2	4	16	$\sqrt[4]{16}$	: the fourth root of sixteen
2	5	32	$\sqrt[5]{32}$	: the fifth root of thirty-two
etc.				

When these values are equal: power = radicand, base = root, exponent = index , we have:

power = base^exponent = radicand = root^index, and:

$\text{base} = \sqrt[\text{exponent}]{\text{power}} = \text{root} = \sqrt[\text{index}]{\text{radicand}}$: a root is essentially the base of a power value

We now know the notation of the expressions to solve for two of the parts (base and power, or root and radicand) of either a power or root expression, and we know the similarities of the power and root expressions. To solve for the exponent or index, a notation called logarithm notation will be used, and this is covered further ahead in this book.

MULTIPLYING RADICALS

Radicals that have the same index (indicated root) can be multiplied. When they are multiplied, the product is a radical with the same index, and the radicand is the product of the radicands. It could also be said that these radicands and radicals that were multiplied together are factors of this new (product) radicand and radical.

Ex. $(2\sqrt{9})(2\sqrt{4}) = 2\sqrt{9}\ 2\sqrt{4} = 2\sqrt{(9)(4)} = 2\sqrt{36} = 6$

Checking by rationalizing the radicals first as indicated in step 1 of the order of operations. Rationalizing a radical expression means ridding or clearing the radical of the radical symbol by solving for the indicated root or expressing it in another form such as with exponential notation which will be discussed further ahead in this book:

$\sqrt{9}\ \sqrt{4} = (3)(2) = 6$

Ex. $3\sqrt{7}\ 3\sqrt{2}\ \sqrt{5}$
$3\sqrt{(7)(2)}\ \sqrt{5}$
$3\sqrt{14}\ \ 2\sqrt{5}$

FACTORING RADICALS

Since radicals with the same index can be multiplied, producing a new radical, we can do the reverse and factor a radical for possible simplification. To factor a radical, the radicand value is factored. These factors can then become radicands of radicals which have the same index as the radical from which they were both factored from.

Ex. $\sqrt{16} = 2\sqrt{(4)(4)} = (2\sqrt{4})(2\sqrt{4}) = 2\sqrt{4}\ 2\sqrt{4}$: The factored radical, where each has the same index as the source radical.

$\sqrt{16} = (2) \quad (2) = 4$

When factoring the radicand for simplification purposes, it is usually best to find factors of it that are indicated powers whose (indicated) exponent is equivalent to the index of the radicand, such as perfect squares (2), cubes (3), fourths (4) , etc., since these radicals are easily rationalized. The indicated root of a value raised to the same indicated power is simply equal to that given value.

Ex. $2\sqrt{18}$

Since the index is 2, factor the radicand for powers that are perfect squares which are values raised to the second power. Note that 18 has factors of 9 and 2, or 6 and 3. Choose the factors of 9 and 2 since 9 is a perfect square of 3. That is, 3^2 = 9, and this radicand can be easily rationalized if the indicated root or index is also 2:

$2\sqrt{18} = 2\sqrt{(9)(2)} = 2\sqrt{9}\ \ 2\sqrt{2}$: factored form. simplifying further, we will factor the radicand of 9 to an indicated (with an exponent) perfect square (2) since the index is 2:

$2\sqrt{3^\wedge 2}\ \ 2\sqrt{2}$ In short, for example, the square root of any value squared (particularly when simply indicated as such) is that value:

$2\sqrt{3^\wedge 2} = \sqrt{3^\wedge 1}\ \sqrt{3^\wedge 1} = 3$: Using the concept that the square-root of any value multiplied by itself (ie squared) is that value, here 3.

$3\ \ 2\sqrt{2}$: Since this is a representation for the square root of 18, this value when squared or raised to the second power should therefore equal 18:

checking: (3 2√2)^2 = (3)^2 (2√2)^2 : after distributing the exponent

= 9 2√2 2√2 : after extending, expressing the indicated square as a multiplication

= 9 2√(2)(2) : multiplying the radicands of like radicals with the same index

= 9 2√4

= 9 (2) = 18 : the original radicand used in this example

Ex. 2√147

2√147 = 2√(49)(3) = 2√(49) 2√(3) = 2√7^2 2√3 = 7 2√3

In short, and as an example to this discussion, the square root of any value squared (especially when indicated as being squared with an exponent of 2), is that same value.

Ex. √ 4^2 = 4 checking:

√ 16 = 4 :It will be shown further ahead in this book that:

indexv√radicand^exponent = radicand^(exponent/index) : even if the exponent = 1

Ex. 3√ 5^3 = √(5)(5)(5) = 5 checking:

3√125 = 5

Since a radicand that is a whole number can easily be factored, this leads to another method to calculate the root of a radicand. You can factor a radicand into radicands that you already know the roots of. You can also completely factor a radicand to its prime factors and use a small table for the (previously solved, calculated) roots of prime factors. Here are the approximate roots of the first 16 prime numbers or factors:

√ 2 = 1.414213562
√ 3 = 1.732050808
√ 5 = 2.236067977
√ 7 = 2.645751311
√ 11 = 3.31662479
√ 13 = 3.605551275
√ 17 = 4.123105626
√ 19 = 4.358898944
√ 23 = 4.795831523
√ 29 = 5.385164807
√ 31 = 5.567764363
√ 37 = 6.08276253
√ 41 = 6.403124237
√ 43 = 6.557438524
√ 47 = 6.8556546
√ 51 = 7.141428429

Ex. √ 105 factoring the radicand:

√ (7)(5)(3) factoring the radical:

√ 7 √ 5 √ 3 using the above table for the square roots of these values:

(2.645751311)(2.236067977)(1.732050808) = 10.24695077

The square roots of negative powers of 10 are also very helpful when the radicand contains a fractional part.

$\sqrt{10^{-1}} = \sqrt{1/10} = \sqrt{10^{-1}} = 0.316227766$: $\sqrt{0.1}$

$\sqrt{100^{-1}} = \sqrt{1/100} = \sqrt{10^{-2}} = 0.1$: $\sqrt{0.01} = \sqrt{0.1}\ \sqrt{0.1} = \sqrt{(10^{-1})(10^{-1})}$

$\sqrt{1000^{-1}} = \sqrt{1/1000} = \sqrt{10^{-3}} = 0.0316227766$: $\sqrt{100^{-2}}\ \ \sqrt{10^{-1}} = \sqrt{0.001}$

$\sqrt{10000^{-1}} = \sqrt{1/10000} = \sqrt{10^{-4}} = 0.01$: $\sqrt{0.0001}$

Ex. $\sqrt{1.05}$: compare this to the last example shown above which has the same digits

$\sqrt{1.05} = \sqrt{(105)(10^{-2})}$: $\sqrt{(105)(1/100)} = \sqrt{(105/100)}$
$\sqrt{1.05} = \sqrt{105}\ \ \sqrt{10^{-2}}$
$\sqrt{1.05} = (10.24695077)(0.1)$: 0.1 = 1/10 = division by 10, so simply move the decimal point 1 place leftward so as to make a smaller number
$\sqrt{1.05} = 1.024695077$

This can also be solved as:

$\sqrt{1.05} = \sqrt{(105)(0.01)} = \sqrt{(5)\,(21)\,(0.01)}$: factored to "primes"
$= \sqrt{5}\ \sqrt{21}\ \sqrt{0.01}$: see the table shown previously for these roots, and then multiply them together.

We see that a radical that has a radicand that is not whole value, but a value that contains a whole part and a fractional part, can essentially be changed or reduced to one of solving the product of radicals or roots with radicands that are whole values.

A RADICAND RAISED TO A POWER EQUAL TO THE INDEX

The root of a radicand that is raised to an indicated power equal to the index of the radical is equal to the base of that radicand.

Ex. $\sqrt[2]{5^2} = 5$: checking: $\sqrt[2]{5^2} = \sqrt[2]{25} = 5$

: also, since $5^2 = 5^1 \times 5^1$, $\sqrt{5^2} = \sqrt{5^1 \times 5^1} = \sqrt{5}\ \sqrt{5} = 5$

Ex. Given the square root of 10, and multiplying it by the square root of 10, we should have 10:

$\sqrt{100} = \sqrt[2]{10^2} = \sqrt{(10)(10)} = \sqrt[2]{10}\ \sqrt[2]{10} = 10$

Ex. $\sqrt[3]{4^3} = 4$: checking: $\sqrt[3]{4^3} = \sqrt[3]{64} = 4$ since $(4)(4)(4) = 64 = 4^3$

Ex. $\sqrt[4]{2^4} = 2$: checking: $\sqrt[4]{2^4} = \sqrt[4]{16} = 2$

Ex. $\sqrt[3]{(2^2)^3} = (2^2) = 4$

checking: $\sqrt[3]{(2^2)^3} = \sqrt[3]{2^{(2\text{x}3)}} = \sqrt[3]{2^6} = \sqrt[3]{64} = 4$

checking: $\sqrt[3]{(2^2)^3} = \sqrt[3]{4^3} = 4$ since $(4^1)(4^1)(4^1) = 4^3$

By observing the examples given, a basic way to rationalize radicals with a radicand raised to an indicated power equal to the index, is to place (or "convert") the radical into an exponential form. This can be accomplished by simply removing the radical symbol, and divide the radicands exponent by the index of the radical.

Ex. $\sqrt[2]{5^2} = 5^{(2/2)} = 5^1$: $5^{(2/2)}$ is the exponential form of $\sqrt[2]{5^2}$

Ex. $\sqrt[3]{4^3} = 4^{(3/3)} = 4^1$

Ex. $\sqrt[4]{2^4} = 2^{(4/4)} = 2^1$

Ex. $\sqrt[3]{(2^2)^3} = (2^2)^{(3/3)} = (2^2)^1 = 2^2 = 4$

If the radicand's exponent is evenly divisible by the index, then the radicand is a "perfect (integer) power" of the index. For example, given the radicands below:

5^4 is a perfect square (2nd power) of $5^{(4/2)} = 5^2$, since $(5^2)^2 = 5^4$.

Therefore, the square root of 5^4 should be equal to 5^2:

$\sqrt[2]{5^4} = 5^{(4/2)} = 5^2$

5^4 is also a perfect fourth (power) of $5^{(4/4)} = 5^1$ since $(5^1)^4 = 5^{(1\text{x}4)} = 5^4$

Hence, 4√ 5^4 = 5^(4/4) = 5^1 = 5 checking:

4√ 625 = 5

Ex. 3√ 7^6 = 7^(6/3) = 7^2 = 49 : 7^6 is a perfect third power or "cube" of 7^2: (7^2)^3 = 7^6

If the radicand's exponent is not evenly divisible by the index when rationalizing, the radicand can be factored into factors having exponents equal to the index. This factorization is essentially the reverse of multiplying like values, or variables as in algebra, where the product is that value and its exponent is the sum of the exponents. Below are some examples with their intermediate steps.

Ex. 2√ 5^3

2√ 5^3 = 2√ (5^2) (5^1) = 2√ 5^2 2√ 5 = 5^(2/2) 2√ 5 = 5 2√ 5

Note that even though the indicated power of the radicand is not evenly divisible by a value equal to the index, still, the result can be correctly indicated as such. This is shown below using the last example, and more will be said about this further in this book.

2 √ 5^3 = 5^(3/2) or 5^1.5 and as shown above, this = 5 2√ 5 , and: (5^1.5)^2 = 5^(1.5 x 2) = 5^3

Ex. 3√ (7^2)^4

3√ (7^2)^4 = 3√ (7^2)^3 (7^2)^1 = 3√ (7^2)^3 3√ 7^2 = (7^2)^(3/3) 3√ 7^2

= 7^2 3√ 7^2 = 49 3√ 7^2 = 49 3√ 49

OR: 3√ (7^2)^4 = 3√ 7^(2x4) = 3√ 7^8 = 3√ (7^3) (7^3) (7^2) =

= 3√ 7^3 3√ 7^3 3√ 7^2 = 7^(3/3) 7^(3/3) 3√ 7^2 = (7^1) (7^1) 3√ 7^2 =

= 7^2 3√ 7^2 = 49 3√ 7^2 = 49 3√ 49

RADICALS WHOSE FACTORS ARE ALL "PERFECT POWERS" OF THE INDEX

The above title is short-hand for saying radicals whose factors are all raised to the same indicated power that is also equal to the index of the radical. This radical can be easily rationalized or simplified by multiplying the base of each power in the radicand's factors.

Ex. $\sqrt[2]{(4^2)(3^2)}$: here, the index is 2, and each base is raised to the 2nd power.
$(4)\ (3)$
12

checking: $\sqrt[2]{(4^2)(3^2)}$
$\sqrt[2]{(16)(9)}$: 16 and 9 are "perfect powers", here, perfect squares which are due to values raised to the second power. Since the index is also 2, these radicand values, when expressed as powers of two, can be used to easily rationalize (ie. remove) the radical expression.
$\sqrt[2]{144}$
12

You can also perform a check by "distributing" the index to each factor of the radicand when converting them to their equivalent or corresponding exponential form so as to rationalize the radical expressions.

$\sqrt[2]{(4^2)(3^2)}$
$\sqrt[2]{4^2}\quad \sqrt[2]{3^2}$
$(4^{(2/2)})\ (3^{(2/2)})$
$(4)\quad (3)$
12

or: $\sqrt[2]{4 \times 4}\quad \sqrt[2]{3 \times 3}$
$\sqrt{4}\ \sqrt{4}\quad \sqrt{3}\ \sqrt{3}$
$4\qquad 3$
12

Another check is this:

$\sqrt[2]{(4^2)(3^2)}$
$\sqrt[2]{(4 \times 3)^2}$
$\sqrt[2]{12^2} = \sqrt{144}$
$12^{(2/2)}$
12

EXPONENTS THAT ARE LESS THAN ONE OR ARE FRACTIONS

Exponents can be any value, they need not be only integers (essentially the familiar basic counting values). This process of dividing the exponent of the radicand by the index leads us directly to exponents that are fractions. This is also a method of rationalizing radicals such as shown on the right hand side of the following equation:

index√ base^exponent = base^(exponent/index) : a general format for converting between radical and exponential expressions.
Note that a power or exponential expression can be a radicand of a radical.
Note also that both sides represent a root.

Ex. 2√ 5^2 = 2√25 = 5^(2/2) = 5^1 Ex. 3√1000 = 3√10^3 = 10^(3/3) = 10^1 = 10

Since a number (ie. base) raised to the first power is still that number, it should be of no surprise that when a number is raised to a value less than one (ie. a fraction), that the resulting (power) value is smaller than that number, hence we find it useful as another way to express some root of a number.

Ex. 2√ 5^1 = 5^(1/2) : "five to the one-half (1/2 = 0.5) power is equal to the square root of five"

2√5 = 5^0.5

Hence, we have found a way to convert a radical form of a root to it's equivalent exponential form and vice-versa.

Ex. 2√25^1 = 25^(1/2) or= 25^0.5 = 5

Ex. 27^(1/3) = 3√27^1 : = 3

Ex. 27^(2/3) = 3√27^2 : = 9

Ex. 2√ 5^3 = 5^(3/2) : = 5^1.5

Ex. 81^(1/4) = 4√ 81 : = 3

Ex. 3√ (5^3)^4 = (5^3)^(4/3) also, by using the "power to a power" rule:

(5^3)^(4/3) = 5^((3/1)(4/3)) = 5^12/3 = 5^4

In general, if the index is less than the indicated power of the radicand, the result is a power of the radicand, and if the index is greater than the indicated power of the radicand, the result is a root of the radicand.

Ex. 0.5√10^2 = 10^(2/0.5) = 10^4 = 10000

2√10^2 = 10^(2/2) = 10^1 = 10

3√10^2 = 10^(2/3) = 10^0.66$\underline{7}$ = 4.64$\underline{2}$

4√10^2 = 10^(2/4) = 10^0.5 = 3.16227766... : also = 10^(2/4) = 10^(1/2) = 2√10^1

A RADICAL TO A POWER

One way to rationalize a radical (ie. an expression for a root) which is raised to a power, is to first convert the radical to its equivalent exponential form. Then use the "power to a power" rule where the exponents are distributed (ie., multiplied).

Ex. (2√ 3)^5

(2√ 3^1)^5 converting the radical to exponential form:

(3^(1/2))^5 "power to a power", "distribute" (multiply) the exponents:

3^((1/2)(5/1))

3^(5/2)

Also, converting 3^(5/2) back to radical form:

3^(5/2) = 2√ 3^5

Hence, (2√ 3)^5 = 2√ 3^5 this equivalence leads to this following statement:

A radical and radicand raised to the same power are equivalent in value. The base of the radicands, and the indexes of the radicals must also be the same. The reasoning behind this equivalence is due to the fact that multiplication is commutative. This can be seen in their exponential (power) form before the exponents are multiplied:

(3^1/2)^(5/1) is the same as: (3^5/1)^(1/2) , both expressions are equal to: 3^(5/2)

Using the above equivalence, this result can also be seen if the exponents are distributed:

3^((1/2)(5/1)) = 3^((5/1)(1/2)) = 3^(5/2)

Before leaving this discussion, it must be pointed out that converting an exponent that is an improper fraction to a mixed number can be useful.

Ex. First: 7^3/2 = 2√ 7^3 = (2√ 7)^3 = 7^1.5

Now, by converting the exponent to a mixed number:

Since 3/2 = 1.5 = 1 + 0.5 = 1 + 1/2 , we have:

7^3/2 = 7^(1 + 1/2) = (7^1) (7^1/2)

7^3/2 = 7 √ 7 = 7^1.5

A RADICAL RAISED TO A POWER EQUAL TO THE INDEX

The root of a radical that is raised to a power equal to the index is equal to the radicand value of that radical.

Ex. $(\sqrt[2]{5})^2 = 5$

checking: $(\sqrt[2]{5})^2$ placing the radical into exponential form :
$(5^{(1/2)})^2$ with a "power to a power", distribute the exponent :
$5^{(2/2)}$
$5^1 = 5$

Or: $(\sqrt[2]{5})^2$
$(\sqrt[2]{5})(\sqrt[2]{5})$: "extended method" (it should also be obvious here that the square root of the same value, is that value, here 5)
$\sqrt[2]{(5)(5)}$: from multiplying "like" radicals (have same index), simply multiply their radicands

$\sqrt[2]{5^2} = \sqrt[2]{25} = 5$ or:
$\sqrt[2]{5^2} = 5^{(2/2)} = 5$

Note that this is very similar to where the root of a radicand in which the radicand is raised to an indicated power equal to the index:

$(\sqrt[2]{5})^2 = \sqrt[2]{5^2} = 5$: Note also for example, that the square (2nd power) of the square-root of number (here a radicand) is equal to that number. If we let letter (r) represent or equal the square root of a number (N), then (r x r) or r^2 will equal that number: This is verified here mathematically:

$r = \sqrt{N}$ then

$r \times r = \sqrt{N}\ \sqrt{N}$: Multiplying both sides by r or $\sqrt{N}$, or either (since they are equal in value), still keeps both sides of the equation in balance. Note that this is therefore also the same as simply squaring each side:

$r^2 = (\sqrt{N})^2$ "extending" the right hand side:

$r^2 = \sqrt{N}\ \sqrt{N} = N^{1/2}\ N^{1/2} = N^{(1/2 + 1/2)} = N^{2/2}$

or $= N^{(0.5 + 0.5)} = N^1$

$r^2 = N$

If r was the cube root of N:

$r = \sqrt[3]{N}$ raising each side to the third power:

$r^3 = \sqrt[3]{N}\ \sqrt[3]{N}\ \sqrt[3]{N} = (\sqrt[3]{N})^3 = N^{1/3}\ N^{1/3}\ N^{1/3} = N^{(3/3)}$

$r^3 = N$

THE ROOT OF A FRACTION

The root of a fraction is equal to the root of the numerator divided by the root of the denominator. The indicated root or index of the roots will also be the same.

Ex. $\sqrt[2]{\frac{36}{4}} = \frac{\sqrt[2]{36}}{\sqrt[2]{4}} = \frac{6}{2} = 3$

Checking using the order of operations more closely where the value (ie. radicand) underneath the radical is simplified first since the division symbol is an inner grouping symbol for this example, and the radical symbol is an outer grouping symbol:

$\sqrt[2]{\frac{36}{4}} = \sqrt[2]{9} = 3$

Here is another check by first converting the radical to exponential notation:

$\sqrt[2]{\frac{36}{4}} = \left[\frac{36}{4}\right]^{(1/2)} = \frac{36^{(1/2)}}{4^{(1/2)}}$: After using the fraction to a power rule of:
: (Distributing the exponent to both the num. and den.)

$= \frac{\sqrt{36}}{\sqrt{4}} = \frac{6}{2} = 3$

RATIONALIZING FRACTIONS THAT CONTAIN RADICALS

There are two basic methods to rationalize (to make sense of) or rid fractions that contain radicals: The equivalent fraction method, and the equivalent radicand method. They are somewhat similar, but different names are used to distinguish them. This discussion also shows how to rationalize a radicand that is a fraction. The main goal in this process is to create a "perfect (indicated) power" of the index , which can then be easily rationalized.

Equivalent Fraction Method:

First, convert both the numerator and denominator to radicals. This creates a fraction of two radicals. Then an equivalent fraction is made by multiplying the fractions numerator and denominator by the denominator raised to a power such that the resulting radical in the denominator will be raised to an indicated power that is some multiple of the index. This denominator, when simplified, is equal to the radicand.

Ex. $\sqrt[3]{\frac{2}{3}} = \frac{\sqrt[3]{2}}{\sqrt[3]{3}} = \frac{\sqrt[3]{2}}{(\sqrt[3]{3})^1}$ Multiplying the numerator and denominator by $(\sqrt[3]{3})^2$:

$\frac{\sqrt[2]{2}\,(\sqrt[3]{3})^2}{(\sqrt[3]{3})^1\,(\sqrt[3]{3})^2} = \frac{\sqrt[3]{2}\,(\sqrt[3]{3})^2}{(\sqrt[3]{3})^3}$ After converting the radical in the denominator to its equivalent exponential form and simplifying. $(\sqrt[3]{3})^3 = 3^{(1/3)3} = 3^{(3/3)} = 3^1$:

$\frac{\sqrt[3]{2}\,(\sqrt[3]{3})\,(\sqrt[3]{3})}{3^{(3/3)}} = \frac{\sqrt[3]{18}}{3}$: In the numerator, the radicands were multiplied since the index (indicated root) is the same for each radical.

Equivalent Radicand Method:

$$\sqrt[3]{\frac{2}{3}} = \sqrt[3]{\frac{2\,(3^2)}{(3^1)(3^2)}} = \sqrt[3]{\frac{(2)(9)}{3^3}} = \frac{\sqrt[3]{18}}{\sqrt[3]{3^3}} = \frac{\sqrt[3]{18}}{3^{(3/3)}} = \frac{\sqrt[3]{18}}{3}$$

The above concepts should be taken into general account and especially when rationalizing (essentially simplifying) fractions containing radicals, or rationalizing radicals whose radicand is a fraction.

A CAUTIONARY NOTE WHEN USING POWERS AND ROOTS WITH FRACTIONS

When creating an equivalent fraction, it is incorrect to "raise" the numerator and denominator to the same power, perhaps in an attempt at creating an equivalent fraction.

Ex. $\frac{4}{8}$ /=/ $\frac{4^2}{8^2}$ or $\left(\frac{4}{8}\right)^2$: /=/ or != are symbols meaning "is not equal to" or "not equals"
Often, this symbol is used: $\neq$

Checking by taking the decimal form of both sides:

0.5 /=/ 0.25 : This is so since the numerator and denominator are not actually being multiplied by the same identical value when you raise them to the same power. For this example, the numerator was multiplied by 4, and the denominator by 8.

Likewise, when creating an equivalent fraction, it is incorrect to take the same indicated root of both the numerator and denominator.

Ex. $\frac{16}{64}$ /=/ $\frac{\sqrt{16}}{\sqrt{64}}$ or $\sqrt{\frac{16}{64}}$: A fraction, and the root of a fraction are two different values, and not equal. This is similar to above example, but the indicated power that the numerator and denominator values would be raised to would be 0.5 or= 1/2.

Checking by taking the decimal form of both sides:

0.25 /=/ 0.5

ADDING RADICALS

Radicals that have the same index and radicand are said to be "like" or similar radicals. Since the radicals represent the same value or quantity, simply add their numerical coefficients (the multiplying factor(s)). If a numerical coefficient is not shown, it is considered as being one (1), and we know that multiplying anything by one is alright since it does not change it's value.

Ex. $\sqrt{9} + \sqrt{9} \quad = \quad (1)\ 2\sqrt{9} + (1)\ 2\sqrt{9}$

$(1 + 1)\ 2\sqrt{9}$
$2\ \ 2\sqrt{9}$: This result should be easily seen since multiplication is really repeated addition of the same value. With further simplification:

$2\ (3)$
6

Checking:

$2\sqrt{9} + 2\sqrt{9}$ Order of operations, step 1 (simplify powers and roots) :
$3 + 3$ Order of operations, step 4 (additions and subtractions; to combine)
6

Ex. $3\sqrt{7} + 2\sqrt{7}$
$(3 + 2)\sqrt{7}$
$5\sqrt{7}$: in general, $\sqrt{7}$ is to be added to itself (or to an initial sum of 0 if you will) 3 times, and then 2 more times for a total of 5 times, hence multiply by 5 since it is essentially being summed (to a starting reference value of 0) a total of 5 times.

Checking:

$3\sqrt{7} + 2\sqrt{7}$ since multiplication is repeated addition:
$(\sqrt{7} + \sqrt{7} + \sqrt{7}) + (\sqrt{7} + \sqrt{7})$
$(1 + 1 + 1 + 1 + 1)\ \sqrt{7}$ After clearing grouping symbols, and expressing
$5\sqrt{7}$ the sum of similar things or values.

MULTIPLYING RADICALS WHICH HAVE UNLIKE INDEXES

It is possible to multiply radicals that have unlike indexes. First, convert and express each radical into an equivalent exponential form, then the exponents can be changed to equivalent fractions with like denominators, and this is essentially creating like indexes for their corresponding radical forms.

Ex. $\sqrt[2]{2}\ \sqrt[3]{4}$
(2^(1/2)) (4^(1/3)) : exponential forms of the radicals

Below, equivalent fractions of the exponents are created in a manner similar to that of adding fractions. A common denominator of 6 was chosen for the fractions and it is also the lowest common denominator (LCD) of the two.

$\frac{1}{2} = \frac{3}{6}$ and $\frac{1}{3} = \frac{2}{6}$

Hence, 2^(1/2) = 2^(3/6) and 4^(1/3) = 4^(2/6) : 2^0.5 and 4^0.3333**...**

Converting each back to its radical form and multiplying:

(2^(3/6)) (4^(2/6))

$\sqrt[6]{2^3}\ \sqrt[6]{4^2}$: created radicals with like indexes

$\sqrt[6]{8}\ \ \sqrt[6]{16} = \sqrt[6]{(8)(16)} =$: multiplying radicands of radicals which have the same index

$\sqrt[6]{128}$

THE ROOT OF A ROOT

The root of another indicated root is equal to a radical whose index is the product (ie., multiplication) of the index of each radical.

Ex. $\sqrt[3]{\sqrt[2]{64}}$: note here that the inner radicand is actually another radical (indicated root to be taken)

$\sqrt[3]{\sqrt[2]{64}} = \sqrt[(3)(2)]{64} = \sqrt[6]{64}$

This is verified below:

Converting the inner radical to exponential form:

$\sqrt[3]{(64^{(1/2)})}$

Then this entire radical is converted to exponential form:

$(64^{(1/2)})^{(1/3)}$

By using the "(indicated) power to a power" rule of multiplying exponents, we distribute the exponents:

$(64^{(1/2)})^{(1/3)} = 64^{(\,(1/2)(1/3)\,)} = 64^{(1/6)}$

Converting this back to radical form, we get:

$64^{(1/6)} = \sqrt[6]{64}$: checks

Due to multiplication being commutative, the exponents of a "power to a power" can be exchanged.

Ex. $(64^{(1/2)})^{(1/3)} = 64^{(\,(1/2)(1/3)\,)} = 64^{(1/6)}$

$(64^{(1/3)})^{(1/2)} = 64^{(\,(1/3)(1/2)\,)} = 64^{(1/6)}$

Converting both expressions on the above left sides to radical form, we get:

$$\sqrt[3]{\sqrt[2]{64}} = \sqrt[2]{\sqrt[3]{64}}$$

checking: first simplifying the "inner radical" radicand:

$$\begin{array}{ccc} \sqrt[3]{\sqrt[2]{64}} & = & \sqrt[2]{\sqrt[3]{64}} \\ \sqrt[3]{8} & = & \sqrt[2]{4} \\ 2 & = & 2 \end{array}$$

This concept can also be used to find some higher integer roots using only square or cube roots. For example, you can find the fourth (4) root of a number (N) by taking the square root of the square root of the number:

$\sqrt[4]{N} = \sqrt[2]{\sqrt[2]{N}}$: the right hand expression is like a "factored index" form of a radical expression

The APPENDIX section has a similar method of how to calculate odd roots, such as cube (3rd) roots, using square roots.

The following discussion is somewhat of an advanced concept, and perhaps not used much in practice, but for completeness and familiarity, it will be presented since it is based on, and is a natural progression stemming from the previous discussions.

A radical that has an indicated power of a radicand, is equal to a radical having that radicand base value, and the index is divided by that indicated power. Expressing this using words as symbolic identifiers or variables:

index\/$\overline{\text{radicand^exponent}}$ = (index/exponent)\/$\overline{\text{radicand}}$

Also consider in this discussion:

index\/$\overline{\text{radicand^exponent}}$ = radicand^(exponent/index) : the exponential form of the radical form

Here is the derivation of the first shown equation:

For simplicity, let: i = index, r = radicand, e = exponent , z = 1/e , therefore e = 1/z

i\/$\overline{\text{r^e}}$ = i\/$\overline{\text{r^(1/z)}}$ = i\/$\overline{\text{z\/r}}$ = iz\/$\overline{\text{r}}$ = i(1/e)\/$\overline{\text{r}}$ = (i/e)\/$\overline{\text{r}}$

Ex. 3\/$\overline{\text{10^2}}$ = (3/2)\/$\overline{\text{10}}$ = 1.5\/$\overline{\text{10}}$ = 10^(2/3) = 10^0.666$\underline{7}$ = 3\/$\overline{\text{100}}$ = 4.641$\underline{6}$

Checking, and a verification using what we know already:

(3/2)\/$\overline{\text{10^1}}$ = 10^(1 / (3/2)) = 10^(2/3) = 3\/$\overline{\text{10^2}}$

EXPRESSING RADICANDS LESS THAN ONE WITH INTEGER RADICANDS

This is an infrequently used method of calculating roots, but if you only have a table of the roots of some integers, it will be very useful. If you plan to calculate roots using other methods, such as those presented in this book, you will at least get another good lesson in mathematical manipulations here. First, represent the radicand in an equivalent proper fraction form, then represent this radical form as the division of two radicals. Placing a value less than one into a (proper) fractional form is discussed ahead in the topic of scientific notation (SN) if you need help doing so.

Ex. $\sqrt{0.5} = \sqrt{5(10^{-1})} = \sqrt{\frac{5}{10}} = \frac{\sqrt{5}}{\sqrt{10}}$: calculate the square root of 0.5 using the square roots of 5 and 10

Or: $\sqrt{0.5} = \sqrt{\frac{50}{100}} = \frac{\sqrt{50}}{\sqrt{100}} = \frac{\sqrt{50}}{10} = \frac{\sqrt{5}\ \sqrt{10}}{10}$

Here is another method to calculate this:

$$\sqrt{0.5} = \sqrt{\frac{0.5^2}{0.5^1}} = \frac{\sqrt{0.5^2}}{\sqrt{0.5}} = \frac{0.5}{\sqrt{0.5}} = \frac{0.5\sqrt{1}}{\sqrt{0.5}} = 0.5\sqrt{\frac{1}{0.5}} = 0.5\sqrt{2}$$

By observing the procedure for the last method above, a formula can be written. Letting N represent (be equivalent to) the radicand in question:

$\sqrt{N} = N\sqrt{\frac{1}{N}}$:The square root of a value is equal to that value times the square root of its reciprocal.
From this we also have: $1/N = (1/N)(N/N) = N/N^2$ = the reciprocal of a number

A check on this formula can be made by converting the radicals to their equivalent exponential form:

$$\sqrt{N} = N^{0.5} \quad \text{and} \quad N\sqrt{\frac{1}{N}} = N\frac{\sqrt{1}}{\sqrt{N}} = \frac{N}{N^{0.5}} = \frac{N^{1-0.5}}{1} = N^{0.5} = N^{(1/2)} = \sqrt{N}$$

Here is a formula, that is somewhat similar to the above formula, that can be used to calculate roots. It is a good mathematical lesson, but is perhaps somewhat advanced or excessive, and the reader may simply skip over it.

$\sqrt{N} = \dfrac{1}{\sqrt{\frac{1}{N}}}$: The square root of N is equal to the reciprocal,
of the square root of the reciprocal of N.

The derivation of this is as follows: The reciprocal of N is 1/N. To do the "reverse", we will express the reciprocal of 1/N to have N:

$\dfrac{\frac{1}{1}}{\frac{1}{N}} = N$: The reciprocal of the reciprocal of N is equal to N. After taking
the square root of both sides, we have the equation above.

The same should be true for any value, including square root values. The reciprocal of: $(1/\sqrt{N})$, or the reciprocal of the reciprocal of the square root of N is:

$$\frac{\frac{1}{1}}{\frac{1}{\sqrt{N}}} = \frac{\frac{1}{1}}{\frac{\sqrt{1}}{\sqrt{N}}} = \frac{\frac{1}{1}}{\sqrt{\frac{1}{N}}} = \sqrt{N}$$

: this can also of been solved by inverting the denominator, and creating an equivalent fraction.

Ex. $\sqrt{5} = \frac{1}{\sqrt{0.2}} \sim 2.23607$

: the "wavy" equals symbol: ~ or ~= means "approximately" or "about" equal to. The reciprocal of 5 is 0.2

RADICANDS THAT VARY BY A CONSTANT FACTOR

This is a method of evaluating radicals where the radicands differ by a common factor. The result is basically the same as that of where a radical is equal to a product of radicals whose radicands are factors of the original radicand. If the many radicands have a common factor, this common factor only needs to be evaluated once. This concept can be of great use if you are creating a table of roots.

Ex. Here, a constant factor between the radicands is 10, and there are others such as 2 and 5:

Since $\sqrt{10} = 3.16227766$ approximately. Now observe this radicand of 100 which is 10 times greater than 10:

$$\sqrt{100} = \sqrt{(10)(10)} = \sqrt{10}\ \sqrt{10} = 3.16227766\ \sqrt{10} = (3.16227766)(3.16227766) = 10$$

$$\sqrt{90} = \sqrt{(10)\,(9)} = \sqrt{10}\ \sqrt{9} = 3.16227766\ \sqrt{9} = (3,16227766)(3) = 9.48683298$$

$$\sqrt{20} = \sqrt{(10)(2)} = \sqrt{10}\ \sqrt{2} = 3.16227766\ \sqrt{2} = (3.16227766)(1.414213562) = 4.472135955$$

A general "formula" for this discussion can be written or expressed mathematically. Below, R is used to represent the initial radicand, N and F represent factors of the radicand, where F is also a common factor between several radicands that you already know the root of:

$\sqrt{R} = \sqrt{FN} = \sqrt{F}\ \sqrt{N}$: for the above examples, F = 10 and its root is 3.16227766

R, F and N are examples of what are called "variables" in algebra, as you can see, each is simply a (symbolic) mathematical representation or placeholder for an actual number value. The actual symbol(s), letters, or words used to represent a variable is sometimes called the variable identifier or variable name. A variable is a general representation of many possible numeric values and-or a particular value being solved for.

LOGARITHMS (LOGS)

For a logarithm (or log) mathematical operation, you are given in the expression a base value and a number (N) equal to some power of that base, and are to find the (indicated) exponent of the base that would make that base equal to this power value or "Number". **Try to think of a log as simply the operation to find an exponent, and-or that a log is equivalent to an exponent.** The word "logarithm" was from that table values or "entries", such as for exponents and power values of a given base that were often logged (written or entered) into a (quick "lookup", find) reference table (list). Instead of using a fancy symbol such as like how a square root symbol is, the symbol chosen for a logarithm operation is simply the world "log".

$\text{exponent} = \text{Log}_{\text{base}} \text{Number}$: GENERAL LOG EXPRESSION, EQUATION OR "FORMULA"

Note, in the expression above on the right side, number is not the exponent of base, but a power of the base, that is:

base^exponent = Number = the actual power value of the base.
The left side of the equation is the indicated or expressed power value.

A simplified notation for a log expression, using simple variable identifiers or names, can be something like this:

$e = \log_b N$: b=base (of the power value), N=number or power value, e=exponent

If no base value is given, it is understood as being 10. Logarithms of base 10 are called "common logarithms" due to the commonly used decimal system that is based on 10.

If you want to view all the basic algebraic relationship between powers, roots, and exponents or logarithms, then see the paragraph called: Algebraically Expressing The More Advanced Mathematical Operations, that is further ahead in this book

Ex. Since 10^3 = 1000, if given just the base and the number (a, or the, power of the base), the notation used to solve for the necessary exponent, of that base so as it would equal that given power value, is the logarithm notation (expression):

$\text{exponent} = \log_{10} 1000$ or: $\text{exponent} = \log 1000$: when a base value is not indicated, it is understood or considered as base 10, the common log base.

$\text{exponent} = 3 = \log_{10} 1000$: since 10^3 = 1000 : 3 is the logarithm or exponent. "The log of 1000, using a base of 10, is 3".

Frequently, a calculator with a logarithm function is used to find logs. Generally, "scientific" calculators have function keys for finding only common and natural logarithms. If the base is not 10 or (e = about 2.72) which is the base for "natural" logarithms what will be discussed in this book, these calculator functions cannot be immediately utilized. Still, most logarithms to be found in common everyday home and scientific usage have either a base of 10 or (e).

Ex. Solve $\log_2 8$: a sometimes used text alternate notation for this expression may be: log2 8

To solve this is to find what would be the exponent of 2 such that the resulting power value of it is equal to 8:

$\text{exponent} = \log_2 8$: here the base of the logarithm or power is 2, and the number or actual power value is 8

$3 = \log_{2} 8$ since $2^3 = 8$

The examples given were very simple and could have been done simply by inspection. More information on finding exponents will be given ahead in the discussion of: Finding Exponents With Logarithms.

The **Number in a logarithm expression must be a positive value greater than 0**. A logarithm (ie., the exponent value) will be a positive value greater than 0 when the number is greater than 1. First, a logarithm is always zero when the number is 1: $\log 1 = 0$: here n=1, consider: $5^0 = 1$, ex. $7^0=1$. Now consider when (n) is greater than 1: Ex. $\log 100 = 2$: here n=100 is greater than 1, and which can be expressed as n>1. Now consider when (n) is less than 1 but still greater than 0 as required: Ex. $\log 0.5 =$ about -0.30103 : here n=0.5 is less than 1, and which can be expressed as n<1 or (n<1), and the logarithm value is therefore less than 0 and is negative in value.

Considering the above statement, some will say for example that given $(-2)^3 = -8$, and therefore: $\log_{(-2)} -8 = 3 = \log_{2} 8$

, and the problem with this is the both the base and Number ambiguity (ie., uncertainty) of the signs of the base and number. Also consider the base ambiguity of this example: $\log_{-2} 4 = 2 = \log_{2} 4$

Without the aid of a modern **electronic calculator**, logarithm tables or mathematical calculation, a mechanical device or simple mechanical calculator or mechanical computer (that which computes, performs or solves computations) called a **slide-rule** can (only) give a good approximation (typically only a couple of decimal places) of a logarithm or anti-logarithm (finding the number or power value of the base). The slide rule gets its name from that it is similar to two rulers constructed to be adjustable by sliding one next to (ie., parallel) or against the other. Basically, a result is indicated by the corresponding value directly opposite and indicated on the other (logarithm) ruler scale. The slide rule is also capable of other mathematical calculations. The longer the slide rule is, the more precision capable in the result since more subdivisions (smaller fractional parts) can be drawn or fitted on the indicated scales.

An alternative to calculating machines is to use pre-made tables of values. These tables generally offer more precision than that capable on a slide rule or graph, but not as much precision as a modern electronic calculator and-or computer.

The first mechanical adding machine is considered to be that made by **Blaise Pascal** (1623-1662), from France, in about 1642. This machine could also perform subtraction. Gottfried Leibniz built an improved adding machine in the late 1600's. There have been many designs and improvements for adding machines ever since, and of which included other mathematical operations.

SOLVING FOR THE BASE OF A POWER

Given a power value of a base value, and it's indicated exponent, what is the corresponding base? An easy way to solve for the base is to place the values into exponential form.

$4 = \log_{\text{base}} 16$: logarithmic equation form , $\text{exponent} = \log_{\text{base}} \text{power}$: power = number

base^4 = 16 : exponential equation form , base^exponent = power : power = number

Since the base is being raised to the fourth power, by taking its root with an index equal to the indicated power (the exponent), the base can be isolated or solved for. This is clearly seen once the radical is placed into exponential form. This operation must be done to the entire values or expressions on both sides of the equal sign of an equation so as to keep the equivalence or balance of both sides. More will be said about this during the discussion of equations. Since a base is effectively the "origin" or "root (of a power)" that the power value (ie., Number) is created or based upon, it should be reasonably obvious that a root operation on this power value will be needed to solve for the corresponding base.

Base^4 = 16 expressing the taking of the 4th root of both sides:

$\sqrt[4]{\text{base^4}} = \sqrt[4]{16}$ expressing or converting the left side to its equivalent exponential form

base^(4/4) = $\sqrt[4]{16}$: exponential form (a rationalized form)

base = 2

hence, $4 = \log_{2} 16$ or 2^4 = 16

FINDING THE NUMBER (POWER VALUE OF THE BASE)

Ex. Find number or power value given: 4 = log number

Here, the base value is understood as the common base of 10. Expressing this in exponential form:

10^4 = number

Solving for the fourth power of 10 using repeated multiplication, or "extending" the indicated power:

10^4 = (10)(10)(10)(10)
10^4 = 100(10)(10)
10^4 = 1000(10)
10^4 = 10000

number = 10,000

Expressing the indicated power 10^4 in log form:

$4 = \log_{10} 10{,}000$ or = $\log_{10}$ 10^4

Ex. Find number given: $\log_{81} \text{number} = \frac{1}{4}$

Again, placing this information into exponential form is the best way to start:

81^(1/4) = number or: 81^0.25 = number : 1/4 = 0.25

Since the indicated power (the exponent) is not an integer, number (the power) cannot be solved for by repeated multiplication. Converting this "fractional power" to its equivalent radical notation:

81^(1/4) = $\sqrt[4]{81^1}$ = $\sqrt[4]{81}$ taking the fourth root of 84:

$\sqrt[4]{81}$ = 3 = number : root form or by switching sides (formally known as the Symmetric Law):

number = 3

Hence, $\log_{81} 3 = \frac{1}{4}$ = 0.25 :log form and 81^0.25 = 3 : exponential form

THE LOG OF 1

The log (exponent) of any base to equal a number (the power value of the base) with a value of 1, is zero (0). This can be shown from the fact that a base with an exponent of zero is equal to one.

Ex. since 10^0 = 1 : extra, 10^0 is also the weight of the ones (1's) column or digit position

Converting and expressing this exponential form to its equivalent logarithmic form, we get:

$0 = \log_{10} 1$: using 0 or zero is necessary since if 10^1 = 10, 10^0 is needed to express 1
When the number is less than 1, specifically between 0 and 1, the log of it will be negative, hence less than 0.

AN EXAMPLE OF LOGS IN EVERYDAY LIFE

The human ear is said to hear or respond to a sound's intensity or energy level it receives in a logarithmic type of manner, and not a linear or "direct" equivalent manner. Light intensity seen is another example of a logarithmic-like sensing or quantification by the body of outside stimulus or input. For example, the sound energy from someone talking may have hundreds of times more sound energy than someone whispering, however, the human ear will only hear or represent this as only several times louder. Placing some examples in logarithmic form where the number (a power of the base) represents the amount of sound energy (actual physical power) or intensity, and the exponent (or logarithm) numerically represents what energy or volume level that the human ear will apparently or effectively hears, senses or perceives.

Apparent volume or energy heard expressed as the log of the actual sound energy

Number represents actual amount of energy.

(Logarithm) , (Number) : logarithm = exponent of the base, and here, base = 10

pin drop: 1 = log 10
whisper: 2 = log 100
talking: 4 = log 10,000
yelling: 6 = log 1,000,000

Clearly it is much easier to express the large range of number values (that change greatly or exponentially) into a highly "compressed", linear-like, and more manageable form such as the logarithmic (ie. exponent) values and representation presented. For example, note that the number of 100 is 10 times (magnification) more than 10, or an increase of 90 from a value of 10, but the log value (or exponent) only increased only by 1 to represent this increase. It could be said that logarithms are "slow (and get slower and slower) growing", and powers are "fast (and get faster and faster) growing".

Extra: In electronic and energy studies, vast increases, gains or comparing two values can be easily expressed and understood as logarithmic or "compressed" values. The common formula used was initially developed for use with the Alexander Graham Bell's telephone system. Since this is somewhat of an advanced example below, the reader may skip of this and review it later.

Ex. A gain, increase or magnification factor can be expressed as: Gain = (output / input), but as we know, gains can be very large and unwieldy, so Bell made a way to compress these values to be more manageable.

Gain in Bel units: log (output / input) Bels : initial Bel unit , and this after an accepted, standardized revision by others, this becomes a tenth of a Bel , hence a deciBel. **1 Bel =10 deciBells** = (10) (0.1Bel) = 1Bel

The deciBel unit is then redefined as: log (output / input) deciBels = dB , and the Bel unit is then ten times this amount:

1 Bel = 10 (1 dB) = 10 log (output / input) dB : this is equivalent to: log (100)(output/input)) dB , the value of 100 effectively magnifies the gain before the log is applied, and this helps to express small gains less than 1.

The Bel unit is also then defined such that a real gain of 10 would be expressed as a gain of 1 Bel or= 10dB.
A real gain of 2, twice as much or double, is expressed as a gain of 0.3Bel = 3dB

For example: If the output power doubled (ratio=2): 10 Log 2 = 10 (0.30103) = 3.0103 dB =~ 3db in gain
If the output power increased by one-million: 10 log (1000000) = 10 (6) = 60 db in gain

For example: If the output halved, such as Pout / Pin = 0.5 , 10 Log 0.5 db =~ 10 (-0.301) = -3 db : : a loss
For example: If the output is a quarter, such as Pout / Pin = 0.25 ,10 Log 0.25 db =~ 10 (-0.602) = - 6 db : a higher loss

We see above that if the power doubles, the dB values increases by 3, and if the power is halved, the dB value decreases by -3. To find the actual gain and-or loss ratio (ie., out value / in value) given an amount of dB gain:

Gain = 10^(gain in dB / 10 dB) Ex: 10^(3 dB / 10 dB) = 10^0.301 = 2 : > 1 is a gain
Ex. 10^(-3 dB / 10 dB) = 10^-0.301 = 0.5 : < 1 is a loss

Other popular use for logarithms are: earthquake intensity measurement, measuring the relative brightness or "magnitude" of stars, and some types of electronic power measurement. Logarithms can also be used as an excellent mathematical tool in any field of study where calculations need to be made, and especially for solving for an exponent. The word "magnitude" essentially means greatness or the level of , and is related to the word magnification which means an increase, bigger or larger.

FACTORING THE NUMBER IN A LOG

The log of a number can be expressed as a sum of the logs of the factors of that given number. This can be remembered as the "(log) product rule" or "(log) factor rule". The log factors must also have the same base as the source logarithm.

log number = log factor_1 + log factor_2 + . . . : . . . = "and so on" since there may be more than two factors

Ex. $\log_{10} 100 = \log_{10} 10 + \log_{10} 10$: using the log factor or log product rule

checking: $2 = 1 + 1$

Also: log 100 = log (10 x 10) = log 10 + log 10 = 2 : shows 100 in factored form, or something like:

log 100 = log (50 x 2) = log (25 x 4) : showing some other factors of 100 for the Number

log 100 = log 50 + log 2 = log 25 + log 4 = 2

The product rule in a reverse manner can be remembered as the "(log) sum rule". The sum of two logs having the same base is equal to a log with the same base, and a number equal to the product of the numbers.

Ex. $\log_{2} 8 + \log_{2} 4 = \log_{2} (8 \times 4) = \log_{2} 32$: log sum rule

checking: $3 + 2 = 5$: since 2^3 = 8, 2^2 = 4 , and 2^5 = 32

THE LOG OF A FRACTION

The log of a fraction is mathematically equal to the log of the denominator subtracted from the log of the numerator. This can be remembered as the "log quotient rule", or "log of a fraction rule":

$\log\left(\frac{\text{numerator}}{\text{denominator}}\right) = \log \text{numerator} - \log \text{denominator}$: log quotient rule

Ex. $\log\left(\frac{1000}{10}\right) = \log_{10} 1000 - \log_{10} 10 = 3 - 1 = 2$

checking: $\log_{10} 100 = 3 - 1$: simplifying first by considering the order of operations step 3; perform multiplications and divisions

$2 = 2$

Ex. $\log 1 = \log \frac{5}{5}$: this is a particular and special example featuring the log of 1.

$\log 1 = \log 5 - \log 5$ combining like values or terms of log 5:
$\log 1 = 0$: Clearly, whatever the value of an expression such as the log 5 is, if you subtracted it from itself, the difference is always 0. The log (regardless of the base used) of 1 is always equal to 0. This is the reverse of the exponential rule that the power of any base with an exponent of 0 is always equal to 1.

$0 = \log_{\text{base}} 1$ and $\text{base}^0 = 1$: using any base for the log, and any base for the indicated power

A cautionary note about the log quotient rule: This rule can only be used if the number in question is a fraction. If the numerator and denominator are both logarithm expressions, the log quotient rule cannot be used. It could, perhaps, be used separately on the numerator and denominator.

Ex. The log rule cannot be used on this expression:

$\frac{\log 1000}{\log 10}$ /=/ $\log 1000 - \log 10 = 3 - 1 = 2$: (incorrect method)

This is also incorrect:

$\frac{\log \text{numerator}}{\log \text{denominator}}$ /=/ $\log(\log \text{numerator}) - \log(\log \text{denominator})$: (incorrect method) Since this value is actually the logarithm of the result, raising the base used to this indicated power, as for finding an anti-logarithm (or the Number), will yield the result.

This correct result is found if the order of operations is followed more closely where the numerator and denominator are simplified separately:

$\frac{\log 1000}{\log 10} = \frac{3}{1} = 3$: (correct method)

The reverse of the quotient rule can be remembered as the "log difference rule". The difference of two logs having the same base is equal to a log with the same base and whose number is the quotient of the minuend number divided by the subtrahend number.

Ex. $\log_3 27 - \log_3 9 = \log_3 \left(\frac{27}{9}\right) = \log_3 (3) = 1$: log difference rule

checking: $3 - 2 = \log_3 (3) = 1$

THE LOG OF A POWER

The log of a number raised to a (indicated, with an exponent) power is equal to the log of that number times the exponent of that number. This can be remembered as the "log exponent" rule" or "log of a power rule". The result is that the indicated (with an exponent) power of a number (N), of which the log is to be found, becomes a numerical coefficient (ie. a multiple, or multiplying factor) of the log of just the base value of that indicated power.

log Number^exponent = (log Number) (exponent) or = (exponent) (log Number) , expressed symbolically:

$\log N^e = e \log N$: LOG (INDICATED) POWER RULE, or the LOG EXPONENT RULE

Ex. $\log_2 4^3 = 3 \log_2 4$: log (indicated) power rule, or the log exponent rule

checking: $\log_2 64 = 3(2)$

$6 = 6$

Here is a verification of this rule:

$\log 5^3$ "extending" the indicated power:
$\log ((5)(5)(5))$ using the log product rule:
$\log 5 + \log 5 + \log 5$ Since multiplication is repeated addition, adding their numerical coefficients (here, 1, for each) we have:
$(1) \log 5 + (1) \log 5 + (1) \log 5$: like values, add their numerical coefficients:
$(1 + 1 + 1) \log 5 = 3 \log 5$: the left side is also a "factored" form of the previous line, and the common factor to all the values summed is (log 5)

There is a simple rule when dividing two log expressions when the base of the logs are the same, and both bases of the numbers (N), expressed as indicated (with an exponent) powers, are also identical. Below, (x) and (y) represent any possible value for the indicated exponents of both numbers that are expressed, indicated powers and which have the same (power) base (here indicated as A) of that indicated power:

$\frac{\log A^x}{\log A^y} = \frac{x}{y}$ this is easily verified using the log exponent rule:

$\frac{\log A^x}{\log A^y} = \frac{x \log A}{y \log A} = \frac{x}{y}$: a value divided by itself is 1, or after canceling out the common factors (here, log A) to both the numerator and denominator.

Even if the base of the indicated power of N is not identical, if you can convert and express N as a power of the other base, the above method will work. In the following example, the base of the expressed power of 2 is converted to its equivalent value having a base of 4:

Ex. $$\frac{\log 4^3}{\log 2^3} = \frac{\log 4^3}{\log (4^{0.5})^3} = \frac{\log 4^3}{\log 4^{1.5}} = \frac{3}{1.5} = 2$$

Note that $4^{0.5} = \sqrt{4} = 2$

checking:

$$\frac{\log 4^3}{\log 2^3} = \frac{\log 64}{\log 8} = \frac{1.806179974}{0.903089987} = 2$$

Another method to simply the original equations is with the exponential log rule:

$$\frac{\log 4^3}{\log 4^{1.5}} = \frac{3 \log 4}{1.5 \log 4} = \frac{3}{1.5} = 2$$

Actually, since the numerator and denominator are both composed of a logarithm expression only, and with no indicated logarithm base, any logarithm base can then be consistently utilized in the equation for the correct solution. If you happen to use a base of 8, this can be solved easily since both Numbers (here 64 and 8) are a power of 8. There are a few other instances shown in this book where any base can be used. Below is a verification of this "any log base" concept:

Given any value, say expressed or represented as N1 (for Number 1), the division of two logarithms of it which always have the same two and different logarithm bases, always results in the same (constant value) quotient, say F.

Ex. $$\frac{\log_2 64}{\log_4 64} = \frac{6}{3} = 2$$: N = 64, b1=2, b2=4

Ex. $$\frac{\log_2 16}{\log_4 16} = \frac{4}{2} = 2$$: N = 16, b1=2, b2=4
Though the numbers differ in both equations, notice that
the result is always 2 when the same two and different bases
bases are used consistently.

Expressing this into a formula:

$$\frac{\log_{b1} N1}{\log_{b2} N1} = F$$

F is a constant when the Number is changed and when log bases are used consistently (ie., the same used values). Mathematically or algebraically:

$$\log_{b1} N1 = (F) \log_{b2} N1$$

: We see that given N, the logarithms with different bases, will only vary by a constant factor of F (or 1/F) when one is divided by the other.

Given another value, say N2, and using the same bases, the quotient will still be F as shown in the last two examples above. This can easily be verified when N2 is some indicated power of N1 and using the log of an indicated power rule and canceling the common factors:

Let $N2 = N1^x$ since (x) can have any possible value, N2 can be any possible value, then:

$$\frac{\log_{b1} N2}{\log_{b2} N2} = \frac{\log_{b1} N1^x}{\log_{b2} N1^x} = \frac{x \log_{b1} N1}{x \log_{b2} N1} = \frac{\log_{b1} N1}{\log_{b2} N1} = F$$

We see that regardless of the Number used, given any two bases, there is a common or constant factor (ie. here a ratio value) between those bases. Mathematically, in the algebraic sense (for a formula) we have:

$$\log_{b1} N2 = (F) \log_{b2} N2$$ dividing the two results, we have another interesting result:

$$\frac{\log_{b1} N1}{\log_{b1} N2} = \frac{(F) \log_{b2} N1}{(F) \log_{b2} N2} = \frac{\log_{b2} N1}{\log_{b2} N2}$$: Same two numbers (N1 and N2) but using another log base for both, will be equal.

Ex. $\frac{\log 25}{\log 5} = \frac{1.397940009}{0.698970004} = 2$: common base of 10, and:

$\frac{\log_e 25}{\log_e 5} = \frac{3.218875825}{1.609437912} = 2$: base of (e), the "natural log base" (about 2.71)

This is further verification that different bases (when used consistently within a problem) can still be utilized to achieve the correct result. Sometimes a log with a base of 10 is converted into one having a log base of (e), and vice-versa. Here, the value of the Number is adjusted so as the actual proper or true result is maintained.

THE LOG OF A POWER OF A PRODUCT

The logarithm of an indicated (with an exponent) power of an expressed product of two or more factors can be expressed as equal to the sum of logarithms where each number (factor of the original expressed Number or product) of the log is raised to the same indicated power as the expressed product of those factors. This rule is similar to the log product rule.

log Number^exponent = log ((factor_1) (factor_2) **. . .**)^exponent = log factor_1 + log factor_2 + **. . .**

Ex. log (1000 x 10)^2 = log (1000^2 x 10^2) = log 1000^2 + log 10^2
log(1,000,000) + log (100)
6 + 2
8

checking: log (1000 x 10)^2
log (10,000)^2
log 100,000,000
8

OR: log (1000 x 10)^2
log (10,000)^2
2 log 10,000
2 (4)
8

OR= 2 log (1000 x 10)
2 (log 1000 + log 10)
2 (3 + 1)
2 (4)
8 : checks

If you were to write a "formula" for the above procedure it would look something like the expressions on both sides of the equality ("equals") sign below where A and B represent the factors of the Number, and x represents the exponent or indicated power.

log (AB)^x = log(A^x B^x) = log A^x + log B^x

Using the log exponential rule on both of the equivalent expressions (an equation) above, we can arrive at other useful "log formulas". We see that the exponent is "distributed" or applied to the exponent of each factor of the number (N).

log (A^x B^x) = log (AB)^x = x log (AB) = log A^x + log B^x = x log A + x log B = x (log A + log B)

Ex. 5 log a + 7 log b considering the log exponent rule, this can be expressed as:
log a^5 + log b^7 considering the log factor and log product rule, this can be expressed as:
log (a^5 b^7)

"SPECIAL" LOG RULE

When the base of the logarithm, and the base of the number are the same, the result or logarithm (ie., the exponent) is equal to the number's exponent.

Ex. $\log_{10} 10 = \log_{10} 10^1 = 1$: special log rule

checking: $10^1 = 10$

Ex. $\log_{10} 10^3 = 3$

checking: $\log_{10} 1000 = 3$

$3 = 3$

A check can also be made using the (log) exponential rule:

$\log_{10} 10^3 = 3 \log_{10} 10 = 3(1) = 3$

If we were to express this concept symbolically or algebraically, so as to be non-specific in values or showing a more "generalized" formula for any possible values used, we would have something like:

$\log_N N^{\text{exponent}} = \text{exponent}$: here, the log base, and the base of the number are the same value of N

Knowing all of the above, it is easy to reason that when the Number is less than the base, that the exponent or log is less than one. When the Number is more than the base, the exponent or log is greater than one:

$\log_b N = 1$: when N = b , "When the Number (or power of the base) equals the base of the logarithm, the log equals 1".

Ex. $\log_{10} 10 = 1$

$\log_b N > 1$: when N > b , "when N is greater than b", the log is greater than 1

Ex. $\log_{10} 100 = 2$

$\log_b N < 1$: when N < b , "when N is less than b, the log is less than 1".

Ex. $\log_{10} 5 = 0.69897$

$\log_b 1 = 0$: when N = 1

You can now imagine that when the number is less than 1, (N<1), but still greater than zero, (N>0), since 0 is not a power value of any base value, that the log will be less than 0. This requires knowing about "negative or signed numbers" that are discussed further ahead in this book.

Ex. $\log 0.99 = -0.0043648\underline{1}$: When (0<N<1), the log is negative or less than 0. Here, since N is almost or close to 1, the log is close in value to 0.

When the Number is greater than 0, and less than 1, (ie. between 0 and 1), this can be symbolically expressed as :

$\log_b (0<N<1) = (<0)$: a value less than 0 is called a negative value, and is indicated with a negative sign, (-) preceding it, as shown in the example above. This will account for the logarithms of all the (fractional) values between 0 and 1. Negative values are used quite a bit when the temperature is below zero degrees = less than 0 degrees = < 0 degrees = < 0°. Negative value < 0. Ex. -1 < 0

The fundamental log rules described up to now will be verified in the ALGEBRA section of this book.

FINDING EXPONENTS WITH LOGARITHMS

Expressing and finding exponents with logarithms is perhaps the greatest use of logarithms.

Ex. Given 10^x = 1000, find the exponent x.

First, take the logarithm (using any consistent base) of each side of the equation:

$10^x = 1000$

$\log 10^x = \log 1000$ using the "log exponent" rule:

$x \log 10 = \log 1000$ now isolate (solve for) x:

Since log 10 is a factor of the left hand side (of the equation), remove it by dividing it by itself, effectively canceling or ridding it from that side and thereby isolating x so as it can be solved for. Of course, to keep both sides of the equation in equivalence or balance, this process must be done to both sides.

$$\frac{x\,\overset{1}{\cancel{\log 10}}}{\underset{1}{\cancel{\log 10}}} = \frac{\log 1000}{\log 10} = \frac{3}{1} = 3$$

: Note, you cannot use: log 1000 - log 10 = 3 - 1 = 2 , since both the numerator and denominator are logarithms.

Extra note: **The log of a negative numbers (less than 0) are undefined.**

If you were to write a generalized representative or algebraic formula for this procedure, it would look something like the following:

given $b^x = N$: Here (b) represents the base of the indicated power, (x) is the indicated exponent of the base, and N represents the number or power value of that base.

$\log b^x = \log N$: after taking logs of both sides

$x \log b = \log N$: using exponential rule, solving for (x):

$$x = \frac{\log N}{\log b}$$

: GENERAL FORMULA FOR SOLVING FOR AN EXPONENT (given: $N = b^x$)

Ex. Solve for x given:

$$x = \log_3 9$$

$$x = \frac{\log N}{\log b} = \frac{\log 9}{\log 3} = 2$$

: Use any base, but the result of 2 can be found by inspection when you consider that both numbers have a factor of 3 in them, and then using a common or consistent base of 3. Note also that:
$\log 9 = \log (3x3) = \log 3 + \log 3 = \log 3^2 = 2 \log 3$

FINDING POWERS WITH LOGARITHMS

Both of the processes for finding powers and roots with the aid of logs essentially results in the need for evaluating an anti-logarithm which is also known as an inverse logarithm. For anti-logarithms, you are to find the number (ie., power value) given the base and the exponent (ie. the logarithm). You can "think of" an anti-logarithm as the reverse of finding the logarithm of a number.

Ex. Evaluate: N = 10^3

Note that this example given can easily be solved by repeated multiplication, but this is not the case when the exponent is not an integer. This simple example was chosen to make the procedure clear.

N = 10^3 taking logs of each side, here, using a base of 10; the common log base:
log N = log 10^3 this can be expressed as:
log N = 3 log 10

Equating (3 log 10) equal to the required exponent of the base (here 10) to equal N (a power of that base):

N = 10^(3 log 10) = 10^(3x1) = 10^3 = 1000

In general, if you were to write a (algebraic) formula for this procedure, it would look something like:

N = b^x : N = power, b = base, x = exponent , taking the log of both sides of this equation:
log N = log b^x or:
log N = x log b therefore, according to the definition of logarithms:

N = 10^(log N) and:

N = 10^(x log b) or= 10^(log b^x) : A GENERAL FORMULA FOR FINDING POWERS
(where N = b^x)

N = 10^(log N) shown above is the general notation for finding antilogarithms (the number) of common (base 10) logarithms. Another, simpler derivation of this notation is from the log definition itself:

x = $\log_{10}$ N : an expression to find the logarithm of a number using a base of 10, therefore:

N = 10^x since x = $\log_{10}$ N, and using substitution:

N = 10^($\log_{10}$ N) : = 10^x, and if any other log base (b) is considered, this formula would be expressed as:
N = b^($\log_{b}$ N) = b^x

Below are some more examples of evaluating powers with logarithms. Included in the examples is more terminology associated with the concepts of logarithms.

Evaluate 10^4 using logs.

N = 10^4 taking the log of both sides, we can use any log base, here we will use the common log base of 10:
log N = log 10^4
log N = 4 log 10
log N = 4 (1)
log N = 4.0

The 4, or the whole portion of the log of (10^4) is technically called the **characteristic** of the logarithm. The fractional portion of the logarithm (here it's 0) is technically called the **mantissa**. Both the characteristic and mantissa are part of the logarithm or exponent. Expressing this in a pseudo (or algebraic) mathematical statement:

log N = exponent = characteristic + mantissa or: characteristic part of the log + mantissa part of the log
= characteristic**.**mantissa : expressed symbolically as decimal mixed number

Therefore, using the inverse log, or anti-log, expression to find the number::

N = 10^logarithm = 10^exponent : since logarithm = $\log_b N$, b^logarithm = base^exponent = N

N = 10^(characteristic + mantissa) OR:

N = (10^characteristic)(10^mantissa) therefore:

N = (antilog characteristic)(antilog mantissa)

Substituting values for the example just given:

N = (antilog mantissa)(antilog characteristic)
N = (antilog 0)(antilog 4)
N = (10^0) (10^4) or = 10^(0+4) = 10^4
N = (1) (10,000)
N = 10,000

Here is a small table to assist in understanding the characteristic and mantissa values (here, using a base of 10):

10^0.0 = 1	: characteristic = 0	mantissa = 0.0 :	log 1	= 0.0
10^0.5 = 3.16228	: characteristic = 0	mantissa = 0.5 :	log 3.16228	= 0.5
10^1.0 = 10	: characteristic = 1	mantissa = 0.0 :	log 10	= 1.0
10^1.5 = 31.62228	: characteristic = 1	mantissa = 0.5 :	log 31.6228	= 1.5
10^2.0 = 100	: characteristic = 2	mantissa = 0.0 :	log 100	= 2.0

All the values from 10 up to 99.999... are said to have a characteristic of 1 when base 10 is being considered. That is, these values are essentially powers of 10 and the characteristic is the integer (whole number) of the indicated power. For all the values from 10 up to 100, where the characteristic of these values is always 1. A log value having an integer value of 1 is characteristic or common of Numbers between, or in, the range from 10 to 100, and the mantissa value of their logarithms will increase from 0.0 to 0.999999... in this range. In short, the characteristic value of the logarithms remains the same (here 1) for this range of values, but the mantissa value of that logarithm increases from 0 to 1 as like a fraction of a unit does. The (common, base 10) logarithms of values in the range from 100 to 1000 have a characteristic of 2, and in the same manner, the mantissa will increase from 0.0 to 0.999999... in this range.

When you see a logarithm (ie. exponent) that has a characteristic of 1, you will know that the anti-logarithm or Number (the power value of the base raised to that indicated power) has a value between 10^1 to 10^2 = 10 and 100. When you see a logarithm that has a characteristic of 2, you will know that the anti-logarithm or Number has a value between 10^2 to 10^3 =100 to 1000, and so on.

Ex. Find the common (base 10) antilog of 2.17

Here, 2.17 is a logarithm of some number, hence it's an exponent value. We see that the characteristic of this logarithm (or exponent) is 2 and the mantissa is 0.17. Since 2 is the characteristic, the corresponding Number is between 10^2 to 10^3 = 100 to 1000.

According to the definition of logs:

2.17 = Log N   and therefore:

N = 10^2.17   : N is the number or antilog. Factoring this indicated power value:

N = (10^2)(10^0.17)
N = (100) (1.479108388)
N = 147.9108388

When solving for the log of a number, the characteristic portion of the log can easily be found by observation or by expressing the number in standard scientific notation (discussed further ahead in this book under the topic of SCIENTIFIC NOTATION which is a form of exponential notation with a base of 10) where the characteristic is equivalent to the whole part of the indicated (as in the exponent) power of 10, that is, it's equivalent to the log of this power of 10, and the mantissa is equivalent to the log of the other factor to the power of 10. Since this other factor (to the power of 10) is less than 10 in value, and the log of (10^1) is 1, its log, and therefore the mantissa, is always less than 1. Another similar method is to express the number using a slightly modified scientific notation where the number is not between 0 and 10, but always less than 1. This second method eventually requires that you know about adding signed numbers as shown below.

Ex. Log of 50 can be found by:

Log 50 = Log (5)(10^1)   or = Log (0.5)(10^2)
Log 50 = Log 5 + Log 10^1   or = Log 0.5 + Log 10^2
Log 50 = 0.698970004 + 1   or = - 0.301029995 + 2
Log 50 = 1.698970004   = 1.698970004

Again, whenever you see (log N), think of it as being an exponent value:
log N = logarithm = exponent = characteristic part + mantissa part = whole part + fractional part
For this example, on its left side, 1 is the characteristic, and 0.698970004 is the mantissa.

Notice that when a number is factored to any form of scientific notation that the digits remain the same, and only the power of 10 changes. If numbers of various values with the same digits in them are all factored to standard scientific notation, then all of them will have the same mantissa portion in their common logarithm. In respect to the above example:

Log 500 = Log (5)(10^2)
Log 500 = Log 5 + Log 10^2
Log 500 = 0.698970004 + 2
Log 500 = 2.698970004

For comparison, if the digits are the same, the mantissas of the logs are identical:

(antilog)	(integer power of 10)	(fractional power of 10)
N	characteristic	mantissa
5	0	0.698970004
50	1	0.698970004
500	2	0.698970004
5000	3	0.698970004

For illustrative purposes, this same sort of "similar digit results" will occur when multiplying (or dividing) any two numbers with the same digits, for example:

$$\begin{array}{r} 123 \\ \times\ \underline{\ \ 57} \\ 7011 \end{array} \qquad \begin{array}{r} 1.23 \\ \times\ \underline{\ \ 5.7} \\ 7.011 \end{array}$$

: both products have the same digits

In this book, you can find more about this subject in the topic of LOGARITHMS OF SIMILAR DIGITS

Ex. Evaluate 2^1.5 using common logarithms.

This example will show that the indicated power value is converted to an equivalent power value, which has a base of 10 and a correctly adjusted exponent, that can be evaluated using common logarithm and antilogarithm tables, etc. For much of this book, the concepts of the characteristic and mantissa of a logarithm are not used much, but you should have an idea of what they are.

N = 2^1.53

log N = log 2^1.53 : after taking the common (base 10) log of both sides
log N = 1.53 log 2 : log power or exponent rule
log N = (1.53)(0.301029995)
log N = 0.460575893 : characteristic = 0, and mantissa = 0.460575893

Since the characteristic is 0, the antilogarithm or the value of the number must be between 1 and 10 since 10^0 = 1 and 10^1 = 10. That is, 0 is a common "characteristic" for the exponents of the values being represented (with a power of a base of 10) between this range. It can also be stated as that the integer portion of the logarithm in question has this characteristic value. If the characteristic was 1, the number would be within the range of 10 and 100, but not including 100, or higher, since 10^2 = 100, and the characteristic would actually be 2.

N = (antilog mantissa)(antilog characteristic) using common antilogs or powers of 10:
N = (10^0.460575$\underline{9}$)(10^0) multiplying like values or variables, add their exponents:
N = 10^0.460575$\underline{9}$ (1) The underlined 9 means rounded to this position.
N = 10^0.460575$\underline{9}$

Usually, to save space and cost, common antilogarithm (base 10) tables range from 0 to 1 for the exponent, hence the antilog of the characteristic must be performed by inspection. Since the antilog of the characteristic is an integer power of 10, simply adjust (ie., move) the decimal point in the antilog of the mantissa in accordance with the indicated exponent in the antilog of the characteristic. It should also be pointed out that log tables are for, or thought as for, the log of numbers whose values are within the range of 0 to 1, or 0 to 10 (when the number is placed in standard scientific notation). It is also possible to use log tables in a sort of reverse type of process to evaluate antilogs (finding the Number value).

After evaluating 10^0.4605759 :

N = 2^1.53 = 2.887858435 : correct to 6 decimal places due to the previous rounding above

Ex. Evaluate 250^2.5

N = 250^2.5
log N = log 250^2.5
log N = 2.5 log 250

Let us try to express or place the Number into a value that's within a log table that goes from log 0 to log 1:

log N = 2.5 log (1000 x 0.250)
log N = 2.5 (log 1000 + log 0.250)
log N = 2.5 (3 + log 0.250) After solving (or from a table) the log of 0.250:
log N = 2.5 (3 + (- 0.602059991))

Note, logarithms of values between 0 and 1 are always negative in sign. Negative in sign simply means that the value is less than zero. More will be said about negative numbers later. Since log 1 = +0, it is easy to reason that the log of a number less than 1, and between 0 and 1, is less than 0 and is indicated as being negative. Continuing the above example:

log N = 2.5 (2.397940009) : after combining (formally, it means joining, addition, summing) values in the second factor, and the result here was essentially due to subtraction.
log N = 5.994850022 : N = antilog (log N) = antilog 5.994850022 = 10^5.994850022

We see that the characteristic is 5 and the mantissa is 0.994850022. Using the basic concepts of logarithms, expressing the antilogarithm of both sides to solve for the number (N):

N = 10^5.994850022
N = 10^(5 + 0.994850022) = (10^5)(10^0.994850022)

Using a table to find the common antilog of 0.994850022, the result is: 9.882117688. This value is to be multiplied by a power of 10 (here, indicated as the 5th power), and the easiest way to do that is to simply move the decimal point a number of places equal to the indicated exponent. Here, the decimal point will be moved 5 places rightward, and this is the same as multiplying by 10^5 = 100,000.

N = (10^5)(9.882117688)
N = (9.882117688)(100,000)
N = 988,211.7688

Ex. Evaluate 1.74^52

To find the value of this indicated power would be very tedious if performed by hand using repeated multiplication.

N = 10^(x log b) : basic formula, previously derived, for finding powers given the base and exponent.
N = 10^(52 log 1.74) factoring 1.74 to have a number less than 1 for solving with a log table:
N = 10^(52 (log (10)(0.174)))
N = 10^(52 (log 10 + log 0.174))
N = 10^((52)(1 + (- 0.759450751)) = 10^((52)(1 - 0.759450751))
N = 10^((52)(0.240549248))
N = 10^ (12.50856091)
N = (10^0.50856091)(10^12) using a scientific calculator or common anti-logarithm table:

$N = (3.225231628)(10^{12})$: this form itself would be typical of an acceptable answer
$N \sim 3{,}225{,}231{,}628{,}000$: approximate, since the last three least significant digits were dropped or omitted and unused during the calculation using a 10 digit calculator, or by visual inspection moving the decimal point.

Note, as mentioned previously, that any base of a logarithm can be used to evaluate a power as long as it is consistent in the calculations. Below is an example of the concept using a base of (e) instead of 10. (e) is well defined and roughly equal to 2.718282, and is used as the base for "natural" logarithms which are often used to mathematically represent things that happen in nature and expressed scientifically or mathematically. Evaluating powers of 10 usually requires a table or calculator to solve, however, all powers of (e) can be solved directly from a formula which will be presented further ahead in this book.

From: $N = b^x$ taking logs (with any base) of both sides:

$\log N = \log b^x$ and if the log taken had a base of (e) instead of 10, this must be explicitly expressed as:

$\ln_e N = \ln_e b^x$ ln indicates a natural logarithm, and is usually substituted for the word log when the base is understood as being (e), the natural logarithm base. This can be also be simply expressed as:

$\ln N = \ln b^x$ Solving for N considering the concept of antilogs:

$N = e^{(\ln b^x)}$ or from the "log of a power rule":

$N = e^{(x \ln b)}$: Finding a power of a value using natural logarithms (given $N = b^x$).

The appendix contains a general method for finding any power.

FINDING ROOTS WITH LOGARITHMS

The process of finding roots with the aid of logarithms is similar to that of evaluating powers with logarithms.

Ex. Evaluate $N = \sqrt[3]{1000}$: here, N is the root value. You can use another variable identifier for N, like R.

First, let's convert this radical form to its equivalent exponential form.

$N = \sqrt[3]{1000}$
N = 1000^(1/3) taking logs of both sides:

log N = log 1000^(1/3) or:

$$\log N = \frac{1}{3} \log 1000 = \frac{\log 1000}{3}$$

Finding N by taking the antilogarithm:

N = 10^((log 1000) / 3) = 10^(3/3) = 10^1 = 10

If you were to write an algebraic formula for the above procedure, it would look something like this:

$N = \sqrt[x]{b}$: N = root, x = index, b = radicand
N = b^(1/x) : exponential form
log N = log b^(1/x) : taking logs of both sides

or: $\log N = \frac{1}{x} \log b = \frac{\log b}{x}$

$N = \sqrt[x]{b}$ = 10^log N = 10^((log b)/x) : A GENERAL FORMULA FOR FINDING ROOTS using logarithms and antilogarithms

An important observation can be made here. The only difference between the (antilogarithm) notation for solving powers and roots is the placement of the variable(x). For powers, (x), the exponent of the indicated power, becomes a multiplier to the exponent of 10 (or any proper base used). For roots, (x), the root-index of the radical, becomes a divisor to the exponent of 10 (or any proper base used).

For powers: N = 10^(x log b)

Ex. 5^2 = 10^(x log b) = 10^(2 log 5) = 10^((2)(0.698970004)) = 10^1.397940009 = 25

For roots, (x) (the index or the indicated root) becomes a divisor to the exponent of 10 (or the proper base used).

Roots: N = 10^ ((log b)/x)

Ex. $\sqrt{25}$ = 10^(log b)/x = 10^((log 25)/2) = 10^(1.397940009/2) = 10^0.698970004 = 5

As like evaluating powers with any base, roots can be evaluated using any base as long as the base is used consistently.

Ex.. **$N = \sqrt[x]{b}$ = e^((ln b)/x) : Formula for finding a root using a power base of (e), and the natural logarithm base of (e). b = radicand, x = index**

Ex. Find the 10th root of 10 , using logarithms for the solution.

$\sqrt[10]{10}$ = 10^(1/10) = 10^0.1 = **e ^(ln 10 / 10)** = e^(2.302585093 / 10) = e^(0.2302585093 = 1.258925412
=~ 1.259 =~ 1.256 =~ 1.25

A proposal by the author of this book, and for logarithm notation in terms of a simple text editor abilities would be:

x = $\text{Log}_b\ N$ = log (b , N) : this is similar to computer programming, function notation with the required parameters expressed. The actual values used are called the specific arguments.

or:

x = $\log_b N$ = log (b , N) or= (log b , N)

or

x = $\log_b N$ = log (b : N) or= (log b **:** N)

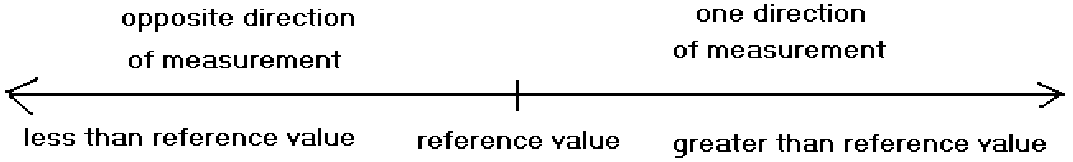
SIGNED NUMBERS

Signed numbers are numbers preceded by a positive (+) or negative (-) mathematical symbol. Numbers preceded by the negative symbol (-) are said to be negative numbers and have a value less than 0 or some other reference value.. Numbers preceded by the positive symbol (+) are said to be positive numbers and have a value greater than or equal to 0 or some other reference value. If a sign does not precede a number, or the sign is not explicitly indicated, the number is to be considered as a positive number. For example:

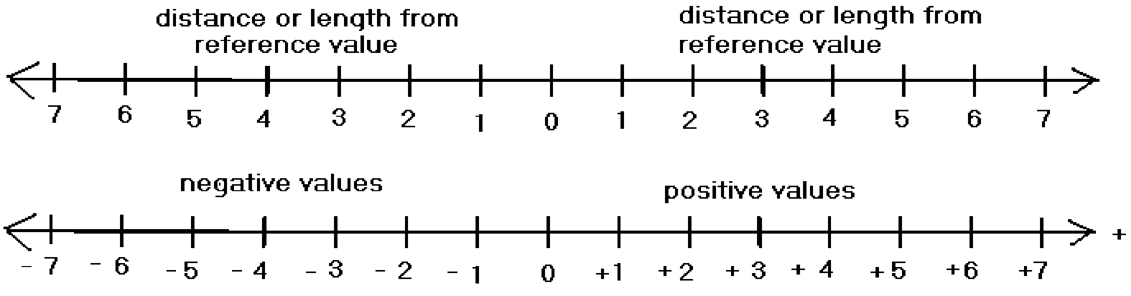
5 = +5 = "positive 5" and -5 = "negative 5"

How can a value be less than 0? A value can be less than 0 when that value is, or is considered as, a negative change, decrease, loss, or reduction from another given value which is considered as the reference value that change value is in reference to. That is, the change is in reference to some other value. So that you can get a good feel or understanding of signed numbers, their are several discussions below.

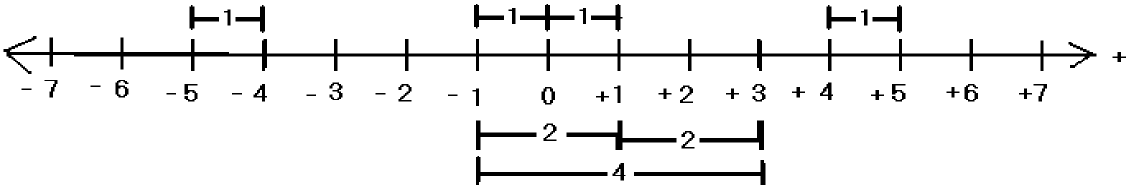
A very common use of both positive and negative numbers is with temperatures. It is common in cold climate areas to have a temperature that is "less than 0 degrees" with either the Fahrenheit or Celsius temperature scales. For example, the temperature may be "negative (or minus) ten degrees", and is indicated as -10°. Since no other reference value was given, this -10 value is in reference to 0 degrees which is the reference value. A negative sign indicates that a value is less than the reference value being considered. Here is a helpful "number-line" that is a graphical or visual reference to consider about signed numbers: [FIG 18]



The reference value can be any value, either positive or negative in sign. Usually when a reference or "starting" value is not given of which a number is in reference to, that number is understood to be in reference to a value of 0.



The length or distance between any two values is calculated as the difference between those two values. For example: The difference between +3 and +1 is: (3 - 1) = 2. The difference between 1 and 0 is: (1 - 0) = 1. The difference between 0 and (-1) is: (0 - (-1) = 1. The difference between +1 and -1 is: (1 - (-1)) = 1 + 1 = 2. The difference between +3 and -1 is: (+3 - (-1)) = +3 + 1 = 4



As you can see in the above drawing, the sign of a value also indicates its physical direction and-or location, and in a mathematical sense, this direction and-or location sign is either: "less than" (ie., - = negative in sign), or "greater than" (ie., + = positive in sign) a reference value.

If you had a starting or reference value of 5 things, and got 2 more things, this value of 2 can be expressed as :
The change of, in, or applied to the value of 5 was an increase of 2 = positive 2 = +2

If you had a starting or reference value of 5 things, and gave away 2 things, this value of 2 can be expressed as :
The change of, in, or applied to the value of 5 was a decrease of 2 = negative 2 = -2

As we can observe above, signed numbers, in particular when they have a mathematical sign (+, -) symbol, give or assign a "direction" or further meaning to that number. This meaning could be that the number represents an increase or gain from an existing or reference value (including 0), and therefore it would be noted with a positive (+) sign or symbol. If the number represents a loss or decrease from any existing or reference value (including 0, or even a negative value), it would be noted with a negative (-) sign. In short, signed numbers are in reference to some existing or reference value, and not necessarily in reference to 0 only.

Since signed numbers represent gains or losses with respect to an existing reference value (0 if none was specified, or if the signed value is a final result of a computation), signed numbers can simply be considered as a "change-value" or simply as the change (as a verb: to modify, or have an affect, and as a noun: the amount of the modification or affect, the numeric change value or value of the change) from the reference value. If a value changed to 5 less, this change would be noted as -5 numerically. Of course, to find 5 less of a value, or a value reduced by 5, this would normally be expressed and processed as a subtraction operation: value - 5 Below, the right hand side of the equations represents expressions for the signed number concepts:

value - 5 = reference_value - 5 : with signed numbers, value becomes a reference value for the change or change-value to be applied to, and have an affect on it

= reference_value with the specific change applied to, added to, or combined (+) with it
= reference _value + change_value

value - 5 = (reference_value) + (-5) : the sign of the change value is still attached to and associated with it

= new_value : the resulting or result value due to a change

Considering this example, note that when signed numbers are considered, expressions such as:

reference_value - 5 , are to be now considered or understood as actually indicating or meaning:

(reference_value) + (-5) = reference_value (+) -5 : reference_value combined (+) with a decrease value

This is so, since when a value changes to a lower value, that value is said to have decreased, or the change in that value is said to be a decrease, and the specific amount of this change or the change value is mathematically said, expressed or represented as negative 5 = -5 , rather than positive 5 = +5 such as if the change was an increase. You can consider -5 as expressing a change or decrease of 5.

What looks like a subtraction expression, is now to be considered or understood to the be combining (as noted with the addition or combine symbol of: +) of signed numbers or values rather than a subtraction expression. The values being combined are called "signed (numeric) values" or "terms". Note that in the original expression above, and in relation or reference to signed numbers, that the combine symbol (+) can be considered as "hidden" or "understood", just as when the positive symbol (+) is considered "understood" when not explicitly indicated for a value greater than 0.

What if you added or combined two decreases or losses? The answer is that the net or total decreases or losses actually gets larger or greater in value when they are combined (essentially signed number addition, which is the addition of signed numbers). The decrease or loss would be said to be greater, a greater loss, hence it would be expressed or represented as a larger negative value. In a notation-like form:

decrease + decrease = larger decrease : the sum of decreases, so as to find the net or total decrease
(-5) + (-5) : add the losses together and keep the (common) sign that they are decreases or losses:
-5 - 5 : here, shown without the "hidden" addition or combine symbol

-(5 + 5) = -(10) = -1(10) = -10 : - (5 + 5) = -1(+5 + 5) = (-1)(5) + (-1)(5) = -5 - 5 = -10
This can also be thought of as:

- (total sum of [signless] decrease values) :And it is also a factored form where (-1) was factored from each term of:
(-5 + -5) = (-1)(5 + 5) = -1(5 + 5) = - (5 + 5) = -(10) = -10

Any positive number has an equivalent negative number counterpart (an (opposite) correspondence or resemblance), and vice-versa. Though the signs are different, they both have the same magnitude (essentially the "plain (signless)" distance or length), value, position or distance from 0. Below is a graphical representation of signed numbers using a "signed number line" graph. From the reference value, here 0, numbers in one direction are assigned (signed) as being positive, and for the opposite direction, they are assigned negative signs and are therefore called negative values, and which could simple be stated or "thought of" as numbers, lengths, distances, changes, etc., in the opposite direction:

```
  <--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|---------->
- ∞ . . . -5      -4      -3      -2      -1       0      +1      +2      +3      +4      +5 . . . +∞
```

∞ is the "infinity" symbol which indicates that there is no limit to the possible values, hence "infinity" has no specific, constant or actual value, and is more of a concept for an unending process. Consider something that is "infinitely big" or "infinitely small". Outer-space is considered as infinitely big or unending.

A change can be either an increase or a decrease. The opposite of an increase is a decrease. The opposite of a decrease is an increase. Increases and decreases are counterparts (or the "negative") of each other. If the change is an increase, the value of that change is noted or expressed with a positive sign: +value. If the change is a decrease, the value of that change is noted or expressed with a negative sign: -value.

You might now ask, how do you mathematically express the opposite of a positive value, and that is to take the negative, or opposite of it:

The opposite or negative of a positive value is: - (positive value) = negative value = -value

Ex. - (increase value) = - (+5) = -5. , a decrease value : this is the same as multiplying the initial value by negative 1 = (-1) = -1, as will be shown later. Consider that if you multiply a value by 1 that the result is still that same (unchanged) value: (value)(+1) = (value) ,and if you multiply that value by (-1), the result is: (-value), or the opposite, whether value itself was actually either positive or negative in sign as a signed value.

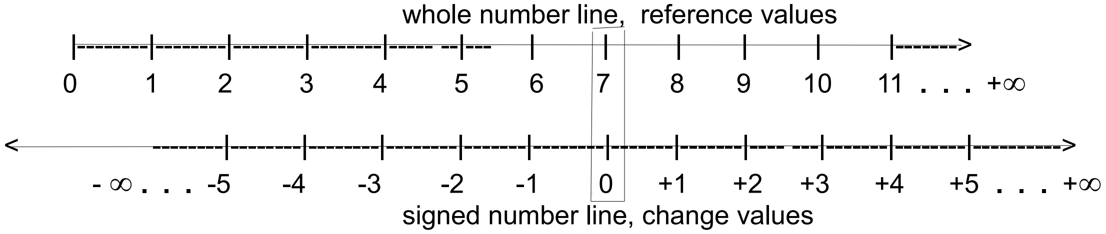
Likewise to mathematically express the opposite of a negative value, you also take the negative or opposite of it, and the result is a positive value:

The opposite or the negative, of a negative value is: - (negative value) = positive value = +value

Ex. - (decrease value) = -(-5) = +5 , an increase value : again, this is also the same as multiplying the value by negative 1 = (-1) = -1, as will be shown later

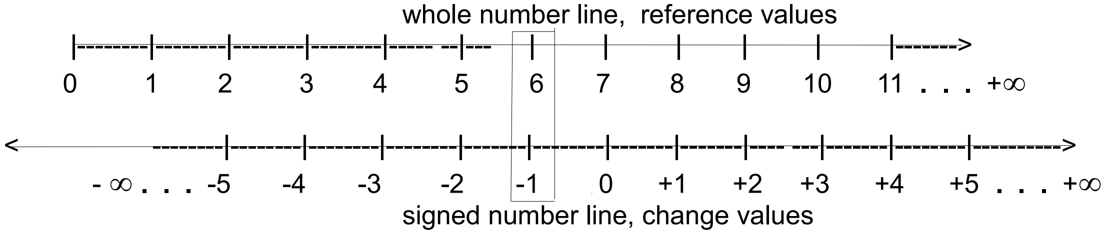
Choosing any signed number value such as graphically expressed on the signed number line, even if it's a negative number, all values rightward of any (reference) value are said to be "more positive" or greater (larger) in value. Likewise, all values leftward, of any value on the line, are said to be "more negative" or less in value (since those values are headed closer to, or towards that direction on the signed number line).

Here is a signed number, or "change value", line positioned or aligned to be in reference to 7 on the common whole number line: [FIG 19]



On the signed number line, or change number line, 0 means no change (yet) applied to the reference value chosen, and here, it's set or indicated as 7. To the left means a decrease or loss. To the right means an increase or gain.

Given a reference value of 7, if the change to 7 is a loss or decrease of 1, move to the left of 7 by 1 position for the result. This process can be indicated and automatically calculated mechanically, by first aligning the 0 change value with the reference value of 7. then move or slide the (amount of) change indicator ("pointer" or "cursor") to the (-1) position. The result is indicated directly across from it on the other ruler or number line, and it is 6.
7 combined with a change of (-1) is 6. 7 + (-1) = 7 -1 = 6 : [FIG 20]



The above concept is also an example of a simple automatic mechanical calculator than can perform addition or subtraction and display the result visually. This construction is a type of "slide rule" system that you can construct with two rulers aligned to be in parallel. To the right of 0 on the signed number or change in values line, you could place a word such as "INCREASE", and to the left of 0, you could place a word such as "DECREASE". To uses this calculator, move or position the zero (or "no change") mark of the signed or changed number line directly across from the reference number in question. Though it may not be apparent, the difference between any two corresponding values on these two number lines as set and shown above, has a value equal to the value in reference (the reference value), and for this example, it is 7:

reference value + change = sum : the change can be either positive or negative.
7 + (-1) = 6 mathematically, if change is subtracted from both sides:

sum - change = reference value : again, the change can be either positive or negative

6 - (-1) = 7 : this should be interpreted as: (+6) + (-(-1)) = (+6) + (+1) = 7

We see that when combining a positive value and a negative value, it results in the difference (or mathematical amount of separation, such as on the number line) between those two values. Considering 7 as the reference value, the difference between 7 and 6 is (7 - 6) = +1 , hence it can be said that 7 is 1more than 6, and-or 6 is 1 less than the reference value of 7. Considering 6 as the reference value, the (signed) difference between it (6) and 7 is (6 - 7) = -1, hence it can be said that 6 is 1 less than 7. The negative value indicates the result is less than the reference value, and this would be so, even if that reference value was also negative in sign.

The common whole number line can also be extended (leftward) to include the negative whole numbers leftward of 0, and so as to make a more functional (mechanical) calculator that can also work with negative (reference, or starting) values.

Where are the sign symbols from? They are a direct result from the addition, adding, or combination (combine, combining, "and", "mixed with" or "joined to or with") symbol of: (+), and the subtraction (remove, take-away, reduce, lessen) symbol (-). However, with signed numbers where the subtraction symbol appears to be utilized, it is rather a negative symbol (-) associated with a value, and is not a mathematical operation symbol.

Ex. If you had zero and added one to it, the expression would be:

0 + 1 = 1 :adding a number to 0, is essentially not adding anything to that number: 1 + 0 = 1, and the result is that same number

Therefore, if you had 1 and subtracted 1 from it, you would have:

1 - 1 = 0 : First, subtracting is applying a decrease or loss. This decrease can be noted mathematically as a negative change, and the actual value of this change will be assigned a negative sign to indicate or express this. Here. the decrease or change is 1, and it is expressed as a signed number as: (-1) or = -1. This change will be applied to the value of 1. 1 combined, added to, or applied with the change = 1 + change = 1 + (-1). Hence: 1 - 1 is to be understood as = 1 + (-1).

1 - 1 = 0, this the same as (+1) - (+1) = (+1) combined with, or applied to (-1) = +1 (+) -1 = 0
Just the same, since the order of addition or combining does not matter, and the sum remains the same, this can be considered a: (-1) combined or applied to or with (+1):
+1 (+) -1 = -1 (+) +1 = 0

Hence when you see: 1 - 1 this can be considered as equal to the sum of two signed values of:
(+1) and (-1) = (+1) + (-1) = +1 -1 = 1 - 1 = (-1) + (+1) = -1 +1 = 0

If you then take this 0 and subtract 1, as in "1 less than 0 (as the reference value)", you would have:

0 - 1 = -1 As a check to this, consider adding 1 to each side, and the equation will still be in balance. Here is where the subtracting operator, operation or symbol becomes the negative symbol or sign, and continuing this concept of notation: 0 + 1 = +1, we have the positive sign.

$0 - 1 + 1 = -1 + 1$: each side can also be expressed as just : $+1 - 1$ or $= -1 +1$ since 0 adds nothing.
$0 = 0$: The combining of an increase and decrease, both having the same value, results as if no (net, total, or final) change has taken place:
(increase) + (decrease) = 0 = (+value) + (-value) = +value - value = 0
Ex. 7 was increased by 3, and then decreased by 3. This can be expressed as:
$(7 + 3) -3 = 10 - 3 = 7 = 7 + 3 - 3 = 7 + 0 = 7$
Mathematically: $7 + 3 - 3 = 7 - 3 + 3 = 4 + 3 = 7 = -3 + 3 + 7 = 7$

OR, it can be said that -1 = "negative one" added to nothing is still that same value of -1:
$(-1) + 0 = 0 + (-1) = -1 = 0\ (+)\ (-1) = 0\ (+)\ -1 = 0 -1$, since when 0 is added to any value, the result is that same value, or that the value is unchanged. So, this is where signs and terms (numbers preceded by a sign) started into use. Rather than say -1 means "subtract one", which is a mathematical operation, people now can even use negative-one (-1) to show that this is a result of a mathematical operation, rather than a mathematical operation that needs to be performed. Writing an expression for the addition of -1 and +1, both being 1 more or less from 0, their combined (+) sum should be 0:

$(+1) + (-1) = 0$: a value summed or combined to its opposite value is 0, or no value.
A value combined or added to 0 is that same value:

$(0 + 1) + (0 - 1) = (1)\ (+)\ (- 1) = 0$ or:

$-1\ (+) +1 = -1 + 1 = 0$: you can either add -1 or +1 to both sides to see that the equation is still in balance.

Rearranging the elements, operands, or addends to be summed or combined , their sum should still be the same, no matter what order they are summed or combined together:

$+1\ (+) -1 = 0$ On the number-line, if given 1, you would go rightward from 0 to +1, then if you were to take away 1, this is indicated as -1, which means to move along the number-line in the opposite direction 1 position leftward. Doing this, we arrive back at 0. We see that signed numbers indicate the new value or change to be added in or combined into the running sum is to reduce (-), or increase (+) the current total of the sum.

The add or combine symbol (+) can be removed if we consider that the sign goes with each operand that is to be combined, and then this combine symbol (+) can be eliminated or hidden, and understood that the signed number operands, or terms, are being added or combined.

Without signed numbers or terms, it would be difficult to solve equations by transposing (essentially eliminating a term, and moving its signed number counterpart) values from one side of the equation to the other so as to keep the equations in balance.

In short, a simple explanation of signed numbers goes something like this:

+5 is five more than something, and -5 is five less than something. or:

+5 is a change that is an increase, and -5 is a change that is a decrease.

If something was 80 degrees and cooled off to 70 degrees, the change in temperature was (80 - 70) = 10 degrees. Since the change in temperature was a decrease in temperature, this would be noted with a negative sign as -10. If the change in temperature was ten degrees higher, this would be noted as +10. -10 means a decrease of 10, or 10 less than something (here its 80 degrees, and for another day it could perhaps mean 10 less than 50 degrees). See, negative numbers don't have to mean less than 0 always, when they are considered as a decrease or a (negative) change from any another value (ie. the reference, initial or starting value, and not necessarily 0).

Ex. Consider we have a "running" (continuously updated) current total or sum, that is, we are to add in all new values as they come along or happen, to the current or accumulated value of the sum. Perhaps we are putting apples into a basket as we pick them. Sometimes there will be a decrease in the number of apples because someone took some apples out of this basket. This essentially causes the sum of apples to change to a lesser or lower value. This decrease or change can be mathematically indicated as a negative sign preceding its (decrease) value. If someone put some apples back into the basket later, this change can be mathematically indicated as a positive sign preceding its (increase) value. With the concepts of signed numbers (numbers that mathematically indicate or represent an increase or decrease), we can mathematically express this running total or sum as a single equation, of running addends or operands, rather than in multiple steps such as something like:

Equation 1: first_sum = number1 + number2 : perhaps various amounts of apples put in the basket
Equation 2: second sum = first_sum - number3 : here, number3 is negative in sign since it is the number of apples that were taken from the basket. This value or term is being summed or combined to: first_sum

These multiple equations can be mathematically expressed (more simply) as:

sum = number1 + number2 - number3 +/- . . .

This expression above is actually a method that would be employed without even knowing the concepts of signed numbers. Since all changes are to be added into, or applied to, the running sum, and if we do not yet know if a change will be an increase of a decrease, we will simply write or indicate this expression as the combining (over time, as changes take place and we know the values of those changes) of known, or yet to be known values.

sum = number1 + number2 + number3 + . . . : here, the word "number " is essentially a formal placeholder (ie. a variable) for any possible value, including its sign, since the value could be either positive or negative,

Using this form of the expression eliminates what appeared to be a subtraction operation in a running summation (sum) and then assuming that the other numbers or operands are always positive in value. With this new notation, it is understood that all terms (a number preceded by its sign) or operands (actual values, constants or variable[any, or many possible values]) or are always considered as signed values that are to be added or combined using the rules (which will be discussed) for signed numbers.

ABSOLUTE VALUE

| | is the absolute value (mathematical) operation symbol. It is used to transform a signed number into its general distance or "magnitude" from zero. The absolute value of a signed number is that number without its sign (hence mathematically equivalent to the positive value).

Ex. $|+5| = 5$: "The absolute value of positive five is five".

Ex. $|-5| = 5$: "The absolute value of negative five is five".

Both of the signed numbers above have an absolute value of 5 since each of the signed numbers has a distance of 5 from 0. This also shows that +5 and -5 are signed number counterparts. Signed number counterparts obviously will sum to 0: value + (-value) = value -value = 0

Consider the difference between 6 and 7. In reference to 6, it could be said that 7 is an increase of 1 and this could be mathematically expressed , noted or indicated as: +1. In reference to 7, it could be said that 6 is a decrease of 1, and this could be mathematically expressed, noted or indicated as: -1. Still, they (6 and 7) both differ from each other by an absolute (or real) value of 1:

$|+1| = |-1| = 1$: if this was a length or distance, it would have to be positive or signless in value since there is no actual physical length or distance that has a negative value.

WHAT ARE THE SIGNS USED FOR?

Values that represent decreases or losses are noted using a negative sign (-) preceding it, and values that represent increases or gains are noted using a positive sign (+) preceding it.

What are terms?

Together, a number and its sign is called a **term**. Terms are the operands of signed number addition or combining. A single term by itself is sometimes called a monomial or single term expression. The word "mono" means "one" (= 1). To solve or "simplify" a multiple (sum of) terms expression, often called a multinomial, is to possibly combine (essentially a summation by signed number addition) the terms into a single term (essentially the sum).

Ex. If the temperature increases by some value, the value of the actual change in temperature would be noted using a positive sign since the temperature increased. If the temperature decreases by some value, this change in temperature would be noted using a negative symbol. Hence, the signs help give meaning to values they precede. In this example, the signs indicate the change in temperature in reference or with respect to an initial temperature of which could also be either positive (pos.) or negative (neg.) in value.

A general expression, statement or formula for the new temperature, in relation to the old temperature, can be:

(old temperature) + (change in temperature) = (new temperature) : each could be either pos. or neg. in sign

For example, if the old temperature was +80° ("eighty degrees") and the change in temperature was 10° cooler, this 10° drop or decrease would be noted as: -10°. The new temperature using the formula above is:

$$(+80^\circ) \quad + \quad (-10^\circ) \quad = \quad +70^\circ$$

Usually, the addition or combine (to add terms mathematically, considering their signs) symbol would be omitted or "hidden", but it still should be understood that these terms are being combined, and the expression would be the familiar looking:

+85° -10° = +70°   showing the hidden or understood combine symbol between terms: +85 (+) -10 = +70

Here, from now on, it will be understood that the terms (+85°) and (-10°), "positive eighty-five, and negative ten", are being added or combined. That is, do not think of the (-) symbol as a subtraction symbol, but rather think of it as the negative symbol that goes with the value of 10, making that term of (-10°). Hence, in a way, there is "no real (formal) subtraction operation" with signed numbers, and there is really just the addition or combining of signed numbers or terms. Differences (or the amount of separation) in values may still need to be found, and then a subtraction operation is used on the signed numbers or terms.

To advance you're mathematical capabilities, it is perhaps better to consider all values as terms or signed values. That is, don't think of signed values or terms as a "special unique feature", but think of them as more like the "main feature", particularly for simplifying and solving equations. With some occasional practice, you will naturally gain more familiarity and confidence using these concepts.

SUBTRACTING A VALUE THAT IS LARGER

With the concepts of signed numbers, it is now mathematically possible to subtract a larger value from a smaller value. As a graphical illustration, observe the drawing below of the number-line: [FIG 21]

```
     <--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|---------->
- ∞ . . . -5      -4      -3      -2      -1       0      +1      +2      +3      +4      +5 . . . +∞
```

If you subtract 1 from 5, you have 4. This can be accomplished using the drawing above and then by moving 1 position leftward (to the lesser values) from the (reference, or "starting") position marked 5. Likewise, if you were to subtract 7 from 5, the result can be found by moving 7 positions leftward from 5. The result is: -2. The mathematical method to get the same results will be shown in the discussions to follow.

ADDING SIGNED NUMBERS

We know that adding two "common or plain" unsigned or positive numbers equals a larger unsigned or positive value. Symbolically:

(positive value or term) + (another positive value or term) = a larger positive value or term

Ex. 5 + 2 = 7 which really means when considering the signs as associated with signed numbers (ie. terms, of an expression):

(+5) + (+2) = +7 : Here, the "hidden" addition operation or combine symbol is explicitly shown between the two terms that are shown parenthesis. The two terms being summed or combined are: positive five: (+5), and positive two: (+2). The result of this expression of a sum of terms is a single term having a value of positive seven, (+7). This may also be expressed sometimes as:

+5 (+) +2 = +7 : here, the implied and understood combine (add) symbol is explicitly indicated or expressed, also:

(+5) (+) (+2) = (+7) : is a possible expression of the above equations

(+5) (+2) = : if the above expressions are expressed this way, it is an error since it now indicates the product of the two values, rather than the addition of the two values, and the result it actually +10, and not +7.

Adding or combining a negative value to another negative value is effectively adding or combining a decrease to another decrease, hence making a larger total or net decrease, and the sign of the sum is therefore negative. Symbolically:

(negative value or term) + (another negative value or term) = a larger negative value or term

Ex. -5 - 2 = -7 which really means:

-5 (+) -2 = -7 : Again, the hidden addition operation or combine symbol is shown here for the understanding that these terms, or a series of terms, are to be mathematically combined (added) to produce a net result or sum term.

If a negative value (or decrease) is added or combined with a positive value, or vice-versa, the resulting (signed) sum is equal to the largest difference of the absolute values of the two, and the sign of this sum is from the operand (here a term) with the largest absolute value. In other words, subtract (take difference) the lowest absolute value from the highest absolute value, and keep the sign of the highest absolute value. On the number-line, the resulting sum will be someplace between those two given values.

(positive value or term) + (negative value or term) = | largest term | - | smallest term | = sign of largest term, difference

Even though the expression is for the sum of two terms, the result is actually found by a difference operation when the signs of those terms differ (are not the same). The result will neither be a larger positive value, or a larger negative value, but a less positive value and-or a less of a negative value.

Ex. +5 -2 = +3 :"positive five added (or combined) to negative two is positive three"
OR.= -2 +5 = +3 : since addition is commutative (commutative law), you can rearrange the terms or (signed) operands being combined, added or summed.

Ex. -5 +2 = -3 : | -5 | - | +2 | = 5 - 2 = 3 applied with the sign of the value that has largest absolute value,
OR. +2 -5 = -3 and since 5 is greater than 3, the proper sign will be from its corresponding term. Here, the term of which 5 was from is: (-5), so therefore, the sign to apply to the resulting sum of the combining of those two terms will be the negative sign. This is so, since although the result is less negative, there is still some of its negative value still remaining after the combine operation, and it must therefore be indicated or expressed as part of the result. Here, the result is negative three = (-3).

If you want, you can easily verify all these results on the number lines shown previously. It is interesting to note that the difference or separation between -5 and +2 on the number line is actually +7, and not -3, and this can be shown by subtracting those two values from each other:

-5 - (+2) = -5 -2 = -7 = 7 in absolute value , or:
+2 - (-5) = +2 +5 = +7 = 7 in absolute, signless value

Again, if given a negative value and you then add a positive value to it, the sum may still be negative, as when the largest of the two signless values was negative, but the sum or result can be said as being "less negative" in reference to its previous and larger negative value. For example, when +2 is added to -5, the sum is -3. -3 is said to be less negative than -5.

Ex. If the temperature outside was -20 and then it "warmed up" to -3, this change is usually said to be better or positive even though it is still below zero (ie. negative) degrees outside. The temperature is headed or getting closer to being a positive value.

If you are performing addition of signed numbers with a standard "home" calculator which does not have a "sign" or "change of sign" key, below is a somewhat "wordy", but simple example of how to add or combine signed numbers in such a situation. First, some calculator that do not have a "sign" key actually allow you to enter negative numbers by first pressing the "minus" or "subtract" key before entering the number (which is essentially the same as entering: 0 - number = -number, and then press = or the next operation key, or by pressing: number - and then = , where the calculator assumes the first operand is 0. For a simple check to see if your calculator can display negative numbers, subtract a larger positive (or signless) value from any smaller positive value, and the result should be negative in sign (indicated before, or sometimes after the result). For example, enter: 2 - 3, and the result displayed should look something like -1. If your calculator does not work with signed values (particularly negative values) you must establish and record the sign of each operand and result mentally or manually on paper.

Add positive five and negative three using a simple "home" calculator.

(+5) + (-3)

Since subtraction of a number is really equal to the addition (combining to make a sum) of the negative, "opposite" or "reverse" of that of that number, we can transform this addition problem back into a common subtraction problem by subtracting the negative, "opposite" or "reverse" of that number.

(+5) + (-1)(-3) : Multiplying by (-1) to have the reverse or counterpart of (-3).

(+5) + (+3) We must change the sign of the operation since we are now adding two positive numbers for an increase, however we want to combine (ie. add) a decrease to (+5) as shown in the original problem, so we must therefore use the common subtraction operation instead of the addition operation:

(+5) - (+3) : as mentioned, this subtraction of a value is equal to the addition of that negative of that value. (+5) - (+3) = (+5) (+) -(+3) = +5 (+) (-3) as first given. And this will be performed on the calculator as:

5 (-) 3 : five minus three
+2

Summarizing the results: +5 (+) -3 in common, non-signed number form = +5 (-) +3

Again, the conceived subtracting a number is really adding or combining the negative of that number when working with signed numbers.

If your calculator does have a (change or enter) sign-key or button (often indicate as: [+/-]), to enter a negative number, first enter the absolute (signless) value of that negative number and then press the "sign key" to display the negative symbol with it. If you press the sign-key again, the value displayed should change back to a positive value.

As an extra note which could be helpful to understanding the difference or separation of absolute values: If the signs of two values being added or combined are exchanged, the result is opposite in sign, hence both sums have the same absolute value:

First note that: |-7| + |+2| = 7 + 2 = 9 , and |-7| - |+2| = 7 -2 = 5

Now consider addition with the operands signs reversed:

+7 -2 = +5 and -7 +2 = -5 , Hence: |+7 - 2 | = |+5| = 5 and |-7 +2| = |-5| = 5 : A difference of 5 for both.

GETTING LESS AFTER ADDITION

Here is a very understandable descriptive analogy of how something can be less after adding or combining.

There is an empty container, its volume or space is first filled halfway with hot water, then the container is filled (ie. combined, or added, (+)) to the top with cold water. Surely, the amount of water has increased, but this is not the case for the temperature. The net (final total or sum) result of the water temperature is that it is not hotter (higher in temperature), but is now only a warm temperature, and that the temperature of the water is now less and is said as being "cooler", "lower" or "less" in value as compared to the original, starting, or reference temperature.. This is commonly thought of as:

"hot plus cold, equals warm" : you can view warm as "less hot", or "not as hot" in temperature, and that
or "cold added to hot, equals warm" is similar to saying a value is less positive than before

Note that the cold water temperature is really in reference to the warm water temperature, and vice-versa. For example, cool 34 degree water can still be called cooler water than 35 degree water, even though its barely noticeable, and when both are actually cold to most people. To account for all possible temperatures, and all possible changes in temperature, a (more generalized) equation such as this is written:

temperature + change in temperature = new or resulting temperature.

Ex. Without using any specific units of measurement such as pounds or kilograms, let's say that a force of 10 is being applied to an object in one direction, and another force of 3 is being applied to the object in the opposite direction. What is the net , effective, or resulting force?

The force in the opposite direction will be assigned a negative sign. The net or effective sum of the forces is:

force_1 + force_2 = new or resulting force or:
force + change in force = new or resulting force

+10 + (-3) = +10 -3 = +7 : The right hand side of the equation shows the expression without the hidden combine symbol since it should be understood by now that the individual terms (+10, and -3) of this expression are being combined.

If the force being applied in the opposite direction had a value of 10, the resulting force would be:

+10 + (-10) = +10 -10 = 0 : Objects usually move when a force is applied to it, and here, the object would not be moving since the net or total force acting upon it is 0.

Ex. Suppose we give an algebraic sign of (+) for the distance an object goes upwards, and a (-) sign for the distance an object goes in the opposite or downward direction. A ball is thrown straight upwards for 50 units of distance, and due to gravity, it will fall downwards 50 units of distance. How far (as in the "signed number" or "algebraic" change in distance from its starting or reference position) did the ball travel?

Total Distance = Sum Of Distances

+50 units (+) -50 units : shown with the implied or hidden combine symbol
+50 units - 50 units combining terms (to simplify):
0 units :the balls ending location is the same as its home, initial or start location

This result might appear to be very odd. You could argue that it went 50 units up, and then turned around and went another 50 units as it fell back, and hence a total of 100 units of distance. This is of course absolutely true if the distances are considered as undirected (essentially the signless or absolute values) or non-signed, but because of the directional mathematics with signed values, the net distance moved is 0 units, as can be clearly seen since the ball is in the same position or location as where it started from. The change in distance of it's ending position and its starting position is essentially 0, whether the ball moved or not.

Although much of this has already been discussed here and there previously in this book, here is another helpful discussion and an example that shows that the sign of a number indicates the difference or change from another (reference) value in such a manor so as indicate (ie. with a sign) if the change was an increase or decrease from the starting or reference value. If no reference value is indicated or known, it is understood that the signed number value is a simple result of an equation, or a basic measurement (which has a reference value of and for that measurement, usually considered or understood as 0, such as on a ruler (a reference scale to measure distance or length) or a weighing scale).

If the value is not considered as a difference, or in reference to some value other than 0, but is a final or a resulting value of some expression, the value is understood at being in reference to a value of 0:

Ex. +10 , "positive ten", without any reference value, is understood as being 10 greater than 0
-10 , "negative ten", without any reference value, is understood as being 10 less than 0

If the value is in fact a difference of two values, it indicates the amount of change in the first value so as to be equal to the second value. This difference can be expressed in two ways:

1. A signless or "magnitude, absolute or plain common numeric value": Ex. 10 , "ten"

2. A signed numeric value: Ex. +10 = "positive ten" , or -10 = "negative ten"

Now consider two values, let v1 = value_1 , and v2 = value_2

Ex. v1 = +10 and v2 = +7 : or if just signless values were given: v1 = 10 and v2 = 7

Lets consider v1 was the initial value and v2 is its final, current, new or resulting value after some change in or of v1. Since these values are different (not the same or identical), a change has occurred to the first, starting or initial value (here, considered as v1). This change (as a measure of the specific or actual difference (a measure of the separation of two values)) or differences in values can be calculated with a subtraction (or "difference operation", since the result of a subtraction operation is a difference) operation.

v1 + change in v1 = v2 or simply:
v1 + change = v2 solving for change:

change = v2 - v1 since the change (in v1) is actually expressed here as a difference (d) value:

change = d = v2 - v1 = ending value - starting value Note, for an unsigned number system, you must use:
d = highest absolute value - lowest absolute value

d = v2 - v1
d = +7 - (+10)
d = +7 - 10
d = -3 : the difference or change was negative, or "negative in value", indicating
the new value is a decrease or less than (<) the starting value. +7 < +10

Knowing there is a difference and its value, it is used to indicate a "numerical comparison or relationship" of one value with respect (in reference) to another. It will indicate if a value is greater than or less than another, and by how much.

If the specific value of d is positive in sign, it indicates an increase or gain, and that the new or ending value is greater (>) than the starting value: new value > starting value.

If the specific value of d is negative in sign, it indicates a decrease, lessening, reduction or loss, and that the new or ending value is less-than (<) the starting value: new value < starting value

For the example, variable (d), the difference or change value is -3.

ending value < starting value : likewise, mathematically: starting value > ending value
$+7 < +10$ $\qquad$ $+10 > +7$

Ex. If $v1 = +7$ and $v2 = +10$

From: $\text{change} = d = v2 - v1$

$\text{change} = d = (+10) - (+7)$
$\text{change} = d = +10 - 7$
$\text{change} = d = +3$: a positive change value or difference indicates a gain or increase has taken place or occurred.
here, ending value > starting value
$+10 > +7$

If you were to apply a change of (-3) to a value, such as (+10), you would express this operation as an addition or combining operation of two or more signed values. Here the combining operation is applied to or upon the starting value of (+10):

starting value + change = ending value , or by switching sides:

ending value = starting value + change
$+7 = +10 + (-3)$
$+7 = +10 \;\; -3$ this is the same as: $+7 = +10\ (+)\ -3$
$+7 = +7$: checks

We see how useful and important the sign is with its corresponding value, as in a signed number system. If the change was only indicated as 3 and without the negative sign or an indication of being "3 less", the ending value would commonly (in an unsigned number system) be calculated to be: $+10 + 3 = 13$ which would be the wrong result and which has a difference of +6 (ie, 6 higher, off or away) from the true result of (+7). In a sign number system, the sign is always kept with the value, and generally not to be discarded, so as it will be used in any further calculations so as to achieve the correct results. The sign is now part of the number or value. (+7) and (-7) are two different numbers. One value, (+7) is 7 more than 0, and the other, (-7) is 7 less than 0 (or possibly some other reference value). (+7) and (-7) are quite different, and expressing this difference mathematically or quantitatively, the difference between them is a relatively huge value of: $(+7) - (-7) = +7 +7 = 14$. The value or number of (-7) is just as important and useful as $(+7) = 7$.

MATHEMATICALLY EXPRESSING SIGNED NUMBER COUNTERPARTS

The mathematical counterpart (corresponding, and "opposite") of a signed value or number is equal to that same value, but with a sign change. Mathematical counterparts of signed values or numbers have the same (signless, or unsigned) absolute value, "magnitude" or distance from 0. To change the sign of a value, simply subtract it from 0, or just take the negative of it by multiplying it by (-1).

The negative (-), "reverse", mathematical or number-line counterpart of a positive value is a negative value. Expressing this mathematically:

Ex. -(+5) = -5 : the negative of positive five is negative five. This is a single term and expression.
If you add 0 to this term (to create a two term expression and to help understand the result), it wont change its value: value + 0 = 0 + value = value
-(+5) + 0 = 0 (+) (-(+5)) = 0 (+) -(+5) = 0 -5
0 - 5 = (0) + (-5) = -5 since 0, or no change, added or applied to any value is equal to that same value. Likewise any value added or applied to 0 is still equal to that same value.

The negative (-), "reverse", or counterpart, of a negative value is a positive value: Expressing this mathematically:

Ex. -(-5) = +5 , or= -(-5) = -1(-5) = +5 = (-1)(-5) = +5 : the negative of negative five is positive five

The expressions on both sides of the equations in the above examples will be mathematically verified in the discussions to follow, such as the multiplication of signed numbers. Technically, the set of whole (common "counting") numbers and their corresponding negative counterparts are classified as the "integer" numbers.

MULTIPLICATION OF SIGNED NUMBERS

The product of two positive terms is a positive term, as expected since it is much like the multiplication of two unsigned values. The product of a negative term and a positive term is a negative term. The product of a negative term and a negative term is a positive term. All these rules can be verified using repeated addition.

Ex. (+2)(+3) = +6 Essentially, this is an example of "repeated increments (addition)". Here two will be added to zero (think of the starting point, a sum that is nothing =0) a total of three times. In other words, three, twos will be summed, or that two will be summed three times.
Note also, (+2)(+3) = (+3)(+2) since the order of multiplying does not matter.

since +2+2+2 or= (+2) + (+2) + (+2) : shown on the right side with the "hidden"
+6 addition or combine symbols.

Ex. (-2)(+1) = (-2)(1) = -2 : any value times one is still that value. If you were to start at the 0 or "reference" position of a number line and reduce this by 2, by going in the leftward or the negative direction (essentially a subtraction), you will arrive at -2. (+0)+(-2) = +0 -2 = -2

Ex. (-2)(+3) = -6 :This is an example of "repeated decrements (subtraction)", so the result should then be less, or more negative. Negative two will be added to 0 a total of three times. This might be more easily seen when rewritten as: (+3)(-2) using the commutative law. Since the second factor is negative, and not positive, the result cannot be positive. Instead of repeatedly adding (+3) a total of (2) times, this is effectively repeatedly subtracting (+3), a total of (2) times, from 0.

since -2-2-2 or (-2)+(-2)+(-2) = (-4) + (-2) = -6

Ex. $(-2)(-3) = +6$ This is verified below:

First, it can be shown that:

$(-3) = (-1)(+3) =$ the negative or counterpart of $+3$ is -3. : adding -1 three times is $(-1)+(-1)+(-1) = -1 -1 -1 = -3$

That is, $(-1)(+3) = -(+3) = -3$: or $= (+3)(-1)$

Then:

$(-2)(-3) = (-2)\ (-1)(+3) = (-1)(-2)(+3) = -\ (-2)(+3)$

Essentially then, the negative or counterpart of (-2) will be used as a multiplicand , and for the repeated addition:

$-(-2) = +2$: the negative or counterpart of (-2) is $-(-2) = +2$
"the negative of negative two, is positive two"
$-(-2)(+3)$
$(+2)(+3)$
$+2+2+2$
$+6$

An alternate verification is:

$(-2)(-3)$
$(-2)(-1)(+3)$ using the commutative law:
$(-1)(-2)(+3)$
$(-1)\ (-6) = -(-6)$ and the negative or counterpart of (-6) is:
$+6 = +6$

A negative value times a positive or signless value results in a larger negative value, and is due to the repeated addition of that negative value. It is not too difficult to then understand that a negative value times a negative value should be of the opposite sign, and cannot have a negative value. The opposite of a negative value is a positive value. Summarizing the signs of the results or products of signed number multiplication:

(positive value) x (positive value) = positive value
(positive value) x (negative value) = negative value
(negative value) x (negative value) = positive value : (negative) (negative value) = - (negative value) = + value

DIVISION OF SIGNED NUMBERS

If the signs of the dividend and divisor are the same, either both positive or both negative, the sign of the quotient will be positive, otherwise, it will be negative. All quotients can be verified using the signed number multiplication rules when multiplying the divisor and quotient together and comparing their product with the dividend.

Ex. $\frac{+10}{+5} = +2$ since $(+5)(+2) = +10$

Ex. $\frac{-10}{-5} = +2$ since $(-5)(+2) = -10$

Ex. $\frac{-10}{+5} = -2$ since $(+5)(-2) = -10$

Ex. $\frac{+10}{-5} = -2$ since $(-5)(-2) = +10 = (-1)(5)(-1)(2)$

$$\begin{gathered}(-1)(-1)(5)(2)\\ -(-1)(10)\\ +1(10)\\ +10\end{gathered}$$

Summarizing the signs of the quotient of signed number division:

$\frac{\textbf{positive value}}{\textbf{positive value}}$ **= positive value** **:** division of values having the same sign

$\frac{\textbf{negative value}}{\textbf{negative value}}$ **= positive value**

$\frac{\textbf{positive value}}{\textbf{negative value}}$ **= negative value** **:** division of values having opposite signs

$\frac{\textbf{negative value}}{\textbf{positive value}}$ **= negative value**

OBSERVATION OF SIGNED NUMBER COUNTERPARTS

The negative (-) or counterpart of a positive value is a negative value.

Ex. -(+5) = -5

Note that the negative symbol preceding (+5) can be interpreted as meaning;

(-1)(+5) = -5

The negative or counter part of a negative value is a positive value.

Ex. -(-5) = +5

Note again that this negative symbol can then be interpreted as being multiplied by (-1).

(-1)(-5) = +5

Also note, -(-5) is actually a single term containing the negative sign that precedes(-5).

Written in this form: (-1)(-5), it is also a single term but it is understood as having a positive sign:

(-1)(-5) = +(-1)(-5) or: +((-1)(-5))
+(+5)
+5

So, the apparent subtraction of a term is really adding the negative of that term. Though differences sometimes need to be found, there is "no real subtraction" operation performed with signed numbers (terms), and there is only their summing or combining.

Ex. +5 -(-2)

This expression is the addition of two terms: (+5) and -(-2) or (-(-2)). The (+5) term is being combined (added) to the negative of the expression inside the grouping symbol which is the term (-2).

That is, +5 -(-2)
(+5) + (-(-2)) : shown with the "hidden" addition (combine) symbol
OR, (+5) + ((-1)(-2))
+5 + (+2)
+5 +2 : now shown without the addition symbol
+7

After practice, many of the intermediate steps will not have to be performed. For the above example:

+5 -(-2)
+5 +2
+7

Noting the above discussion, the same can also be said about the positive symbol. These rules are very helpful when clearing or ridding grouping symbols when simplifying expressions.

+(+5) = +1(+5) = (+1)(+5) = +5
+(-5) = +1(-5) = (+1)(-5) = -5

Subtracting a negative number is essentially removing a negativity or loss from the sum, because the result is a positive value to be added into the sum. Therefore, the result is more positive. Since we are working with signed numbers, it is best to think of subtracting a negative number as the addition of a positive number:

Ex. First: 2-5 : combining with a negative term
2 (+) -5
-3

Now with the combining of the negative of a negative term which can be thought of as subtracting a negative number, and we know this is essentially the addition of a positive number:

2 - (- 5) showing the "hidden" addition symbol (+) between the terms:

2 (+) -(-5) : - (-5) = (-1)(-5) = +5 :
2 +5 : the expression resolved to the addition of a positive number
7

Checking, the difference added to the subtrahend (when the original expression is considered as an expression of subtraction) should equal the minuend:

7 + (-5) removing or hiding the addition symbol:
7 - 5
2 : checks

Ex. -2 - (-5)
-2 +5
+3

Checking: +3 + (-5)
+3 -5
-2 : checks

WATCH THOSE SIGNS

Here is a common example where by not observing the signs, an error could result.

Simplify: $-3 - \frac{-20 + 7}{5}$: The term -3 can be understood to have a denominator of 1

This is a two term expression, it is a sum of terms.

The first term is: -3 The second term is: $-\frac{-20 + 7}{5}$

The lowest common denominator of both terms is (1)(5) = 5. After creating an equivalent fraction of the first term:

$\frac{(5)(-3)}{5} - \frac{(-20 + 7)}{5}$ combine the numerators over the like denominators:

$\frac{-15 - (-20 + 7)}{5}$ distributing (-1) to clear grouping symbols, this will essentially reverse the sign of each term in the grouping symbol. You can think of this as multiplying the entirety of what is in the grouping symbols by (-1), and here, each term in the grouping symbols.
$-(-20 + 7) = -(-13) = +13 = -(-20 + 7) = (-1)(-20) + (-1)(+7) = (+20) + (-7) = +13$

$\frac{-15 + 20 - 7}{5}$ combining the negative terms in the numerator:

$\frac{-22 + 20}{5}$

$\frac{-2}{5}$ an alternate method of displaying this is:

$$\frac{-2}{5} = \frac{(-1)(2)}{(1)(5)} = \frac{(-1)}{(1)}\frac{(2)}{(5)} = -1\left(\frac{2}{5}\right) = -\left(\frac{2}{5}\right) = -\frac{2}{5}$$

Checking: $-3 - \frac{-20 + 7}{5}$

$-3 - \frac{-13}{5}$ showing with a "hidden" addition symbol:

$$-3 \; (+) - \frac{(-13)}{(5)} = -3 \; (+) \frac{(-1)(-13)}{(+1)(5)}$$

$$-3 + \frac{(+13)}{(5)} = -3 + (+2.6) = -3 + 2.6 = -0.4$$

$-0.4 = \frac{-4}{10} = -\frac{2}{5}$: made an equivalent fraction (divided both the num. and den. by 2)

Checking: $-3 - \frac{-20 + 7}{5}$

$$-3 - \left(\frac{-13}{5}\right) = -3 - (-2.6) = -3\ (+)\ (-1)(-2.6) =$$

$$-3 + (+2.6) = -3 + 2.6 = -0.4$$

$-0.4 = -\frac{2}{5}$: -0.4 is the decimal number equivalent of the fraction on the right hand side

"MINUS" OR "NEGATIVE"?

People frequently use the words minus and negative as interchangeable or meaning the same thing. but as a good rule, think of minus or the minus symbol (-) as the operation to find a difference (subtraction) of two values, and think of negative, which happens to have the same sign (-), for values (operands) or results of an operations(s). For example, if you see (-5) by itself, then it is best to not say that it is "minus five" since if this is perhaps the result of some operation(s), what are you subtracting (minus is the symbol for a subtraction operation, and not its result) it from if this is the answer or result you are looking for? It is perhaps more correct to say one of the following when you see something like (-5) by itself: "five less than 0", or simply: "negative five".

NEGATIVE EXPONENTS

Negative exponents can be created when you are canceling or reducing fractions using the exponent rules when dividing like values, or variables as in algebra. Typically, a negative exponent is the result when a larger value exponent in the denominator is subtracted from a smaller value exponent in the numerator.

Ex. $\frac{5^1}{5^2} = \frac{5^{(+1(-)+2)}}{1} = \frac{5^{(+1-2)}}{1} = 5^{-1}$

Checking by multiplying the divisor and quotient to have a product equal to the dividend:

$(5^2)(5^{-1}) = 5^{(2+(-1))} = 5^1$: checks

Note: $\frac{5^1}{5^2} = \frac{\overset{1}{\cancel{(5^1)}}}{\underset{1}{\cancel{(5^1)}}(5^1)} = \frac{1}{5^1}$: if canceling is used. Also : $(5^1) / (5^2) = 5/25 = 1/5$

Since $5^0 = 1$, we have:

$\frac{1}{5^1} = \frac{5^0}{5^1} = \frac{5^{(0-1)}}{1} = 5^{-1}$

Hence, $\frac{5^{-1}}{1} = \frac{1}{5^{+1}}$: We see that a value with a negative exponent really means, or is equal to, a division by that value with a positive exponent. The inverse or "negative" of multiplication (repeated addition) is division (repeated subtraction). As an extra note, the inverse or "negative" of a power (which includes both the base and the exponent; either expressed or simplified to a value) is a root.

Also note that the exponents can also be subtracted in the denominator instead of the numerator:

$\frac{5^1}{5^2} = \frac{1}{5^{(2-1)}} = \frac{1}{5^1}$

Hence, a value with a negative exponent in the numerator is really a division by that value with a positive exponent in the denominator, or in simpler words, multiplying by a negative power is essentially division by its corresponding positive power.

Ex. Simplify $+100(5^{-2})$

$\frac{+100(5^{-2})}{1(\;1\;)} = \frac{+100}{1}\left(\frac{1}{5^2}\right) = \frac{+100}{5^2} = \frac{\overset{+4}{\cancel{+100}}}{\underset{+1}{\cancel{25}}} = \frac{+4}{1} = +4$

Negative exponent form is sometimes desired when simplifying the product of multiplying like values (or variables in algebra), where to simplify is to add the values exponents, and keeping the same value.

Ex. $(3^3)\left(\frac{1}{3^1}\right)$ without using direct multiplication to simplify:

$(3^3)(3^{-1})$ multiplying like values or variables, add their exponents to simplify, keeping that base:
$3^{(3-1)}$ and this can be simplified to:

3^2

Or by representing 1 as = 3^0, like values in both the numerator and denominator can be shown:

$$(3^3)\frac{1}{(3^1)} = \frac{(3^3)\,(3^0)}{(\;1\;)(3^1)} = \frac{(3^3)(3^{(0-1)})}{1} = (3^3)(3^{-1}) = (3^{(3-1)}) \quad \text{combining the exponents:}$$

3^2 = 9 checking: 3^3 / 3^1 = 27 / 3 = 9

Another method to convert a power which has a negative exponent to an equivalent value which has the same exponent which is positive in value comes from the concept of reciprocals, a fraction to a power, and the previous discussion on negative exponents.

Ex. 3^-4 = 1/3^4 = 1^4 / 3^4 = [1/3]^4 = 0.333333333^4 These steps are also verified more below:

1/3^4 = 1 / 81 = 0.012345679 = 0.3333333333...^4 = 0.012345679

$$3^{-4} = \frac{1}{3^4} = \frac{1^4}{3^4} = \left(\frac{1}{3}\right)^4$$

In general, if you were to write a (algebraic) formula for this, you would create something like:

$$N^{-x} = \frac{1}{N^x} = (1/N)^x$$

: (1/N) is the reciprocal of N and (1/N)^x is the reciprocal of N^x , By observation, it could be said that the reciprocal of an expressed power (such as N^x) is equal to that same indicated power (such as x) of the reciprocal of the base of that power.

A reciprocal of some value, say N is sometimes expressed as N^(-1), and this is verified here with several intermediate steps which can be omitted during simplification of expressions:

The reciprocal of N is usually expressed as:

$$\frac{1}{N} = \frac{(1)(1)}{N} = \frac{(1)(N^0)}{N^1} = (1)\,N^{(0-1)} = (1)\,N^{(-1)} = N^{-1} = \frac{1}{N}$$

Some formula express reciprocal values using an exponent of (-1), and it may be odd for example to see something such as (pi) to the negative 1 power:

$$(\text{pi})^{-1} = \frac{1}{(\text{pi})} = (3.14\ldots)^{-1} = \frac{1}{3.14\ldots}$$

THE ROOT OF A PERFECT SQUARE

The square root of a positive perfect square (of a value) is both positive and negative in sign, that is, a positive perfect square has two roots, one is positive, and one is negative.

Ex. What is the square root of 25?

$\sqrt{+25}$ = ±5 : ± means both positive and negative

That is, $\sqrt{+25}$ is +5 and -5, but not both. 25 is said to be a perfect square (value) of both of its square roots.

Checking by squaring (raising to the second power) both roots:

(+5)^2 = (+5)(+5) = +25
(-5)^2 = (-5)(-5) = +25 , symbolically or algebraically expressed: (-n)^2 = n^2
checking: (-n)^2 = (-n)(-n) = (-1)(n)(-1)(n) = (-1)(-1)(n)(n) = +1n^2 = n^2

Ex. $\sqrt{20^2}$ = ±20^(2/2) = ±20^1 = ±20 : to put this radical in exponential form, and at the same time, solving for the square root, divide the exponent of the radicand by 2

Ex. $\sqrt{4^8}$ = ±4^(8/2) = ±4^4

Ex. $\sqrt{50.9796}$ = ±7.14 : usually, a calculator would be used to find this root

Generally, the "principle" (main and positive) roots have more practical or useful importance, and therefore it is usually the intended and formally defined root of any radical. Negative roots are usually meaningless, such as negative lengths or distances, but don't completely ignore the possibilities of negative roots, for example, they are very important when drawing curves that are symmetrical to either an axis of that curve, or to an axis-line of a coordinate system - where the points [ie. a tiny part of a line or curve] have corresponding or counterpart positive and negative value coordinates (corresponding locations, or simply the location or "address", of a point [drawn as a dot on paper]).

Here is a note on the difference between a negative valued base being squared, and the negative of a value squared.

Consider this: (-5)^2 /=/ - 5^2

This above is read as: "Negative five square is not equal to the negative of five square.":

(-5)^2 /=/ - 5^2
(-5)(-5) /=/ -(5^2)
+25 /=/ -(+25)
+25 /=/ -25

For -5^2, due to powers and roots having a higher precedence than combining of terms (signed values, and-or partial or intermediate sums of the sum), this expression really indicates and is to be evaluated as: -(5^2). To indicate or "force" the square of negative five, parentheses must be used as shown above as: (-5)^2. You could also say: "the square of negative five is not equal to the negative of the square of five".

Also consider these possibilities: -(-5^2) /=/ - (-5)^2 or = - ((-5)^2)
-(-25) /=/ -(+25)
25 /=/ -25

[This space for book edits.]

THE DISTRIBUTIVE PROPERTY , DISTRIBUTION

The distributive property means that the product of two factors, in which one or both is a sum of terms (ie., an expression), is equal to the sum of all possible products of each of the terms of one factor, with all of the terms of the other factor. This should be easily seen, as presented below, since multiplication is really repeated addition. Distribution was also briefly mentioned previously in this book. The word distributive comes from the fact that the terms of one factor are "distributed", as in a distribution of something, to be used (here multiplied) with all the terms of the other factor. Frequently, the words "distribute" and "multiplication" are exchanged or used in place of each other due to their similarity or process.

Ex. $+5(+1+2)$ So simplify this expression, distribute the +5 factor to each member of the other factor in the grouping symbols:

$+5(+1)\ (+)\ +5(+2)$: an intermediate step frequently omitted, showing the "hidden" addition or combine symbol shown here as (+).
$+5(+1)\ +5(+2)$ distribute or multiply to clear the grouping symbols in each term:
$+5 \quad +10$ add (combine terms):
$+15$

Checking, using the order of operations more closely where the expression within the grouping symbols is simplified first:

$+5(+1+2) \quad = \quad +5(+3) \quad = \quad +15$

Ex. $2(10) \ = \ 10(2)$ expressing multiplication as repeated addition on the left side, and a factor composed of, or reduced to, partial sums (here of 2) on the right:
$10 + 10 \ = \ 10(1 + 1)$
$10(1) + 10(1) \ = \ 10(1 + 1)$: this expression is of the basic format of the distributive property, and the expression on the right side is essentially a factored form of the left side where 10 is a common factor to each term, and is then factored out of each term and expressed as a product on the right side.

For more verification of the distributive property, here is a slightly different way of expressing the above example:

$2(10) \ = \ 10(2)$ expressing each side using repeated addition:
$2+2+2+2+2+2+2+2+2+2 \ = \ 10 + 10$ expressing 2 as partial sums:
$(1+1)+(1+1)+(1+1)+(1+1)+(1+1)+(1+1)+(1+1)+(1+1)+(1+1)+(1+1) \ = \ (1)(10) + (1)(10)$
$10(1+1) \ = \ 10(1) + 10(1)$: this expression is of the basic format of the distributive property

You may also consider this:

$10 + 10 = 20$ dividing both sides by 10 will keep the equation in balance, that is, both expressions will still be equal:

$\frac{10 + 10}{10} = \frac{20}{10}$ the fraction on the left hand side can be considered as the sum of two "like-fractions" that have the same denominator of 10:

$\frac{10}{10} + \frac{10}{10} = 2$

$1 + 1 = 2$

Since the original equation was divided by 10, we can multiply both sides of this new equation by 10 to undo what was taken out. A multiplication by a number, and then a division by that same number, or vice-versa, will still keep things in balance since that whole process is essentially multiplying by 1 which does not change a value:

number **/** number = 1, or , = (number)(1**/**number) = 1. : a number divided by itself equals 1 which equals the number times its reciprocal.

10(1 + 1) = 2(10)
10(1 + 1) = 20 hence, in relation to original equation, we can see another verification of the distributive law:

10(1 + 1) = 10(1) + 10(1) = 10 + 10 = 20

If you were to create a minimal formula to represent this distributive property concept, letting A, B and C to represent (or be "placeholders for") any values (not yet specifically known), it would be:

A (B + C) = AB + AC **: a symbolic or algebraic formula for the distributive law**
Note that AB = (A)(B) = A x B = "A times B", and AC = (A)(C), etc.
Since letter "x" used as the symbol for multiplication might be considered as a variable, it's use is therefore problematic, and parenthesis or brackets are recommended where needed, such as to clarify an expression.

This expresses that A times the quantity of B + C, is equal to A times B, plus A times C. The right side of the equation is known as a simpler form of the left side. This is so since it's a simple sum of terms rather than an indicated multiplication (which itself represents another mathematical operation). The left side of the equation is also known as the factored form of the right hand equation (where both terms contain a (common) factor of A), and more about this will be said ahead.

A single term is called a monomial, and a sum of two terms is called a binomial. The expressed product of: A(B+C) is technically a single term product which consists of a monomial (A) times a binomial (B+C). After distributing and multiplying the factor of A to each term in its binomial factor, the simplified or "simpler" result is a binomial expression that is a sum of terms.

A(B + C) = AB + AC : distributed form, showing all possible products of the two factors
AB + AC = A(B + C) : factored form , each term on the left side has a factor of (A) in it

The above is just the basic representation of distribution, and the factors A or (B + C) could actually be composed of more terms and the basic concepts can still be applied to those just the same.

For additional verification of the distributive property, consider this where it is expressed like a common (vertical) multiplication problem:

A (B + C) = (B + C) A : due to the commutative law, the expressed order can be switched

$$\begin{array}{r} B + C \\ \times\ \underline{\quad\quad\quad A\ } \\ (AB) + (AC) \end{array}$$

For example:

$$2\,(10 + 8) \;=\; \begin{array}{r} 10 + 8 \\ \times\ \underline{\quad\quad 2} \\ 20 + 16 \\ 36\quad \end{array} \;=\; \begin{array}{r} 18 \\ \times\ \underline{\ 2\ } \\ 36 \end{array}$$

: this right side is the result simplifying the expression in the grouping symbols first, and then multiplying

2(10 + 8) = 2(10) + 2(8) : 18 multiples of 2, is the same as 10 multiples of 2, plus 8 multiples of 2
20 + 16 = 36

Note also that the second (from the left) vertical multiplication expression above essentially shows the right hand multiplication as a multiplication of its positional sums in the decimal system. It could also be said that 10 and 8 are "partial sums" of 18. In short, each "partial sum" (whatever values they may be) of the multiplicand is to be multiplied by the multiplier once. Below, integer numbers 9 and 10 are expressed as the sum of two integer "partial sums". This will help give a deeper understanding of partial sums that are integers, and of the concepts of distribution such as that distribution can be "thought of" as either one or all factors converted or expressed as a sum of partial sums of it. After some intermediate multiplications, the result is essentially that of repeated addition, as expected since multiplication is essentially repeated addition. Though in these examples, it is easier to simplify the expressions in the grouping symbols first before using distribution, it also helps verify using the concepts of distribution with values, such as variables, in grouping symbols that cannot be simplified first or further. Here in a pseudo expression or formula:

(factor1) (factor2)
(factor1) (sum of partial sums of factor2)
(factor1) (partialsum1 + partialsum2) Now expressing the distribution of factor1 to each partial sum in factor2:
(factor1) (partialsum1) + (factor1)(partialsum2)

Ex. (5) (2) : This example verifies the concepts of distribution.
(5) (1 + 1) The multiplication of 5 and 2, expressed as a repeated addition of 5:
(5)(1) + (5)(1) : shows the addition or sum of the partial products of
5 + 5 which are also partial sums of the final product
10

Or, since the result is the same if the order of the multiplication is changed:

(2) (5)
(2) (1 + 1 + 1 + 1 + 1)
(2)(1) + (2(1) + (2)(1) + (2)(1) + (2)(1)
2 + 2 + 2 + 2 + 2 : extra, for example, = (2+2)+2+2+2 = (4+2)+2+2 = (6+2)+2 = 8+2 = 10
10 A summation by grouping , showing partial or intermediate sums

Here is a verification of distribution

Since: (5)(2) = (5)(1 + 1) : a factor expressed as a sum of partial sums
And: (5)(2) = 5 + 5 : multiplication is repeated addition of that value, equating the equivalences:

(5)(1 + 1) = 5 + 5 : which would result after multiplying the first factor to each partial sum of the second factor

Consider these partial sum integers that an integer value can have, and even these partial sums can be expressed as other partial sums.

9	10
(1 + 8)	(1 + 9)
(2 + 7)	(2 + 8)
(3 + 6)	(3 + 7)
(4 + 5)	(4 + 6)
	(5 + 5)

: after this, the values start repeating, for example (6+4) was already expressed as (4+6)

Clearly, an integer (N) will have the whole portion of (N/2) integer partial sums. 9/2 = 4.5, and 10/2 = 5
Note that all the values from 1 to (N-1) will be included in these partial sums. Any value plus 0, is not considered as a partial sum. Any number or factor can be expressed as partial sum:

number x 9 = number(9) = number(sum of 9's partial sums) , for example:

number x 9 = number(1+8) = number(1) + number(8) = partial sum or product + partial sum or product = product

In short, if given number added once, and given number added eight times, the sum of those two values is equivalent to number being added nine times. Number being added nine times is the same as number times 9.

A factor can also be expressed as the sum of more than two partial sums, even up to the point where that factor is expressed entirely as the sum of values that are 1.

Ex. 7(4) = 7 (+1 + 1 +2)
28 = +7(+1) +7(+1) +7(+2) :shown with indicated (ie. expressed) distribution
Now multiplying (it is also distributing, even if just one term), and it will "clear the grouping symbols".
28 = +7 +7 +14 Now combining the terms on the right hand side:
28 = 28

Ex. +3(2+1) Using distribution (D):
+3(+2) +3(+1) : an expression with indicated distribution and the resulting indicated products
+6 +3 : after distributing to clear grouping symbols, and here its a single multiplication in each term
+9

Ex. +2 +(3-7) -(5-7) this can be rewritten for better clarity as:
+2 +1(+3 -7) -1(+5 -7) distribute (+1) and (-1) to clear grouping symbols:
+2 +1(+3) +1(-7) -1(+5) -1(-7) : expressing the distribution, now multiplying to clear grouping symbols:
+2+3-7-5+7 optionally summing up all positive terms, and negative terms separately:
+12 -12
0

Here is another generalized formula of the concept of distribution. Variables, or placeholders representing any value, are used rather than specific values:

$(A + B)(C + D)$
$A(C + D) + B(C + D)$: an intermediate step often not shown. Note that each term now includes the same factor of $(C + D)$.
$AC + AD + BC + BD$

OR : $(A + B)(C + D)$
$(A + B)(C) + (A + B)(D)$ this can be expressed as:
$(C)(A + B) + (D)(A + B)$: here, each term has a factor of $(A + B)$
$CA + CB + DA + DB$ this can be expressed as:
$AC + BC + AD + BD$ which can be expressed as:
$AC + AD + BC + BD$: the same as above

Ex. (+2+3)(+1+4)
+2(+1) +2(+4) +3(+1) +3(+4) : showing the sum of the indicated products of distribution
+2 +8 +3 +12 : after distributing again to clear grouping symbols
+25 : after combining terms

checking: (+2+3)(+1+4) = (+5)(+5) = +25 : here the expressions in the grouping symbols were simplified first

Ex. -1(+4 -5 +2) Distributing the -1:
-1(+4) -1(-5) -1(+2) Distributing or multiplying to clear grouping symbols in each term:
: Note, this is three terms being combined (summed): -1(+4) and -1(-5) and -1(+2) since it is understood that these terms are being summed or combined, and that the combine symbol (+) is hidden or understood as being there
-4 +5 -2 Combining these terms:
+5 -6
-1

checking: -1(+4 -5 +2)
-1(+6 -5)
-1(+1)
-1

Ex. Given a value of 1.5, this value can be expressed as a sum of the whole value and the fractional value:

1.5 = 1.0 + 0.5

If this value of 1.5 is multiplied by 2, then 1.5 and any possible expressed equivalence of 1.5 is effectively multiplied by 2:

2 (1.5) = 2 (1.0 + 0.5) distributing:
3 = 2 (1.0) + 2 (0.5) : expressed or indicated distribution and the sum of the products
3 = 2 + 1 : the right hand side is the sum of a multiple of 2 + a fraction (part) of 2
3 = 3

Notice that the specific fractional portion of 0.5 in 1.5 corresponds to a specific fractional portion of the value of 2, that is, the portion will be less than 2, and here, that this portion of 2 is the value of 1. 1 is numerically this portion (ie. fraction) of 2:

$\frac{1}{2}$ = 0.5 : the decimal equivalent of the fractional part (here, it's 1) of 2

Ex. 5.2 (10) = (5 + 0.2) (10) = (10)(5) + (10)(0.2) = 50 + 2 = 52

The distributive property is used widely in algebra, especially when the expression inside a grouping symbol of one factor cannot be simplified further. To continue simplifying, distribution will create a sum of terms which is a simpler expression. The ultimate goal when simplifying expressions is usually to produce a single value or term if possible.

Note: (+2 +3)(+1 +4) and +2+3(+1+4) are actually very different.

In the expression +2+3(+1+4), only the value of +3 is being multiplied to (+1+4), that is, this is a two term expression. The first term from left to right is +2, the second term is +3(+1+4) which represents a product of two factors +3 and (+1+4). Multiplication has a higher precedence of performing than combining. In the expression (+2+3)(+1+4), the total quantity or value inside the first grouping symbol is being multiplied to (+1+4). That is, (+2+3) is an expression of a factor to be multiplied to (+1+4). The whole expression (+2+3)(+1+4) actually represents only one term, and since the sign is not indicated, it is considered positive in sign, however this does not necessarily mean the result after evaluating (simplifying, solving) the expression will be positive in sign.

(+2+3)(+1+4) /=/ +2+3(+1+4)
+2(+1)+2(+4)+3(+1)+3(+4) /=/ +2+3(+1)+3(+4) , and:

+2+8+3+12 /=/ +2+3+12
+25 /=/ +17

Checking by first using simplification within the grouping symbols:

(+2+3)(+1+4) /=/ +2+3(+1+4)
(+5)(+5) /=/ +2+3(+5)
+25 /=/ +2+15
+25 /=/ +17

Here is a generalized or algebraic version or representation of this process where variables represent any valid number:

(a + b)^2 = (a + b) (a + b) = (a)(a) + (a)(b) + (b)(a) + b^2 = a^2 + 2ab + b^2

Ex. (a + 1)^2 = (a + 1)(a + 1) = a^2 + a + a + 1 = a^2 + 2a + 1 : (a + 1)^2 = (1 + a)^2

CANCELING TERMS IN FRACTIONS

Only terms that are factors of the entire numerator and denominator can be canceled. This is a very important concept such as when there are variables being used in algebraic or symbolic expressions.

Ex. $\frac{(2+10)}{2}$

Here, the 2 in the denominator cannot be directly canceled with the 2 in the numerator or the factor of 2 in the value of 10 since neither term in the numerator is a factor of the entire numerator. That is, the entire numerator, and not just a term or selected terms of it, is being divided by 2. If canceling were to occur as just described, you would get the incorrect result. The correct result is actually 6. This can be checked by using the order of operations more closely where the grouping symbols in the numerator and denominator are to be cleared first if possible. Actually, the grouping symbols in the numerator are not needed in this example. To clear grouping symbols here, distribute a (+1) factor preceding it:

$$\frac{(2+10)}{2} = \frac{+(+2+10)}{+2} = \frac{+1(+2+10)}{+2} = \frac{+2+10}{+2} = \frac{+12}{+2} = \frac{6}{1} = 6$$

As a check, consider the expression as the result of a sum of fractions with like or common denominators:

$\frac{(2+10)}{2} = \frac{2}{2} + \frac{10}{2}$: now, both fractions have a common factor of 2 in their entire numerators and denominators, and can easily be divided out or canceled:

$$\frac{(2+10)}{2} = 1 + 5 = 6$$

Another check can be made by factoring the expression or value in the grouping symbols so as a possible common factor to both the entire and numerator can be created. Factoring each of the terms in the numerator we find that each has a common factor of 2, and this is also a common factor to both the entire numerator and denominator:

$$\frac{(2+10)}{2} = \frac{((2)(1) + ((2)(5))}{2} = \frac{\cancel{2}(1+5)}{\cancel{2}} \text{ or= } \frac{2}{2}\frac{(1+5)}{(\ 1\ )} = (1)(6) = 6$$

Notice that the factorization of the terms in the numerator expression is the same as the distributed form of those factors.

Ex. $\frac{-3(2+6)}{15}$ Here, rather than performing distribution to simplify the numerator, "canceling out" can be used due to that the entire numerator and denominator have a common factor (here, its 3, or -3, and we will use 3) among them:

$$\frac{\overset{-1}{\cancel{-3}}(2+6)}{\underset{+5}{\cancel{15}}} \text{ or } = \frac{\overset{-1}{\cancel{-3}}(2+6)}{\cancel{3}(5)} = \frac{-1(2+6)}{5} = \frac{-2-6}{5} = \frac{-8}{5} = -1.6$$

: note 15 = (3)(5) or= (-3)(-5)

Checking using distribution to clear grouping symbols (ORD., step 2):

$$\frac{-3(+2+6)}{15} = \frac{-6-18}{15} = \frac{-24}{+15} = -1.6$$

Checking using an alternate version (ORD., step 4, combining, simplification within the grouping symbols first):

$$\frac{-3(+2+6)}{15} = \frac{-3(+8)}{15} = \frac{-24}{15} = -1.6$$

Dividing A Several Or Multi-Term Expression

A several or multiple ("multi", meaning several or many) term expression is called a multinomial. For the specific number of terms present or used, for example, a binomial is a 2-term multinomial, and a trinomial is a 3-term multinomial. A single (one or "mono") term expression is called a monomial. To divide a sum of terms by a monomial or single term, divide that term into each and every term of the given sum of terms. To initially express this concept in the example below, the order of operations is not strictly followed in the following example:

Ex. $\frac{(+7+14)}{7} = \frac{7}{7} + \frac{14}{7} = \frac{+21}{7} = +3$: a multinomial divided by a monomial

Expressing or explaining this in word form:

$\frac{\text{value1 + value2}}{\text{value3}} = \frac{\text{value1}}{\text{value3}} + \frac{\text{value2}}{\text{value3}}$ even these expressions can be expressed as something like:

$\frac{v1 + v2}{v3} = \frac{v1}{v3} + \frac{v2}{v3}$: expressed by essentially using a "shorthand" version, simple indication, notation or identification of the values used.

This concept above should be clearly seen since for the addition of like fractions (have the same denominator), the numerators are combined (added) and placed over that same denominator:

$+\frac{7}{7} + \frac{14}{7} = \frac{(+7+14)}{+7} = \frac{+21}{+7}$ Ex. $\frac{25}{5} = \frac{(20 + 5)}{5} = \frac{20}{5} + \frac{5}{5} = 4 + 1 = 5$

Each term of a multinomial or several term expression can be divided by a multinomial denominator expression as long as that entire multinomial denominator is considered as like one single divisor and-or value within grouping symbols, and it is then essentially representing and acting as one single value, monomial or single term.

Ex. $\frac{+3+9}{+2+1} = \frac{+3+9}{(+2+1)} = \frac{+3}{(+2+1)} \ (+) \ \frac{+9}{(+2+1)} = \frac{3}{3} + \frac{9}{3} = \frac{+12}{3}$, or = 1 + 3 = +4

checking: $\frac{+3+9}{+2+1} = \frac{+12}{+3} = +4$

Ex. $\frac{(+3+9)+6}{(+2+1)}$

Note that the numerator is indicated or expressed as having two terms: +(+3+9) and +6. Dividing each of these terms by this multinomial denominator:

$\frac{(+3+9)}{(+2+1)} + \frac{+6}{(+2+1)}$: here, the numerator of the first fraction contains two terms: +3 and +9, then we have:

$\frac{+3}{(+2+1)} + \frac{9}{(+2+1)} + \frac{6}{(+2+1)} = \frac{3}{3} + \frac{9}{3} + \frac{6}{3} = \frac{(3 + 9 + 6)}{3} = \frac{18}{3} = +6$, or = 1 + 3 + 2 = +6

Multinomials are sometimes called polynomials, but more formally and in terms of algebraic variables and advanced mathematics, polynomials are multinomials that are a sum of terms that are algebraically related such as having the same variable but which are raised to different indicated powers - often to the next whole number exponent so as to produce a sum of terms that are ascending integer powers of the variable. A polynomial may then be simply said to be a sum of terms which contain several powers of the same variable.

CDC Is Another Helpful Plan For Simplifying Expressions

C, D and C are the first letters for the words: Cancel, Distribute, and Combine. Taken together, they represent an easy method, steps or plan to remember or follow when expressions are to be simplified. This plan closely follows and can be used along with the standard order of operations plan. To help you learn this plan, you should frequently write these letters, or the words they represent, next to the problems you are solving:

C - Cancel : Try to reduce or possibly cancel (eliminate) fractions, that is, rid the denominators of fractions (make them +1 if possible). One way is to cancel out common factors to both the numerators and denominators.

D - Distribute : Use the distributive property to eliminate complex (multiple term) factors such as expressions within grouping symbols, or simply multiply to produce a product. Basically, to distribute is to clear grouping symbols.

C - Combine : Combine (add) terms using the rules for signed numbers, or variables as in algebra where the terms must be "like terms" that have the same exact variables.

Ex. Simplify $\frac{8(2+1)}{4} + \frac{5}{1}$ C , cancel common factors in the fraction (here, the +4):

$\frac{\overset{+2}{\cancel{8}}(2+1)}{\underset{+1}{\cancel{4}}} + \frac{5}{1}$ D , distribute, or multiply (here, the +2) :

$\frac{+4+2}{1} + \frac{5}{1}$ C , combine or add terms (here, in the numerator):

$\frac{+6}{1} + \frac{5}{1}$: C , combine, add terms (here, that are fractions with the same denominator of 1):

$\frac{+11}{1} = +11$

Ex. Simplify $2(6\text{^}2 + \sqrt{16}\,) +5$

Note that this is a two term expression (a binomial). The terms are: $+2(6\text{^}2 + \sqrt{16}\,)$, and +5. 2 is a factor of this first term. $(6\text{^}2 + \sqrt{16}\,)$ is also a factor of the first term, and which itself contains multiple terms, hence it is surrounded or "delimited" (set-apart, bounded, identified) by grouping symbols. It is a factor of the indicated product of 2 and $(6\text{^}2 + \sqrt{16}\,)$.

First, there is nothing to "cancel" here since there are no fractions or division in the expression.

$2(6\text{^}2 + \sqrt{16}\,) +5$ ORD. step 1 (simplify powers and roots), ORD means ORDer Of Operations:

+2(+36+4) +5 ORD. step 4 (combine values or like terms):
+2(+40) +5 D , Distribute ("distribute to clear grouping symbols"), ORD. step 3:
+80+5 C , Combine, ORD step 4:
+85

[This space for edits.]

Dividing Or Factoring A Several Term Expression

This procedure stems from, and is effectively the inverse of distribution. Given a several or multiple term expression (a multinomial) as a dividend or numerator of a fraction, we can divide by any value:

Factor or divide this expression by 2: (value1) + (value2)

$$\frac{\text{(value1) + (value2)}}{2} = \text{quotient} \qquad \text{mathematically:}$$

$$\text{(value1) + (value2)} = 2\,\text{(quotient)} \qquad \text{: a factored from of the multinomial dividend}$$

$$\frac{\text{(value1) + (value2)}}{2} = \frac{\text{value1}}{2} + \frac{\text{value2}}{2} = \text{quotient}$$

We see that the left side expression is equal to that of the right side of adding the like fractions with the same denominator, hence this division or factorization process of the numerator is essentially the reverse of adding like fractions together. It can also be said that a multinomial divided by a monomial or single term expression is equal to each term of that multinomial divided by that monomial.

Ex. Divide (8 + 6) by 2.

We see that this is a multinomial (8+6) divided by a monominal (2).

$$\frac{(8+6)}{2} = \frac{8}{2} + \frac{6}{2} = 4 + 3 = 7 \qquad \text{checking:}$$

$$\frac{(8+6)}{2} = \frac{14}{2} = 7$$:checks , multiplying the divisor and quotient together as a check of the dividend:

$(2)(7) = 14 = (8+6)$: checks

A good way, if possible, to factor a several term expression is to is to divide it all, or each term, by a factor that is common to all the terms of that expression. Usually, when greater simplification is concerned, the largest, greatest, or highest common monomial factor (HCMF) of all the terms is chosen as the divisor.

The result after canceling common factors in both the entire numerator and denominator will be another multinomial. As similar to basic concepts of division, the product of this quotient and divisor (denominator) is equal to the original multinomial numerator or dividend. The indicated or expressed product of the quotient and divisor is formally called a factored form of the multinomial.

Ex. Factor the expression: +10+20

First, checking for any common factors, we find that the highest common factor (HCF) of or within all the terms is 10. Other examples of common factors of both terms are 2 and 5. Since 10 is larger, dividing the entire expression by 10 we have:

$$\frac{+10+20}{+10} = \frac{+10}{+10} + \frac{+20}{+10}$$: dividing each term by 10, or "factoring 10 out of each term"
: here 10 is the highest common factor to all the terms in the dividend, and:

$$\frac{\overset{+1}{\cancel{+10}}}{\underset{+1}{\cancel{+10}}} + \frac{\overset{+2}{\cancel{+20}}}{\underset{+1}{\cancel{+10}}}$$: Cancel

$$\frac{+1+2}{1}$$ Combine (the fractions):

(+1+2)

Hence $\frac{+10+20}{+10} = (+1+2)$

Expressing the product of the divisor and multinomial quotient is a factored form of the multinomial dividend:

+10(+1+2) : this is also the result after multiplying both sides of the above equation by 10 and canceling. Hence: +10+20 = (+10)(+1+2) in a factored form, and the left side is the equivalent result after using distribution on the right side.

The "golden rule of factorization" is to first factor out any factors common to all the terms. Usually, the HCMF is chosen since the resulting expression will be completely factored.

As already indicated, to factor a multinomial, you don't necessarily have to divide by a factor common (ie common factor) to all the terms, but can perform a division by any value:

Given +10 + 20 we can factor by any value such as 2, 5, 7, 9, 1.2, -5.3, or any other value needed:

$$\frac{+10 \ +20}{7} = \frac{10}{7} + \frac{20}{7} = 1.4285\underline{7} + 2.8571\underline{4} = 4.2857\underline{1} \text{ hence:}$$

$+10 +20 = 7\,(4.2857\underline{1})$: = 29.99999$\underline{7}$ = almost 30.0 which is the correct result. A slight error of only (30.0 - 29.999997) = 0.000003 is due to rounding. This error value could be indicated with a negative sign since the result we calculated of 29.999997 is 0.000003 less than the true result. You can also rather use this formula to find the error value, and the sign will be automatically placed:
(calculated value) - (true value) = (error value)
The sign of the error value will be in reference to the calculated value being more (+), or less (-), than the true value.

FACTORING A BINOMIAL OF PERFECT SQUARES

To factor a binomial (a two term expression) that is composed or consists of terms that are both perfect squares (indicated with an exponent, or not), one, and only one, of the terms must be a negative term. The expression is therefore much like a difference of perfect squares. The result of factoring a binomial of perfect squares is a product of two binomial factors where one binomial factor contains a sum of the terms square roots, and the other binomial factor contains the difference of the terms square roots. This is a "special factorization" that you should try to memorize so as to recognize it and-or quickly solve some math problems when it can be applied, and including the reverse of this procedure. Symbolically, this concept can be expressed as:

(squared value1 - squared value2) =

(square root value1 + square root value2) (square root value1 - square root value2) : factored form of the binomial of perfect squares

Ex. Factor $(3^2 -9^2)$: both terms are (indicated or expressed) squares of a value, here 3, and 9
The second term (-9^2) is the negative term, or it could be said that the entire binomial expression is a difference of perfect squares.

$(3^2 -9^2) = (+3 +9)(+3 -9)$: the binomial of perfect squares factored, continuing:
$(3^2 -9^2) = (+12) \quad (-6) = -72$ checking, using distribution:

$(+3+9)(+3-9)$ expressing the distribution of the factors:
$+3(+3) +3(-9) +9(+3) +9(-9)$ distribute:
$+9-27+27-81$ combine, note that the "counter part" terms of -27, and +27 cancel out or sum to 0 :
-72 checking, using the order of operations:

$(3^2 -9^2)$ ORD. step 1, simplify powers and roots:
$(9-81)$ combine:
-72

If $(3^2 -9^2)$ was initially expressed as $(9 - 81)$ you would have the same result, and a general or algebraic representation for the above procedure would be:

$\mathbf{(a - b) = (\sqrt{a} + \sqrt{b})(\sqrt{a} - \sqrt{b})}$: **Formula for factoring a binomial of perfect squares.** You can check this by using distribution in the right side expression:

$$\sqrt{a}\ \sqrt{a} + \sqrt{a}\ (-\sqrt{b}) + \sqrt{b}\ \sqrt{a} + \sqrt{b}\ (-\sqrt{b})$$

$$a - \sqrt{a}\ \sqrt{b} + \sqrt{a}\ \sqrt{b} - b$$ combining like terms:

$$a - b$$

In short, a difference in terms could be viewed or thought of as equivalent to the product of the sum of the terms square roots and difference of the terms square roots. Actually, in more simplified words, and perhaps where the above mathematical derivation stems from, it could be said that the product of the sum and difference of two values is equal (=) to the difference of those two values when they are both squared. A general symbolic or algebraic representation of this might look like:

$\mathbf{(a^2 - b^2) = (a + b)(a - b)}$: **Factored form of a binomial (a sum of two terms) of the difference between two perfect squares**

Ex. Given (8+2)(8-2) , this can be expressed in simpler terms with the values squared as:
Expressing each value as the square of their square roots:
(8^2 - 2^2)
(64 -4) = 60 : As a check, all these expressions equal (8+2)(8-2) = (10)(6) = 60.

Ex. Factor (25-1)

First, there are no common factors here except 1 of course. Each value (term) here is (considered to be, or can be considered as) a perfect square, and therefore, there is the expressed difference (ie. has the - symbol) of perfect squares.

Note, actually the term of: -1 is not a perfect square of 1, it is though a perfect cube of (-1):

(-1)^3 = (-1)(-1)(-1) = (+1)(-1) = -1

Hence, when factoring binomials of perfect squares, the sign of the negative term is meant to be taken as meaning the difference of positive values, or adding the negative of a positive value. For the above example, "think of"
(25-1) as (25-(+1)), which are equivalent.

(25 -1) with 5 as the square root of 25, and 1 as the square root of 1:
(5^2 - 1^2) : expressing the binomial of perfect squares, simplifying:
(5+1)(5-1) : the factored form of the initial binomial. Here, we have the product of the sum and difference of the square roots of the terms of the binomial of perfect squares.
(6)(4)
24 checking:

(+25-1) combining terms:
+24

or

(+5 +1)(+5 -1) distribute:
+25 -5 +5 -1 combine:
+25-1
+24

As an extra note or thought, when two binomials (here, as a factored form of the difference of two squares) differ only in sign as shown above, they are often called **conjugate** forms of each other. Do not confuse the above discussion with the square of a binomial which is usually expressed in the form of: (a + b)^2 or (a - b)^2

COMMON FACTORS CONTAINING THE SAME TERMS WITH DIFFERENT SIGNS

Sometimes, common factors to both the entire numerator and denominator of a fraction appear that they cannot be canceled because all the signs of the terms within one factor are not the same as the corresponding terms of the other factor. That is, all the corresponding terms are opposite in sign. A method to overcome this problem will be shown below.

Ex. Simplify $\frac{(+5+3)}{(-3-5)}$ By use of the commutative law of addition, this can be expressed as:

$\frac{(+5+3)}{(-5-3)}$ After factoring (-1) out of each term in the denominator, and expressing the factored form or product:

$\frac{(+5+3)}{-1(+5+3)}$

$\frac{\overset{+1}{\cancel{(+5+3)}}}{-1\underset{+1}{\cancel{(+5+3)}}}$: now we can cancel, using the common factor of (+5+3), and then distributing in the denominator:

$\frac{+1}{-1}$:clearly, the result here should be a negative value since the signs of the numerator (or dividend) and denominator (or divisor) are different.

$\frac{\overset{-1}{\cancel{+1}}}{\underset{+1}{\cancel{-1}}}$:canceling to clear the fraction of its denominator and the ridding of the fraction. Here, both the numerator and denominator are divided by -1. This will leave a standardized or commonly expected value of +1 in the denominator. In short, any value divided or multiplied by (-1) is the "(number line) inverse" or signed number counterpart of that value. For example: -1 (-1) = +1, and -1/(-1) = +1

$\frac{-1}{+1} = -1$: since any value divided by 1 is that value, or: (+1)(-1) = -1 when checking by multiplying the divisor and quotient to produce the dividend.

Checking, here the numerator and denominator expressions will be simplified first:

$\frac{(+5+3)}{(-3-5)} = \frac{+8}{-8} = -1$: checking (-8)(-1) = (-1)(-8) = +8 , "the negative of negative eight, is positive eight"

The initial problem above could have been solved, perhaps more easily, by "factoring out" or dividing all the terms of the numerator by -1. This would be similar to the concept of dividing a multinomial by a monomial (and here it would be -1), and expressing the product of that monomial divisor and multinomial quotient:

(+5 + 3) = -1 (-5 -3) and therefore

$\frac{-1\overset{+1}{\cancel{(-5-3)}}}{\underset{+1}{\cancel{(-5-3)}}} = -1$: note that canceling does not mean to eliminate completely or to make it a value of 0, but rather make it a value of 1, which does not change anything when using it as a factor or divisor.

Ex. $\frac{(+5-3)}{(-5+3)} = \frac{\overset{+1}{\cancel{(+5-3)}}}{-1\cancel{(+5-3)}} = \frac{+1}{-1} = -1$ checking: $\frac{(+5-3)}{(-5+3)} = \frac{+2}{-2} = -1$

[This space for edits.]

AVERAGE AND STANDARD DEVIATION

Average, or average value, which has been previously discussed in this book, is a basic requirement for understanding the concepts of both average deviation and standard deviation. Average gives us a single value to represent a set of data, but it does not guarantee that the data values used are even close to that ("central") average value. Are the date values dispersed (set apart or away from, their difference) close in value to the average, or are the data values dispersed far away in value from the average? The standard deviation value was defined to answer this question so as to get a better idea of the actual values of a given data set.

Here is a simple example to observe:

Data Set 1: 48.5, 50.5, 51
Data Set 2: 2, 50, 98

The average of both data sets above is the same value of 50. However the dispersion or deviation of data values from the average value is clearly greater (in difference) in the second data set. 2 and 98 are not very close to 50, as compared to the data values in the first data set. How far are they from the average? The answer is the amount they differ (as in a difference value) or deviate away from the average:

data - average = deviation : the (signed) deviation that a data value is from the average value, The sign of this deviation indicates if the deviation was greater (ie.: +deviation_value) or less (ie.: - deviation_value) than the average value.

Though the sign of the deviation is not required for the computation of the average and standard deviation values, the sign with its corresponding deviation can be used elsewhere to indicate if that deviation value is less than (- , in sign) or greater than (+ , in sign) the average. The deviation with it's sign is the (pos. or neg.) change or difference from the reference value, and here, it is the average value of all the data. For example, if the average of a given set of data was 10, and one of the data values was 7, that data value has a deviation of:

data - average = deviation
7 - 10 = -3 : the negative deviation indicates that this data value is three less than the average value of the data set. This value can be said as being "below (the) average (value)".

If you find out the deviation from the average for each member of a set of data, you could sum up all the deviations and divide by the number of deviations (or number of data values of the set) to find the average deviation for that set of data (values, "members" or "elements"). This seems to be a correct method but it will not work (without an adjustment) due to the mathematical fact that the average of the data has created, in which the sum of deviations below (less than) the average, plus the sum of deviations above (greater than) the average is always equal to 0. To overcome this, an adjustment is used, and that is to simply use the absolute (ie. unsigned, or positive) value of each deviation. Mathematically, when a value is placed within two vertical lines (ex. | value |) it means to take the absolute or signless value, whether the value is positive or negative. The average value of a set of data (values) may be either positive or negative in value, but the average deviation is considered as a signless value, or as a generic or basic "distance" value from the average in order to represent all the deviations of the all the data values. Due to using only the absolute value of the deviation, you may optionally use this next formula that still gives the deviation a sign, but it wont be used in the formal average deviation formula shown below: average - data = deviation

$$\text{A.D.} = \text{Average Deviation} = \frac{\text{sum of } |\text{ deviations }|}{\text{number of data values}}$$: **AVERAGE DEVIATION , A.D.**

Ex. For the first data set above, the (signed) deviations are:

data - average = deviation

48.5 - 50 = -1.5, use for example: | -1.5| = 1.5 when finding the A.D.
50.5 - 50 = +0.5
51 - 50 = +1.0

The average deviation is:

$$\text{average deviation} = \frac{1.5 + 0.5 + 1}{3} = \frac{+3}{3} = 1$$

: Average, and average deviations are mathematical concepts of the entire data considered, and it does not necessarily mean that any, or all data value(s) are equal to the average or average deviation value.

Ex. For the second data set above, the deviations are:

2 - 50 = -48 use: |-48| = 48 when finding A.D.
50 - 50 = + 0
98 - 50 = +48

The average deviation is:

$$\text{average deviation} = \frac{48 + 0 + 48}{3} = \frac{96}{3} = 32$$

Standard deviation (S.D.) is close in value to the average deviation, but the standard deviation is more like an expectation or prediction, rather than an actual mathematical fact like average deviation. Standard deviation is the deviation that most data values could have from the average deviation, hence standard deviation could be called or thought of as something like: "the most likely deviation".

For example, given the data set of: -5, +5

,the average is 0 and it is easy to see that most values (hear, actually all the values) deviate from it by 5.

Given the data set of: -5, 0, +5,

,the average is 0 again, and most values (the -5 and +5) deviate from it by 5.

Given the data set of: -5, -5, -5, -5, -4, +4, +5, +5, +5, +5

,the average is 0, and most, but not all, values deviate from it by 5. You should expect the standard deviation value to be close to 5. Let's derive the formula for standard deviation:

The derivation of standard deviation is similar, at first, to average deviation:

1. For each data value, find its deviation from the average.
   average - data = deviation

2. Rather than take the absolute value of negative signed deviations for their effective positive value, square each deviation since any value squared is positive in sign. This also has the effect of magnifying a larger deviation (at least >1) much more than a smaller deviation. Small deviations (particularly those less than 1) are therefore very small in value and practically eliminated since any fractional value squared is a smaller value since a "fraction of a fraction" yields a smaller value.

3. Find the average of the squared deviations:

$$\text{average of the squared deviations} = \frac{\text{sum of squared deviations}}{\text{number of data items} - 1}$$

Notice 1 is subtracted from the total number of data items. This is due to the fact that one of the data items is predicted to be at least near or equivalent to the average, and that this data value should not be counted (included) in the set since it does not deviate from the average and therefore cannot play much of a role in any expected or predicted deviation. Remember, we are not looking for a true mathematical value as like average deviation, but we are looking for a "most-likely" value. If one is not subtracted, you will have another form of standard deviation that yields a "compromise" value that is a value between the average and standard deviation values of a set.

4. Since we squared the deviation values in the formula, the result is essentially another squared value, and we need to do the inverse (or reverse if you will) and take its' square root to effectively arrive at the square root value before it was squared:

$$\text{Standard Deviation} = \sqrt{\text{average of the squared deviations}}$$:**STANDARD DEVIATION (S.D.)**

For example, given the set of:

-5.0, 0.1, +5.0

The average of this set is +0.033333333.

By observation, you could then say that most values have a deviation, from the average, of about 5. and that the standard deviation for this set should be about 5.

The deviations are:

-5.033333333, +0.066666666, +4.966666666

The deviations squared are:

25.33444444, 0.004444444, 24.66777777

Using the formula shown above for the average of the squared deviations (using data items -1), we get:

25.00333333

Taking the square root of this we arrive at:

standard deviation = 5.000333322

Notice that this value is slightly larger than the predicted value of 5. This is due to the "greater magnification" of the larger deviation values after squaring them.

For comparison purposes:

$$\text{average (unsigned) deviation} = \frac{5.033333333 + 0.066666666 + 4.966666666}{3} = 3.355555555$$

For the data set given, most values had a deviation of 5 from the average value, and the standard deviation value yields a better deviation value for most of the data than the average deviation value shown here does.

The "compromise value", as discussed above, is calculated to be: 4.082755061

SCIENTIFIC NOTATION

Scientific Notation (S.N.) is a standard numerical notation to expresses any numbers, and in particular, very large or small numbers that have many digits where its value perhaps can't be easily realized or worked with. The notation still uses the same digits values of that number, but has only one whole number between, or including, 1 and 9, and with all the fractional (less than one) digits appended on, and a multiplying power of 10 attached to the number. This notation helps with manually processing calculations, or for expressing the results of calculations to make them appear presentable and intuitively manageable. Since numbers expressed in scientific notation contain powers of 10, the rules for multiplying and dividing like values with exponents, such as with powers of 10, will allow for greater agility and speed for calculating or estimating some results.

To convert a number greater than one to scientific notation, move the decimal point to the right of the most significant digit (MSD), and the multiplying power of 10, to this newly created lesser value, will have a positive exponent equivalent to the number of digit positions ("decimal places") it was moved. Any trailing zeros can be omitted.

Ex: 70 = 7.0 (10^1)
Ex: -3579.2 = -3.5792 (10^3)

To convert a number less than one to scientific notation, move the decimal point to the right of the most significant, non-zero digit (MSD), and the multiplying power of 10 will have a negative exponent equivalent to the number of digit positions the decimal point was moved. Any trailing zeros can be omitted. Note, that since the number was made apparently larger, there must be a value that would decrease or divide it so that it would be equivalent to its original (lesser) value from which it was created or derived from. This value is the negative power of ten which actually means division by an equivalent positive power of ten.

Ex: -0.00123 = -1.23 (10^-3)

Ex. Convert 35,000 to scientific notation (SN)

35000 = 3.5(10^+4)

checking: 3.5(10^+4) = 3.5(10,000) = 35,000

Ex. Convert 50.0250 to scientific notation

50.0250 = 5.0025(10^+1)

checking: 5.0025(10^+1) = 5.0025(10) = 50.025

Ex. Convert 0.0047 to scientific notation

0.0047 = 4.7(10^-3)

checking: 4.7(10^-3) = $\frac{4.7}{1}\left(\frac{1}{(10^{+3})}\right) = \frac{4.7}{1000} = 0.0047$

Ex. Multiply 20,000 by 3,000

(20000)(3000)
2(10^+4)3(10^+3) : each factor represented or expressed in scientific notation
(2)(3)(10^+4)(10^+3) : associative law

$6(10^{(+4+3)})$: when multiplying like values or variables, add their exponents
$6(10^{7})$: 10^{7} effectively places 7 zeros after the value and moves the decimal point seven places rightward:

60,000,000 = "sixty-million"

Another method to convert decimal values to fractional values and vice-versa, is to use some of the concepts of scientific notation.

Ex. Convert 0.247 to an equivalent (proper) fractional form

$0.247 = 2.47(10^{-1}) = \frac{2.47}{1}\left(\frac{1}{10^{+1}}\right) = \frac{2.47}{10}$: "two point forty-seven, tenths", OR:

$0.247 = 24.7(10^{-2}) = \frac{24.7}{1}\left(\frac{1}{10^{2}}\right) = \frac{24.7}{100}$: "twenty-four point seven, hundredths", OR:

$0.247 = 247(10^{-3}) = \frac{247}{1}\left(\frac{1}{10^{3}}\right) = \frac{247}{1000}$: "two-hundred and forty-seven thousandths"

Note, as seen above, the first factor in the indicated products need not be between and including 1 and 9, as in true scientific notation, as long as the power of 10 is adjusted correctly and the resulting expressed values are equivalent. This type of (exponential) notation is then a modified form of the standard scientific notation.

Ex. Convert 52.3/100 to scientific notation, and then convert this equivalent scientific notation to its equivalent decimal form.

$\frac{52.3}{100} = \frac{52.3}{10^{+2}} = 52.3(10^{-2})$: = 0.523

$52.3(10^{-2}) = 5.23(10^{+1})(10^{-2}) = 5.23(10^{(+1-2)}) = 5.23(10^{-1})$: scientific notation

$5.23(10^{-1}) = \frac{5.23}{1}\left(\frac{1}{10^{1}}\right) = \frac{5.23}{10} = 0.523$: decimal notation. Hence the same as the above, but without any multiplying factor such as the power of 10.

checking: $\frac{52.3}{100} = 0.523$

Scientific calculators and computers often represent values in a modified scientific notation format with a symbol of (E), meaning "exponential", instead of indicating or displaying the common base value of 10. The exponent (of 10) will follow the (E) symbol.

Ex. If the calculator display is: 1.234E-12
This is to be interpreted as: 1.234E-12 = $1.234(10^{-12})$ = 0.000,000,000,001,234 : "1.234 pico"

This notation is very helpful since the calculator may only have 8 or 10 digits. It should also be pointed out that these digits of the calculator display are for only the significant digits of the result of an operation, and any lesser valued. least significant digits not capable of being displayed, stored, processed, or entered by the user, are essentially lost and won't be available for further calculations. If the calculator "truncates" or discards some least significant digits of a value, this "error" or deviation from the true value can eventually "build up" (increase in value) and may need to be considered when using that value (with some slight, or insignificant error) for any possible further calculations.

MULTIPLYING AND DIVIDING BY NUMBERS TOO LARGE FOR AN ELECTRONIC CALCULATOR

Most hand-held electronic calculators are either the 8 to 10-digit display types, hence they are limited to that maximum amount of digits, and therefore, any value or calculated result with more digits than this maximum amount of digits cannot be fully entered or displayed. The value, as entered, is too large for that specific calculator to use and work with (ie., process). The least significant digits will then be lost, and the result will usually be rounded at the least significant digit that is displayed. A loss of trailing digits and fractional amounts can eventually lead to incorrect accuracy of the result(s) if this "shortened" or approximated value is used as an operand for further operations. In general, multiplying an operand having N1 (some number of) digits by another operand with N2 digits will yield a product with about (N1 + N2) digits, give or take 1 digit, and which may be more than your calculator can display. If the product is too large for your calculator to display, your calculator will either signal an "overflow error" (the value is greater than the maximum value that can possibly be displayed on and-or processed within that calculator), or it may display a "scientific" (exponential, power of 10) form with only the most significant digits and "dropping" (disregarding, truncating or loosing) the least significant, "last" digits. For most cases this wont be a problem, and is acceptable. Below are some basic examples of how to overcome this number of digits limitation if you need to. These examples assume that your calculator is an 8-digit (for internal calculations, and display) type and you want to maintain the least significant digits within a calculation using that calculator. However, as will be shown below, you may need to perform a final calculation by hand.

Ex. (7)(4321.567895) : the second factor contains ten digits, and this can be expressed as:
(7)(4321 + 0.567895) distributing :
(7)(4321) + (7)(0.567895)
30247 + 3.975265 summing by hand (ie. the calculation performed by you using a pen on paper) :
30250.975265 : an eleven digit result

Ex. (5) (1234567891) : the second factor contains ten digits, and this can be expressed as:
(5) (1234500000 + 67891)
(5) ((12345)(10^5) + (5) (67891))
(61725) (10^5) + 339455 multiplying by observation :
6172500000 + 339455 summing by hand :
6172839455 :a ten digit result

Ex. Divide 3 by 10,000,000,000 factoring 10,000,000,000 into two (or more) factors:

$$\frac{3}{10{,}000{,}000{,}000} = \frac{3}{(1{,}000{,}000)\,(10{,}000)} = \frac{0.000{,}003}{10{,}000} = 0.000{,}000{,}000{,}3 = 3(10\text{^}{-10}) = \frac{3}{10\text{^}10}$$

The example above can be solved in a variety of ways, and specifically determined by the powers of 10 used.

METRIC SYSTEM OF UNITS

The sub-units (ie., fractions of a unit), and multiples (ie., powers of a unit) of a unit of measurement within the metric system are all based on 10 of the specific "base" or fundamental units in use, such as for example, the fundamental unit of length called a meter. Why 10? The answer is that since the decimal system that we count with is based on 10, there should then be a standard system of units that are also based on 10. The word "metric" is based on the words and concepts of "to meter", which means "to measure", and "numeric". The metric system was created to be a practical, world-wide accepted standard system of measurements, and so as to avoid the many, and with some being antiquated (old and-or unused), systems of measurements in use which can cause many problems for those not familiar with them and-or the conversions between two or more different measuring systems. The metric system was created in France in 1795 as their new standards of measurement.

Type of Measurement	Base units in the U.S.A. system of measurements (Many are also now using the metric system.)	Base units in the metric system of measurements.
Distance or Length	mile or feet (mi)	meter (m)
Weight	pound (lb)	Newtons (N) for weight or force, and gram (g) for mass or matter
Volume	gallon (gal)	liter (L)

The Appendix Section of this book contains many conversions and constants.

Within the metric system of measurements, to change from larger to smaller units (technically called a reduction of units within the system, and commonly (although somewhat incorrectly) referred to as a "conversion" of units which is actually for converting between units of two different measuring systems and their units) that are some multiple or fraction of the base, fundamental or standard reference units, simply multiply or divide by a power of 10. The same process of simple multiples or division of units cannot generally be said about the English or British system of units. For example, in reference to the English length measurement units, 1 foot is 12 inches, 1 yard is 3 feet, 1 mile is 5280 feet. Here, the (conversion) factors vary widely: 12, 3 and 5280, and therefore, there is no systematic or logical approach to the relation of the units within that measurement system. One advantage of anything based on 12 units, such as a dozen or 12 inches, is that it can be evenly divided by or into 2 (a half), 3 (a third), 4 (a fourth or quarter), and 6 (a sixth) smaller fractional parts or fractional units. Half of (1/4) will give (1/8), half of the (1/8) will give (1/16), and half of the (1/6) will give (1/12). A system based on 10 units can only be evenly divided by 2 and 5, and with half of 2 being 1 step or unit.
.
In the metric system, the powers of 10 of the derived units are frequently represented as word or alphabetical abbreviation prefixes before the base unit. These prefixes are usually written as abbreviations of the corresponding name given to that power of 10. For example, all the units of measurement for distance or length values are based on, or are in reference to, the unit of measurement called the meter (m). Hence the base units for length are called meters. A centimeter (cm) is defined as one-hundredth of a meter. A centimeter is a sub-unit or fractional unit and part of a meter. The word or unit prefix "centi" (as previously discussed with the concept percentages) numerically means the multiplying factor of: (1/100), "one-hundredth", or= (1)(10^-2), and its abbreviation is (c). Thus, 1 centimeter = 1cm = (1)(10^-2)m = 0.01m, which is one-hundredth of a meter. There are 100 centimeters in one meter. In other words, 1 meter is equivalent in length as 100 centimeters, and vice-versa. A kilometer (km) is one-thousand meters. The prefix kilo (k) means (1000) = (1)(10^+3) = 10^3. 2km = (2)(10^3)m = (2)(1000)m = 2000m.

Here's an example of a conversion (although it's technically or formally a "reduction") within the metric system:

Since there are 1000 meters per kilometer, (1000m/1km), or one kilometer per 1000 meters, (1km/1000m), to convert meters to kilometers, simply divide the quantity of meters by 1000. In short, when converting from smaller units to a larger units, use division, otherwise, use multiplication when converting from larger units to smaller units since there is many more smaller things within a larger thing such as larger sized units of measurement. Here is a mathematical verification and example:

$1000m = 1km$: this is the known, given and basic equivalence between these two units of measurement. Solving for (1) meter by dividing both sides of the equation by 1000:

$$\frac{1000m}{1000} = \frac{1km}{1000}$$ after canceling common factors:

$1m = \frac{1}{1000}$ km : "one meter is one-thousandth of a kilometer". This can also be expressed as: 1m = 0.001km

Multiplying each side by some number (N) such as some number or multiple of meters:
N (1 meter) = N (1) meters = N meters, and we must do the same to both sides to keep their equivalence:

$$(N)1m = N\left(\frac{1}{1000}\right)km = Nm = \frac{N}{1000}\ km = (0.001\ N)\ km$$

or:
$1000m = 1km$
$N\ (1000m) = N\ (1km)$
$(1000N)\ m = N\ km$

Hence. when converting (some number or multiple of) meters to kilometers, divide the magnitude (value) of meters by 1000. For example, to convert 4752 meters to it's equivalent distance with kilometers units:

$$4752\ m = \frac{(4752)}{(1000)}\ km = 4.752\ km$$

You may also wish to consider this method which considers the ratio of one unit to that of the other to find the proper multiplier to use when converting between those units. With the division of like or similar values rules, the process to find the multiplier is easy, such as by subtracting the exponents. Consider this example of converting centimeters to kilometers:

$$\frac{1\ cm}{1\ km} = \frac{10^{-2}\ m}{10^{+3}\ m} = \frac{10^{(-2 - (+3))}}{1} = 10^{(-2-3)} = 10^{-5}$$

: shown with some intermediate steps.
: the units essentially cancel out or are eliminated since its a strict numeric, or unit-less value, here just a ratio.

Now, mathematically, (dividend = quotient x divisor), and from this equation above we have:

$1cm = 10^{-5}\ (1\ km)$: the multiplier is: $10^{-5} = 1/100{,}000 = 0.000{,}01$
$1cm = 0.000{,}01\ km$

Multiplying both sides by N, as for some given number of centimeters:

$N\ cm = (0.000{,}01\ N)\ km$ mathematically, we also find:

$$N\ km = \frac{N cm}{0.000{,}01} = \frac{N cm}{10^{-5}} = N\ 10^{5}\ cm$$

Ex. $$1km = \frac{1cm}{0.000{,}01} = 1(10^{5})cm = 100{,}000\ cm$$

Since the metric standards were created, many of the units have also been modernly, well defined scientifically, and in often in terms of universal constants so as to improve their precision and standard reference accuracy. An example to express why this needs to be done is: suppose the Earth gains more mass due to cosmic dust and meteorites, it will then have more gravity, and the reference kilogram of mass will weight more, but its mass is still the same.

Here are the common metric prefixes for the base-units of measurement:

tera(T) = 1(10^+12) = 1,000,000,000,000 : trillions
giga (G) = 1(10^+9) = 1,000,000,000 : billions
* mega (M) = 1(10^+6) = 1,000,000 : millions
* kilo (k) = 1(10^+3) = 1,000 : thousands Ex. 5km = 5 (1000)m = 5000m
hecto (hc) = 1(10^+2) = 100 : hundreds
deca (dc) = 1(10^1) = 10 : tens (of units)

1 = 1 : "ones" or "whole", complete or entire units,
no unit prefix used, but explicitly indicated
deci (d) = 1(10^-1) = 0.1 : tenths (of a unit)
centi (c) = 1(10^-2) = 0.01 : hundredths Ex. 100cm = 100 (0.01)m= 1m
* milli (m) = 1(10^-3) = 0.001 : thousandths
* micro (u) = 1(10^-6) = 0.000,001 : millionths
nano (n) = 1(10^-9) = 0.000,000,001 : billionths
pico (p) = 1(10^-12) = 0.000,000,000,001 : trillionths

* Note that these (*) indicated base-unit prefixes differ by a factor of 1000, and including the prefix centi, these prefixes are perhaps the most commonly used. A discussion on CHANGING UNITS given further ahead in this book shows how to make conversions between the Metric and English systems of measurement, or within a single particular system.

The base unit of mass (a measure of the amount of actual physical substance [like atoms], matter or material) in the metric system is the gram (g). The word of "gram" is rooted in words of: "grain", "measure", "measurement", and "weight", and originally meant a small weight or piece of something. A gram of water is defined as having the measurement of one cubic centimeter (1 cc, a volume measurement, ie., "space" or "three dimensional spacial area") when its temperature is just above the freezing temperature of water. 1000 grams of matter or a substance is equal to 1 kilogram of that mass: 1000g = (1k)g = 1kg = (10^3)g. 1cc volume of water is defined as equal to 1g of mass of water. 1cc of other substances will be more or less grams of mass since their density (mass/volume = amount of matter per volume) is different than that of water. 1000cc volume of water is defined as having 1000g of mass = 1kg of mass. A cube shape, 10 centimeters long, 10 centimeters wide, and 10 centimeters high is (10cm x 10cm x 10cm) volume = 1000cm^3 = 1000 cubic centimeters = 1 liter unit of volume size.

For spacial, space, or volume measurements, the liter (L) is the base unit of measure in the metric system. 1liter = 1L = 1000cc. 1 liter volume of water is defined as having 1kg of mass, and has a "proportional, corresponding or associated weight (technically a force)" indicated as 1kg on a weight scale, however, 1 liter volume of some other substance like copper, gold, zinc, sodium, lithium, plastic, foam, etc., will have a "corresponding weight" of more or less than that of water, due to that the (mass) density (= mass/volume) of that particular substance is not the same as the density of water which is 1gram/1cc.

One-thousandths of a liter = 1L/1000 = 1000cc/1000 = 1cc = 1(10^-3)L = 1 milli-liter = 1ml

For conversion purposes:

1 fluid ounce , water = **1fl. oz** , essentially a volume oz measurement, = **29.5735cc** = 29.5735 grams if water (Often in the U.S.A food industry, 1 fl. oz. is set as equal to an even 30 grams of "corresponding scale weight".)

1 pound = 1lb , a weight measurement, = 0.453592 kilograms = 453.592 grams
1 ounce = 1oz , a weight measurement, = 1lb/16 = (1/16)lb = 0.0625lb = 453.592g/16 = 28.3495 grams

SECTION 2: BASIC ALGEBRA

ALGEBRA

Algebra is a form of mathematics where symbols or letters are used to (symbolically) represent numbers. The English word "algebra" is just a couple of hundred years old and is derived from the older Arab word al-jbar. The basic interpretation of this word is: "the combining of several things, so as to have one thing". Simple algebraic-like methods have also been used since ancient times, primarily by the Egyptians, Greeks, and Hindus. This mathematical "invention" or knowledge could be said as always being someplace within the ability of humankind right from the start of our first basic civilizations, and therefore it was surely destined to happen, grow and "sprout up" like a nurtured seed as time went by, and to this day, it is still growing and being useful.

When a value remains the same and-or cannot change in value, that number is said to have a constant value, and it is therefore called a **constant**. When a number is not a constant or a specific known value, or that number is an unknown value yet to be known and-or solved for, it is or has a value that can variate (from the words vary (changeable), and various (several)) and which means that it is non-specific, non-constant, and that it can be one of many possible values, and-or change in value. The symbolic names, letters, identifiers, representatives or any other symbolic placeholders for numbers that can vary in value and-or are yet unknown in value are therefore called **variables**. Variables are often found in mathematical expressions and equations. Constants can also be given symbolic identifiers or names. On of the most common natural constants is Pi ("pie") which equals about 3.141592654 and is the result of any circle's circumference length divided by the diameter length of that circle.

If the temperature of something can variate, fluctuate or change in value, we can use something like the word: "Temperature" itself since it makes a good identifier for the value it represents. Simply using the letter T is more compact and usually acceptable, and when it is understood as to what it represents. Temperature or T, or some other identifier, can be used as a symbolic placeholder yet to be set to a specific numeric value and-or for an updated numeric value of the temperature.

Consider this analogy: Within a box, the current temperature is written on a piece of paper. That box is essentially a placeholder for the temperature value, and this box could be identified and labeled with the letter T on it. That box and value it contains within it can also be mathematically represented and expressed with that identifier of T. Since the temperature can fluctuate or vary in its value, the identifier of T is a therefore also called or identified as "variable T". T is now understood to identify, represent, and mathematically express and be equivalent to a varying and-or unknown value of the temperature.   The value of T can be set (assigned, written), changed (updated, adjusted), or read (viewed, obtained), since it is a placeholder for a value.

T = this letter or symbol identifies and represents both the temperature and its corresponding numerical value. If the temperature can vary or change in value, T is called a variable, and is specifically known as:"variable T". If the temperature measurement was 70 degrees, T will be set or assigned with this value of 70:   temperature = 70, and since T = temperature, T = 70.

To use identifiers or variables as equal to, and as if they are, actual numbers is very helpful and useful in mathematics. For example, unknown values can therefore be expressed and mathematically worked with as if they were a (literal, actual or specific) numeric value. Another advantage is that variables don't then need to be a specific numeric value so as to be mathematically useful, and it is understood that the variable is a general representation of one of many possible and-or changing values. Note that even though a variable can have a changing value, it is still only equal to one specific value at a time or measurement, and it should be said, indicated or understood that its value is a current (as of now, or at this time) value. Even after saying all this, it is still possible for a variable to have the same value for quite a long time, and therefore it acts or appears as if it were a (unchanging) constant.

Mathematical operations involving variables are performed in a manner very similar to using actual numeric values. It is easy to work with variables when you begin to "think of" or treat them just like actual numbers. Some examples of variables are: A, B, C, X, Y and Z. Usually, if you are to create a variable's name (symbol(s)), or "identifier" (often used as a general name for any variable as for computer languages), and as previously mentioned, it is best to choose one that will be descriptive to what the value represents. Sometimes, rather than use A or L to represent length, it is better to use a descriptive name like: LENGTH since this will be helpful for your future reference and-or for anyone else who sees it used in a formula or calculations.

Two or more variables written side by side are considered as being multiplied together. For example, AB means "A times B", (A x B) , or (A)(B). Since multiplication is commutative, the order of performing or expressing it does not matter. for example: AB = BA. A value in front of a variable(s) is called it's numerical coefficient (ie. cofactor). A numerical coefficient is a multiplying factor of the indicated product. For example, 2A = (2)(A). Due to multiplication being associative, the numerical coefficient can be, or perhaps was previously, associated with any other factors of that term of which it is in. For example, 2AB = 2(AB) = (2A)(B) = A(2B) = AB2. For conformity, the numerical coefficient is usually placed first. If a variable does not have a numerical coefficient indicated, it is considered to have a numerical coefficient of one (1) which of course does not change its value. Likewise, for example, 2A can be considered as the coefficient of B in the term of: 2AB. This coefficient then has a numeric part and factor: 2, and a variable part and factor: A.

It is also of importance to understand that a variable, being just a placeholder, can represent any numeric value, positive or negative in sign, and may even represent the resulting value of some other expression. It should be generally understood that the actual numeric value of a variable can be either positive or negative in sign.

Ex. If variable A is equal either to: -10, this can be correctly expressed as: A = -10,
It is incorrect to express this situation with the equation of: -A = -10, that is: -A is not equal to -10. As a verification of this, if you divided both sides by -1, you will have this equation: A = 10 which we know is wrong.
It is possible to express the correct equation of: A= -10 as: -A = 10 because the equation is still in balance and you can check, determine or verify this if you divide both sides by -1, and the result is A = -10.

Ex. Total = reference value + C : here C represents some change (from and with respect to, or in reference to, the given reference value)

If C = +10, Total = reference value + (+10) = reference value +10
If C = -10, Total = reference value + (-10) = reference value - 10

Notice that with two possible signs for the value of the variable, here C, that only one algebraic formula is needed as originally stated in the example. If the formula was expressed or written as: Total = reference value - C, hence as a difference between the values, the resulting value of the equation would be different, and specifically for this equation, it would result in opposite signed values.

Another thing to be aware of with variables is when a variable is expressed as being raised to an indicated (with an exponent) power. For example:

XY^2

Above, only the Y variable is to be squared, not both (the product of X and Y) of the variables. The exponent (ie. indicated or expressed power) is applied only to the immediate variable and not to a product of variables or an expression unless those are explicitly indicated within grouping symbols as being raised to the indicated power. Perhaps this rule would be more clear if the commutative or associative law was considered, and the expression was re-written as:

From: XY^2 to= Y^2X to show that only Y is being raised to the second power. or, by using parentheses:

From: XY^2 to= X(Y^2) = (Y^2)X

If the indicated product of X and Y were to be squared, it would be noted with grouping symbols such as parentheses as:
(XY)^2 expressing or "extending" the indicated operation:

$(XY)(XY) = XYXY = XXYY = X^2Y^2$, hence: $(XY)^2 = X^2Y^2$: a product to a power, then distributed the exponent

Note that with: XY^2 , it is incorrect to think that the two factors here are just (X) and (Y). The factors of this product are actually: (X) and (Y^2).

In daily life, we often need to make what are actually, and can be expressed as, simple algebraic equations to solve a problem. Take the information from the problem stated and apply variables and constants, known or unknown, so as to form an equation to mathematically represent the situation. For example, Mike is three years older than Tom, and we can express this as an equation. Actually, this can be expressed three ways, and that each equation can be mathematically derived from each other:

Let variable M = Mike's age and
Let variable T = Tom's age

1. $M = 3 + T = T + 3$

2. $M - T = 3$: here the left side expression is a difference of the variables set equal to the constant difference value of 3.

3. $M - 3 = T$ and this is equivalent to after switching sides: $T = M - 3$

Mathematically (or "algebraically"), all of the equations above can be derived from any one of the other shown equations. Any initial choice in the equation you do create and use, and if correct mathematically such as one of these equations above, will still yield the correct result.

LIKE TERMS

Terms that have the same exact variables are called similar or like terms. The exponents of corresponding variables of two or more like terms must also be the same. That is, the indicated powers of a variables must also be the same so as to still represent the same numeric value. The numerical coefficients or multiplying factors of like terms do not need to be the same.

Examples of like or similar terms:

AB and BA
A^2B and BA^2
5X^2 and 2X^2 : here, the numerical coefficients are different.
4XYZ and 3YZX : Often, you will want to arrange these terms so that they appear more visibly as being like terms. Ex., 4XYZ and 3XYZ , or any other possible way.

If A=10, and B=2: AB = (10)(2) = 20 and BA^2 = (2)(10^2) = (2)(100) = 200 = A^2B

Clearly AB and BA^2 or = A^2B are not like terms since they represent different values.
Here, 20 is not equal to 200. AB and A^2B are not like terms.

ADDING LIKE TERMS

"Like" or similar terms can be combined (added, summed). For example, 2X + 3X is a two-term (algebraic) expression. The terms +2X and +3X are like terms (both have the exact same variable(s), here X, including their indicated powers, and therefore can be combined just like being the same numeric value to produce a multiple of that value.

Given +2X and +3X, how do we combine these (like) terms?

First notice that a common factor (in both terms) of X can be divided (ie. factored) out of each term:

2X + 3X = X(2 + 3) = (2 + 3)X = (5)X = 5X

If you had 3 of a certain value, and also 5 of that same value, you then have (3+5) = 8 of that value, and which also means 8 times that value.

Hence, **to combine like terms, combine their coefficients, and keep the same variable(s).**

Here is a check using the concept of multiplication to represent repeated addition:

(2X) + (3X) "extending" the indicated products and expressing their "partial sums" or terms:
(X + X) + (X + X + X) distributing (+1) to clear the grouping symbols:
X + X + X + X + X using multiplication to represent this repeated addition of X, here five times:

X5 or = 5X : The left hand side is the "common mathematical form" of expressing this result, and it has the form of a number or variable to be multiplied 5 times. The right hand side is the equivalent "algebraic form" where the multiplier is placed first and is called the numerical coefficient of the variable.

We see that summing or combining the numerical coefficients of like terms is a shorthand way to repeatedly add like terms (which may be already some existing multiple of the variable(s))..

Ex. $4X + BAX = X(4 + BA)$: here X, the common factor of each term, was factored out (divided out of each term) and is expressed as a factor to the resulting quotient so as the two expressions remain in balance.

Another, perhaps simpler, analogy or verification of the addition of like terms stems directly from the basic concept of adding things which are similar or have like units. To use units as variables is non-standard, but it serves as a good illustration. In a strict sense, variables are a symbolic (representative) numeric concept of representing a numeric magnitude or quantity (of the units) that is known or unknown with symbolic letters, text or other symbols. For example, we could let letter, or the symbol, B (or perhaps: *, or notches such as | or 1) represent an object such as a brick or "brick unit", rather than some numeric or variable value. If there are five bricks, this can be algebraically represented as 5B, meaning 5 Bricks = "five bricks". If you divided or separated the bricks into a group of three bricks, and another group having two bricks, the total sum of the bricks is still equal to five bricks:

2 bricks + 3 bricks = (2 + 3) bricks = 5 bricks
B, B + B, B, B = (B + B) + (B + B + B) = B + B + B + B + B : optional, for clarity
$2B + 3B = (2 + 3)B = 5B$

If we then let B=Bricks, variable X = 2, and Y = 3 for the quantity of that variable or unit, the above could then be expressed as:

$XB + YB = (X + Y)B$
2 Bricks + 5 Bricks = (2+5)Bricks = 7Bricks

In the standard sense of mathematical understanding, when B represents a numeric value, variable or constant, and not some object identifier or unit of measurement as temporarily used here to illustrate the summing of "like" or similar terms concept and method, the equations and operations as expressed here are still the same, except that then the numerical coefficients (here, X and Y) of variable or value B, are actually to be considered as (multiplying) factors to B. Likewise, B would also be considered a multiplying factor in each term, and since it is in both terms, it is a common factor to and of those terms, and can be factor or divided out from each term and then expressed in the "factored form" (of the original terms). The factored form of the expression is the product of B and a product that is the expressed sum of the remaining terms. Doing the reverse is called the "distributed form" of the expression.

Ex. Simplify $5X -3X$

$+5X -3X = (+5-3)X = (+2)X = +2X$: After combining the numerical coefficients of like terms and keeping the variable(s). You can check this result by first factoring variable X out from each term, and that it is indicated here in the second equivalence: $(+5 -3)X$ or= $X(+5 -3)$

The intermediate steps shown above are often considered as "understood" (known) and hence they are usually omitted in practice for the sake of some speed, efficiency and clarity, however, its always good to see what has actually taken place.

Ex. Simplify $-3X +4B +3B -X$

The terms -3X and -X are like terms, and the terms +4B and +3B are like terms.

$-3X -X = -3X -1X = -4X$, and $+4B+3B = +7B$

The sum is therefore:

-4X+7B or = +7B -4X : since combining terms is commutative, so therefore, the order of which term comes first, or is expressed first (perhaps for some clarity), has no affect on the result.

If X=3 and B=2 above, the value of the expression is found by assigning or substituting these values into their corresponding variable numeric placeholders:

-4X +7B = -4(3) +7(2) D (distribute, from the CDC method mentioned previously):
-12 +14 C (combine terms using the laws for the signs):
+2

ALGEBRAICALLY VERIFYING DISTRIBUTION

The concept of distribution has already been mentioned, discussed and used several times in this book, and now we are at the point to where it can be algebraically described and verified below:

$a + a + a + a + a + \dots$: The mathematically expressed repeated addition, of a variable or value. an endless or infinite amount of times, hence the sum is not an expressible value, other than mentioning that it is infinitely large.

If we consider a total, or limited number, say (n) of the above terms by using grouping:

$(a + a + a + a + a) = an = na$: Expressing the repeated addition as multiplication.

Now grouping terms of this set of (n) terms into two groups or sets of terms of variable (a), with one set containing a total of (b) like terms ,and the other, a total of (c) like terms; (here, (b) will actually be 2, and (c) will be 3 for this analysis example):

$(a + a) + (a + a + a)$ expressing these groups of repeated addition, as multiplication:

$ab + ac$: $ab + ac = ba + ca$ is a more common form with the coefficients of (a) first

Since $n = (b + c)$, : n = the total number of repeated additions of the like terms

$a + a + a + a + a = an = na = (b + c)a = ba + ca = a(b + c) = ab + ac$: verifies distribution

$2a + 3a = a(2 + 3) = a5 = 5a$

Also notice that $a(b + c)$ is the factored form of $(ab + ac)$, where each term has a common factor of (a).

Ex. $(a + b) (c + d)$ expressing an important intermediate step of distribution that is often omitted:

$a (c + d) + b (c + d)$: Notice, and as a verification, that each term here has a common factor of $(c + d)$, and if you were to factor this out of each term, you would then have the original expression.

$ac + ad + bc + bd$: this is the distributed form of the above expression, and you can verify that this is correct by factorization, and it is essentially a reverse process - such that during multiplication, a factor is put into each term, and during factorization or division, a factor is essentially pulled back out from each term:

$(ac + ad) + (bc + bd)$: grouping like terms, one group has (a), and the other group has (b) for each term.

$a (c + d) + b (c + d)$: factoring out the like variable(s), or values, from each grouping of like terms

$(c+d) (a + b)$: here, $(c + d)$, an expression, is treated like a single variable or value contained in the grouping symbols, and was factored from each term. This can be expressed as, using the commutative or order law:

$(a + b) (c + d)$: this is the initial expression shown above. This gives verification to how distribution was used and expressed starting from the initial expression.

Below, a few generalized examples of expressing and working with algebraic values, equations, and distribution will be shown.

Ex. If you were to add and subtract the same value, say (b), to or from another value, say (a), what is the difference (d) in the resulting two values?

Letting: $N1 = a + b$, and $N2 = a - b$: N1 and N2 represent binomials (2 terms), and N2 is a difference of terms.

Let: $d = N1 - N2$

$d = (a + b) - (a - b)$: subtracting (or adding the negative of a value) to find the difference
Distributing (+1) and then (-1) to clear grouping symbols:

$d = a +b -a +b$ combining like terms of variable (a), and variable (b):

$d = 2b$: You can imagine or see this when you take any value (a) on a numbered-line and increase it by (b), and also decrease it by (b). This change in value, or (b), can be thought of as a line segment graphically, and the difference in the values of N1 and N2, is 2b. The specific value of (a), which we can think of as the starting or reference value, which is also centered on the entire length of 2b, does not affect or play any role in the difference value, and is therefore absent from the resulting equation or formula (for d) for this situation. If (b) was called the change of or from the starting value (a), then (d) could then be expressed as: d = 2(change).

Ex. If a=0 and b=5: $d = (0+5) - (0-5) = 5 - (-5) = 5 + 5 = 10$
$d = 2(b) = 2(5) = 10$

Ex. What is the formula for the difference (d) between (a + b)^2 and (a - b)^2 ? Note that this is similar to the above example, but here the terms, or its (equivalent) value, are now squared.

$d = (a + b)^2 - (a - b)^2$: mathematically expressing the difference. Extending the squared terms:

$d = (a + b)(a + b) - [(a - b)(a - b)]$ using distribution (D) within the grouping symbols:

$d = [a^2 + ab + ab + b^2] - [a^2 -ab -ab +b^2]$

$d = +1[a^2 +2ab + b^2] - 1[a^2 -2ab +b^2]$: notice in the two grouped terms, that the term 2ab is present and either pos. or neg. Distributing +1 and -1 to clear grouping symbols:

$d = a^2 +2ab +b^2 -a^2 +2ab -b^2$ combining (C) like terms:

$d = 4ab$: When a=b, $(a-b)^2 = (a-a)^2 = (b-b)^2 = 0^2 = 0$, yet this formula is still valid.
When (a) and-or (b) is equal to 0, there is no difference possible, and d is always 0.

If (a) and (b) are always equal, a=b, this difference (d) formula here could be written as (using algebraic substitution):

$d = 4aa$ or $= 4bb$

$d = 4a^2$ or $= 4b^2$

Ex. The sum or difference between a variable squared and that variable results in an multiplication expression:

$a^2 + a = a (a + 1)$, ex. $5^2 + 5 = 5 (6) = 30$, $a^2 - a = a(a - 1)$, ex. $5^2 - 5 = 5(4) = 20$: check with dist.

Ex. What is the difference (d) between the sum of two squared values and the difference of two squared values?

$(a^2 + b^2) - (a^2 - b^2) = d$ after clearing each grouping symbol by distributing (+1), and (-1):
$a^2 + b^2 - a^2 + b^2 = d$ after combining like terms, and switching sides:
$d = 2b^2$

Ex. Algebraically show that (a/b) and (b/a) are reciprocals of each other. The easiest way to do this is by knowing the fact that a reciprocal times its own reciprocal is equal to 1:

$$(\text{reciprocal})\left(\frac{1}{(\text{reciprocal})}\right) = \frac{\text{reciprocal}}{\text{reciprocal}} = 1$$

$$\left(\frac{a}{b}\right)\left(\frac{b}{a}\right) = \frac{ab}{ba} = \frac{ab}{ab} = 1$$: their product of 1 indicates the values are reciprocals of each other

Let $(a/b) = n$, then $1/n$ is its reciprocal, $= 1/(a/b) = (b/a)$: algebraic verification that (a/b) and (b/a) are reciprocals of each other

MULTIPLYING LIKE VARIABLES

Multiplying like variables is performed just like the multiplication of like values or numbers. To multiply like variables, add their exponents, and multiply their numerical coefficients together.

Ex. (A)(A) = A^2

Checking: (A)(A) = A A = (1)A^1(1)A^1 = (1)(1)A^(1+1) = (1)A^2 = A^2

If A = 5, (A)(A) = AA = (5)(5) = A^2 = 5^2 = 25

Ex. A^2A^3 = A^5

Checking: A^2 A^3 = A^(2+3) = A^5
Checking: A^2 A^3 = (AA)(AAA) = AAAAA = A^5

Ex. This example shows that when multiplying like variables that have numerical coefficients other than 1, multiply those numerical coefficients, and add the exponents of the variable.

(2A)(2A) = 4A^2

Checking: (2A)(2A) = (2)(A)(2)(A) = (2)(2)(A)(A) = 4A^2

Ex. (10A^2)(2AB) = 20A^3B

Checking: (10A^2)(2AB) = (10)(2)A^2A^1B = 20A^3B

Ex. (2A^3)(B)(-5A^ -4) = -10BA^ -1 Or=: $\frac{-10B}{A}$ Or: _ $\frac{\_10B\_}{A}$

A POWER TO A POWER

To simplify a "power to a power", that is, an indicated power that is itself raised to an another indicated power, simply distribute (multiply) the exponents.

Ex. (A^2)^3 = A^(2x3) = A^6

Checking by "extending" the indicated operation, and then using the multiplication of like variables rule of adding the exponents:

(A^2)^3 = (A^2)(A^2)(A^2) = A^(2+2+2) = A^6

If the base of the indicated power contains multiple factors, "distribute" (multiply) the (outer) indicated power to each of the factors exponents.

Ex. (x^3y^1)^2 = x^((3)(2)) y^((1)(2)) = x^6y^2 checking by extending (using multiplication) the indicated power:

(x^3y^1)(x^3y^1) = x^3y^1x^3y^1 = x^3x^3y^1y^1 = x^(3+3)y^(1+1) = x^6y^2

MULTIPLYING SIMILAR (INDICATED) POWERS

To simplify the product of like or similar indicated powers (have the same indicated exponent), raise both the product of the numerical coefficients and then the product of the variables to that indicated power.

Ex. $(2X)^2 (3XZ)^2 = ((2)(3))^2 ((X)(X)(Z))^2 = (6)^2 (X^2 Z)^2 = 36 X^4 Z^2$ checking:

$(2^2 X^2)(3^2 X^2 Z^2) = (4X^2)(9X^2 Z^2) = 36X^4 Z^2$ or:

$(2X)(2X) (3XZ)(3XZ) = (2)(2)(3)(3)(X)(X)(X)(X)(Z)(Z) = 36X^4Z^2$

Another way to simplify this is to consider that the two (same) indicated powers have been previously factored out from a single power of:

$(6X^2Z)^2$: this is the result after multiplying the bases of the same indicated powers together and indicating that same power. This can be expressed as:

$(6XXZ)^2$
$((2)(3)(X)(X)(Z))^2$ which can be expressed as:
$((2X) (3XZ))^2$ distributing the exponent to each of the indicated factors:
$(2X)^2 (3XZ)^2$: this is the original example given

Now checking by distributing the exponent of the single (or unfactored base product) power:

$(6X^2Z)^2$ we have:
$6^2 X^{(2(2))} Z^{(1(2))}$
$36 X^4 Z^2$:checks

Hence the bases of similar (indicated) powers can first be multiplied together, and then the exponent can be distributed. Also, as indicated here, you can factor the base of an indicated power, and each factor will have that same indicated power or exponent: $(ab)^n = a^n b^n$, which is the same result after initially distributing the exponent to each factor.

DIVIDING LIKE VARIABLES

As with numerical values, just take the difference (or add the negative of) of the exponents when dividing like variables.

Ex. $\frac{A^5}{A^2} = A^{(+5-2)} = A^{+3}$ checking: $(A^2)(A^3) = A^{(2+3)} = A^5$

Ex. $\frac{A^2}{A^5} = \frac{A^{(+2-5)}}{1} = A^{-3}$: with a negative exponent

OR: $\frac{A^2}{A^5} = \frac{1}{A^{(5-2)}} = \frac{1}{A^3}$: with a positive exponent

checking: $\frac{A^2}{A^5} = \frac{\overset{+1}{\cancel{A^2}}}{(A^3)\underset{+1}{\cancel{(A^2)}}} = \frac{1}{A^3} = \frac{A^{-3}}{1}$ or: checking: $(A^5)(A^{-3}) = A^{(5+(-3))} = A^{(5-3)} = A^2$

OR: $\frac{A^2}{A^5} = \frac{A^2\,A^{-5}}{1} = A^{(2+(-5))} = A^{-3}$: using the multiplication of like values or variables rule to add or combine their exponents and keep that base value

Dividing A Several Term Expression By A Single Term Expression

To divide a several or multiple term expression (often called a multinomial) by a single term expression (often called a monomial), divide the denominator term into each term of the numerator expression. As discussed previously using only numeric values, this concept is simply the reverse of the concept of adding "like" fractions that have the same denominator. The process is also a form of simplifying a fraction.

Ex. $\frac{10X + 5}{5} = \frac{10X}{5} + \frac{5}{5} = 2X + 1$

Checking: $5(2X + 1)$: Multiplying the quotient and divisor together, and this is also a factored form of the multinomial dividend. Distributing the factor of 5 to each term in the second factor which is an expression that is a binomial since it is two terms being combined:

$5(2X) + 5(1)$

$10X + 5$: checks, since this is equal to the dividend

Ex. $\frac{30X^3 + 15X^2 + 10X}{5X}$

$\frac{30X^3}{5X} + \frac{15X^2}{5X} + \frac{10X}{5X}$

$6X^{3-1} + 3X^{2-1} + 2X^{1-1}$: $X^{1-1} = X^0 = 1$, and this instance of variable X is essentially eliminated as being a factor.

$6X^2 + 3X^1 + 2$

Checking: $5X(6X^2 + 3X^1 + 2)$ indicating the distributing of the 5X factor:

$5X(6X^2) + 5X(3X^1) + 5X(2)$ distributing:

$30X^3 + 15X^2 + 10X$: checks with the original numerator or dividend

Dividing A Several Term Expression By A Several Term Expression

This is about dividing a several or multiple term expression, often called a multinomial, by another several or multiple term expression. First, so that you can accept the concepts and process, here is a simple verification using only numeric constants, partial sums, equivalent fractions, and summing fractions, and without using any (algebraic, or symbolic placeholder) variables:

$$\frac{200}{100} = 2 = \frac{100 + 100}{100} = \frac{100}{100} + \frac{100}{100} = \frac{100}{(50 + 50)} + \frac{100}{(50 + 50)} = \frac{100 + 100}{50 + 50}$$

: expressed as a multinomial expression divided by a multinomial expression

Now an example using variables:

since $(x+2)(2) = 2x + 4$, then mathematically, dividing both sides by the $(x+2)$ factor we should have (2):

$x + 2 \overline{)\,2x + 4}$: the quotient should obviously be equal to 2, since dividing a product by one factor yields the other factor of that product.

To get the first term of the quotient, divide the first term of the divisor (or denominator if you will) into the first term of the dividend (or numerator if you will). Then continue as in normal division.

$$\frac{2x}{x} = 2$$

$$\begin{array}{r} 2 \\ x + 2 \overline{)\,2x + 4} \\ -\ \underline{(2x + 4)} \\ 0x + 0 \end{array} \quad = \quad \begin{array}{r} 2 \\ x + 2 \overline{)\,2x + 4} \\ +\ \underline{-2x - 4} \\ 0x + 0 \end{array}$$

: after using distribution (of -1) to rid the grouping symbols.

: remainder of 0, division is complete

Checking by multiplying the quotient and divisor: $2(x+2) = 2x + 4$: checks, since the product equals the dividend

Also: $$\begin{array}{r} x + 2 \\ 2 \overline{)\,2x + 4} \\ -\ \underline{2x} \\ 0 + 4 \\ -\ \underline{+4} \\ 0 \end{array}$$, and $2(x+2) = 2x + 4$

A method to make the process of the division of values that contain variables easier is to first place the terms containing the variable in an order of descending or decreasing (indicated) powers or exponents. Do this for both the dividend and divisor. If a power of a variable is absent or unused, replace it with a "0 placeholder". That is, express as a term that (unused) power of the variable, and with a 0 constant. This effective 0 value added in to the sum will obviously not change the value of the dividend (or numerator) or divisor (or denominator). For example, if the numerator or denominator is:

3 + x + 5x^3 rearrange this for the division process as:

5x^3 + 0x^2 + x^1 + 3 :the last term could also be indicated as having a factor that is a power of x: 3X^0 , since 3x^0 = 3(1) = 3

Actually, you can think that you have been dividing polynomials by polynomials all along without even realizing it. This can easily be seen by representing the strict (number only) numeric values of the numerator and denominator in an expression form where each term is the positional product of each digit of that number:

Ex. $\frac{385}{11} = 35$ Creating a positional sum by expressing each digit as the positional product of the digit value and its corresponding decimal weight in the decimal number:

$$\frac{385}{11} = \frac{3(100) + 8(10) + 5(1)}{1(10) + 1} = \frac{3(10^2) + 8(10^1) + 5}{1(10^1) + 1}$$

Here above, it is quite obvious that instead of a "polynomial in x (a variable)" we have a "polynomial in 10". If you were to replace each power of 10 above with a corresponding power of x, the results would be the same.

$$\begin{array}{r|l} & \underline{\ 3(10^1) \ + \ 5\ } \\ 1(10^1) + 1 & 3(10^2) + 8(10^1) + 5 \\ & - \underline{[\,3(10^2) + 3(10^1)\,]} \\ & 0(10^2) + 5(10^1) + 5 \\ & \qquad - \underline{[+5(10^1) + 5]} \\ & \qquad\quad 0(10^1) + 0 \end{array}$$

:start by dividing 3(10^2) by 1(10^1), these are the first terms of the dividend and divisor

: Note, the negative sign preceding the [ ] grouping symbols and it can be thought of as the factor (-1) to distribute and then do the combining.

Checking, using multiplication of the divisor and quotient so as to see or compare if it equals the dividend:

(1(10^)1 + 1) (3(10^1) + 5) distributing:
3(10^2) + 5(10^1) + 3(10^1) + 5 combining:
3(10^2) + 8(10^1) + 5 distributing:
300 + 80 + 5 combining:
385

Another check is to use the order of operations more closely, simplifying the expressions within the grouping symbols first:

(1(10^)1 + 1) (3(10^1) + 5) using distribution on the inner grouping symbols:
(10 + 1) (30 + 5) combine (add):
(11)(35) distribute (multiply)
385

As like during the process of dividing two plain numbers, when dividing multinomials, if the difference after subtracting is 0, the division is complete. If the first term (ie. monomial) or variable in the difference has a lower power than that of the first term of the divisor, then the divisor cannot divided (not even once) into that difference, and then the remaining part of the dividend becomes the remainder.

It should also be mentioned that it is mathematically possible, but maybe not practical, to divide each term of the dividend (or numerator if you will) by the entire divisor (or denominator if you will). Here, the entire multinomial divisor, perhaps set within grouping symbols for clarity, is used to represent a single value divisor.

[This space for edits.]

EQUATIONS

Two expressions that represent the same value can be expressed or set as being numerically equivalent (ie., "equal", =) in value, and this expression of equivalence is called an equation. An equation can be mathematically worked with and manipulated much like a conceived imaginary numerical weighing scale or balance. Whatever you do mathematically to one (entire) side of the equation, you must also do to the other (entire) side of the equation so as to keep both expressions or sides equal and the entire equation in balance. More specifically, whatever change in total value you apply to one side, you must also apply that same change in total value to the other side. All of this will be of great importance since it will allow us to solve for the equivalent value or expression of a variable or unknown value used in that equation.

When both sides do not represent the same value, they are said as "not equal", and the equation is "unbalanced". When the two sides or expressions are equal, there is no mathematical difference between their values, and the equation is therefore balanced. When the two sides or expressions are not equal, there is a mathematical difference between them, and therefore, those expressions or sides are unbalanced with respect to each other. One side is greater in value than the other, and therefore, one side is less in value than the other. Given an equation, the difference of a side value with respect to the other side value = side value - the other side value. A difference can also be thought of as the amount of separation or unbalance between two things such as the two sides or expressions of an equation.

Ex. Given the two expressions of: Eq.1: $(5+2)$ and Eq.2: $(3+5)$, are they equivalent in value?

First simplifying each expression to find their resulting net worth, total, sum, value or weight:

Eq..1: $5+2$ Eq.2: $3+5$
7 8

$7 - 8 = -1$:The amount that Eq.1 is different in value than Eq.2 ,
Since the result is not 0, the equations are not in balance.

$8 - 7 = +1$:The amount that Eq.2 is different in value than Eq.1

Notice, the absolute (or signless) value of each difference (or numerical separation), or numeric separation or "distance" between them is the same value of 1.

Since the net worth, sum or weight of each expression does not have the same value, there is a difference in or of value among the sides, and therefore, we can not equate those two expressions. We can however indicate or express their mathematical relationship with a special (mathematical, values) relational or relationship operators:

$7 < 8$: < , when read from left to right, it is called the "less-than" symbol. , "seven is less-than eight"
$8 > 7$: > , when read from left to right, it is called the "greater-than" symbol. , "eight is greater-than seven"

In either case, the arrow's smaller point end always points to, indicates or expresses the smaller or less value, and the open or large end of the arrow is near the greater or larger value.

7 |=| 8 : expressing that 7 is not equal to 8, and-or that 8 is not equal to 7

Ex. Given the two expressions of: Eq. 1: $(10-3)$ and Eq. 2: $-(257-249)$, are they equivalent in value?

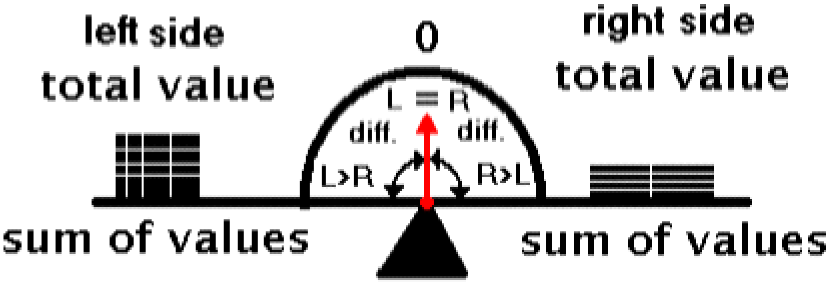
First simplifying each expression to find their resulting net worth, total, sum, value or weight:

Eq.1: $+10-3$ Eq.2: $-(-257+249)$
$+7$ $+256 -249$
$+7$

Checking for any difference: (+7) - (+7) = 0, hence there is zero or no difference of the values of each expression. Since the net worth, sum or weight of each expression has the same value (here, 7), we can equate those two expressions and create an equation with sides of those equations:

10 -3 = -(-256 +249)

Here is a graphical representation of a balanced equation where: left side = right side: [FIG 22]



A BALANCED EQUATION

When the scale is balanced, both sides are equivalent in weight, and if any weight is added to or removed (ie., subtracted) from just once side, there will be an unbalance. When two values on either side of the scale are not equivalent (ie., =|=), there is a difference (diff.) between those two values. If we subtract one value from the other, we can find if there is any difference between those two values, and the actual value of that difference.

Given: value1 and value2 — Checking to see if those two values are equal or different:

value2 - value1 = difference : difference is the amount that value2 is different than value1

Note also that:

(value1 - value2) = difference

Here, difference will be the same (signless or absolute) value as:
(value2 - value1) = difference
, but will now have a different sign indicating if value1 is greater or less than value2. Expressed this way, the sign of the difference is in reference to the first term,and that is value2.

value2 and value1 can be in placed in balance or equivalence when the specific amount of their unbalance, here the difference value, is combined with value1, and their difference will then be 0. This is much like a checking a subtraction problem when the difference is added to the subtrahend, so as to equal the minuend.

Now given:

(value1+ difference) and value2 or: value1 and (value2 + difference) if the signed difference is used

Checking to see if those two values are equal or different:

value2 - (value1 + difference) = 0 : since there is no difference, these two values are equivalent:
value2 = (value1 + difference) : both sides of this equation balance. This can be expressed as:
value2 = value1 + difference : as like all variables, these should be considered as signed values which can be either positive or negative in sign.

Ex. If value1 is 3, and value2 is 7:

We immediately can see that these two values are not equal since one value is larger or greater than, or with respect to, or in reference to the other value. Likewise, one value is therefore less than the other value:

value2 > value1 and-or: value1< value2 and value2 /=/ value1 : mathematical or numerical relationships

$7 - 3 = 4$: +4 is the difference between 3 and 7, which could also be said as the difference between 7 and 3. 7 is 4 greater than 3. Likewise it could be said that 3 is 4 less than 7. Note: $3 - 7 = -4$, here the negative sign of the difference means that the initial term and reference value of +3 is 4 less than +7.

$7 - (3 + 4) = 0$
$7 = (3 + 4)$
$7 = 3 + 4$: a balance scale having a weight of 7 units on one side will be in balance if the other side
$7 = 7$ has a weight of 3 units and another weight of 4 units.

Below are some examples of equations and mathematical manipulations on them.

Ex. $14 = (7)(2)$: each side can be simplified to a value of 14, therefore the equation is true, and not unbalanced and false.
$14+6 = (7)(2)+6$: Lets add 6 to each side
$20 = 14 + 6$: after combining on the left side, ORD step 3 (ie. mult.) on the right side
$20 = 20$: after combining the right side, ORD step 4 (ie. combining). The resulting equivalent values on both sides of the equals sign indicate that both sides were, and are still in balance after the same mathematical operations were applied to them.

Ex. $(8+2) = (5)(2)$: each side can be simplified to a value of 10
$(3)(8+2) = (5)(2)(3)$: multiplying 3 to each side
$+24+6 = +30$: after distributing
$+30 = +30$: after combining

Ex. $75 = (5)(15)$

$$\frac{\overset{+15}{\cancel{75}}}{\underset{+1}{\cancel{5}}} = \frac{\overset{+1}{\cancel{(5)}}(15)}{\underset{+1}{\cancel{5}}}$$

: dividing each side by 5, and canceling (canceling out, dividing both the num. and den. by a common factor(s))

$15 = 15$

Ex. $100 = (25)(4)$ taking and expressing the square root of both sides:

$\sqrt{100} = \sqrt{(25)(4)}$ factoring the radical:

$10 = \sqrt{25} \quad \sqrt{4}$ simplifying (here, rationalizing) each radical:
$10 = (5) \quad (2)$ distribute or multiply:
$10 = 10$

Let's say expression1 equals some value that we can set equal to and call as: x. If another different expression, such as equation2 also equals this value of x, then we can equate expression1 and expression2 since we know they are equal to the same value, here x. Showing or expressing this mathematically:

expression1 = x = expression2 therefore:
expression1 = expression2

Ex. If, or given: $(7 + 3) = 10$ and $\sqrt{100} = 10$ therefore, the expressions can be equated since they both equal the same value of 10:

$$(7 + 3) = \sqrt{100}$$
$$10 = 10$$

ALGEBRAICALLY EXPRESSING THE MORE ADVANCED MATHEMATICAL OPERATIONS

Previously in this book, examples of concepts, expressions, equations and formulas, with many using a pure or strict numerical form were given, such as for powers, roots, logarithms, etc. Some simple algebraic or introductory algebraic-like methods were also utilized where needed. Below, in a more pure algebraic sense, the mathematical and corresponding relationships of a base (b), exponent (e) or (x), and number (N) are expressed in a pure or strict algebraic mathematical form using variables, and in three fundamental mathematical operations and equations. Also take note of the various locations of the variables (N, b, x) within each equation, and that each variable also has the same value in each equation:

$N = b^x$: **Powers**

In a power expression or equation, the number (N) is often called the power value, (b) is often called the base or "base of the power value", and (x) is often called the exponent or the "indicated power".

$b = \sqrt[x]{N}$: **Roots**

In a radical expression or equation, the base (b) is often called the root, (N) is often called the radicand, and the exponent (x) is often called the index (i) or "indicated root".

$x = \log_b N$: **Logarithms**

In a logarithmic expression or equation, the exponent (x) is often called the logarithm, (b) is called the base of the logarithm, and (N) is often called the Number. Number is actually equal to a power of that indicated base: $b^x = N$

Expressing the above equations in a somewhat unconventional format or way so as to help make the three relationships more clear using just the same three names or identifiers for the parts of all the equations:

powers	roots	logarithms	: expression type
$\text{power} = \text{root}^{\text{logarithm}}$	$\text{root} = \sqrt[\text{logarithm}]{\text{power}}$	$\text{logarithm} = \log_{\text{root}} \text{power}$	

Expressing the above by using the more formal, common, standard identifiers or names for the values, along with an equivalent variable or identifier:

$$\text{power} = \text{base}^{\text{exponent}} = \text{Number}$$

$$\text{root} = \sqrt[\text{index}]{\text{radicand}} = \text{base} = \sqrt[\text{exponent}]{\text{power}} = \sqrt[\text{exponent}]{\text{number}}$$

$$\text{logarithm} = \log_{\text{base}} \text{Number} = \text{exponent}$$

We see in all three equations above that each of the three values can have a new or alternate meaning as a different part of each equation of each of the three mathematical operations, but it's actual value is the same in all three equations:

These will have the same numeric values:

base = root
exponent = logarithm = index,
power = Number = radicand

Given all the corresponding values for (N), (b), and (x) from one equation, they will satisfy (ie. keep both sides in balance and equivalence) all of the three equations given above. For example, if b=10, x=2, and N=100:

Powers	Roots	Logarithms
$N = b^x$	$b = \sqrt[x]{N}$	$x = \log_b N$
$100 = 10^2$	$10 = \sqrt[2]{100}$	$2 = \log_{10} 100$

Given any two values of: (b), (x), and (N), there is only one possible and corresponding third value. The instance of, and the specific set of three corresponding values is unique and essentially happens only once, and all the corresponding values are specifically related according to the equations shown above.

Some of the following has been mentioned about exponents, but here it is presented in algebraic terms:

$b1^x = b2$ therefore, $b2^{(1/x)} = b1$ checking that this is true using substitution for b1:

$b1^x = (b2^{(1/x)})^x = b2^{(x/x)} = b2$: as shown above. Also:

$b1^x = b2$ therefore, $b2^{(1/x)} = \sqrt[x]{b2} = b1$: the exponents of b1 and b2 are reciprocals.

$b1^x = b2$ therefore $b1 = \sqrt[x]{b2}$: or $b1^x = N$ and $\sqrt[x]{N} = b1$

Ex. $3^{2.5} = 15.588\underline{5}$ and $15.5885^{(1/2.5)} = \sqrt[2.5]{15.5885} = 15.5883^{0.4} = 3$

BASIC METHODS OF SOLVING FOR A VARIABLE

To solve for the value of a particular variable that's part of an equation is to isolate the variable on one side of the equation, and then the other side of that equation will be the equivalent value of that variable. First, if possible, simplify each side of the equation using the order of operations and-or the CDC method discussed in this book. Some other helpful steps are to place all terms that have the variable in question on one side of the equation, and place all the other variable terms and constants on the other side of the equation. This moving, shifting or arranging of terms to the other side of an equation is referred to as transposing (T). To transpose, add the negative of the term to both sides of the equation, then after combining like terms, the variable that was transposed will have a numerical coefficient of 0, and therefore, that variable is effectively eliminated from that side of the equation since anything times zero is equal to zero, and adding zero does not affect the value of that side.

equation

expression1 = expression2

term1 + term2 = term3 : To solve for term1, or a variable that is within term1, isolate term1 to one side of the equation; and here, by keeping term1 where it is and removing term2 from that side of the equation by the transposition (change position) process of adding the negative of that term to both sides of the equation:

term1 + term2 -(term2) = term3 -(term2) using distribution, here of and by: -1, to clear grouping symbols:

term1 + term2 -term2 = term3 -term2 combining like terms:
Note, +term2 -term2 = (+1)term2 (+) (-1)term2 =
(+1 + -1)term2 = 0 term2 = 0

term1 = term3 -term2

Ex. Solve for (x) given: $x+4 = 7$

$x+4 = 7$
$x+4 -4 = 7 -4$:T. +4, so we then add the negative of $(+4) = -(+4) = -4$ to each side of the equation
$x = +3$: after combining

Once the value of a variable is found, it can be checked by substituting (setting equal to, replacing) the value back into the variables place (placeholder) or position in the original equation. That is, the variable itself is to set equal to that found value. If both sides of the equation are found to be equal, then the value of the variable is correct.

Using the last example where $x=+3$:

$x+4 = 7$: original equation, substitute the solved or calculated value for x:
$+3+4 = 7$ combine:
$7 = 7$: checks

Ex. Solve for X given: X - Y = 5

$X - Y = 5$ First, let's T. (-Y) = Transpose (-Y) = add the negative of (-Y) = -(-Y) = +Y to both sides
$X - Y + Y = 5 + Y$ combining (C.) like terms:
$X + 0Y = 5 + Y$
$X = 5 + Y$: We find that X is equal to an expression containing a variable (here it's Y) whose actual value has an affect on determining the corresponding and specific value of X.

If a variable being solved for is being multiplied by some multiplying factor, other than one, that variable can be isolated by dividing both sides of the equation by its multiplying factor or numerical-coefficient.

Ex. 25X = 50, solve for X

$\frac{25X}{25} = \frac{50}{25}$: to rid X of its multiplying factor of 25, simply divide by 25. This would also be equivalent to multiplying each side by (1/25).

$\frac{\overset{+1}{\cancel{25}}X}{\underset{+1}{\cancel{25}}} = \frac{\overset{+2}{\cancel{50}}}{\underset{+1}{\cancel{25}}}$: cancel

$+1X = 2$ or simply: $X = 2$

If the variable to be isolated is being divided by some value, the variable can be isolated by multiplying both sides of the equation by this value, and then using canceling to effectively rid it from that side.

Ex. $\frac{X}{2} = \frac{50+Y}{1}$: solve for X

$\frac{(2)(X)}{(1)(2)} = \frac{(50+Y)(2)}{(\quad 1 \quad)(1)}$: to rid (x) of its "dividing factor", here 2, multiply both sides by this "dividing factor" and then cancel it out:

$\frac{(\overset{+1}{\cancel{2}})(X)}{(1)(\underset{+1}{\cancel{2}})} = \frac{(50+Y)(2)}{(\quad 1 \quad)(1)}$: cancel on the left side, and using distributing on the right side:

$X = (+2)(+50) + (+2)(+Y)$:indicated distribution

$X = +100 + 2Y$:after distributing

Ex. Solve for X given: $\frac{X}{5} - \frac{X}{7} = \frac{6}{35}$

There are several ways that X can be solved for, and for the first, we will combine the like terms of: (1/5)X and (-1/7)X :

$\frac{X}{5} - \frac{X}{7} = \frac{6}{35}$ combine like terms on the left side (here, essentially combining fractions with the LCD = 35):

$\frac{7X}{35} - \frac{5X}{35} = \frac{6}{35}$: showing the newly created and equivalent fractions on the left side

$\frac{(+7X-5X)}{35} = \frac{6}{35}$: indicating the combining of the numerators of the like or similar fractions that have the same denominators

$\frac{+2X}{35} = \frac{6}{35}$ now rid X of its' dividing coefficient factor of (35), and multiplying coefficient factor of (2): This can also be done in a single step by multiplying both sides by the reciprocal of 2/35 which is 35/2.

$\frac{\overset{+1}{\cancel{(35)}}+2X}{(1)\ \underset{+1}{\cancel{35}}} = \frac{6\ \overset{+1}{\cancel{(35)}}}{\underset{+1}{\cancel{35}}(1)}$: cancel fractions (rid denominators)

$2X = 6$ Isolate X, rid X of its multiplying factor of 2, by dividing by that value of 2:

$\frac{\overset{+1}{\cancel{2}}X}{\underset{+1}{\cancel{2}}} = \frac{\overset{+3}{\cancel{6}}}{\underset{+1}{\cancel{2}}}$: cancel

$X = +3$

The method below uses the CDC method. Here, the fractions are to be eliminated or canceled first rather than combining them. To eliminate the fractions on one side of the equation, multiply both sides of the equation by a common denominator (LCD preferred) of that side of the equation. To eliminate all fractions of the entire equation at once, then multiply both sides by the LCD of all the fractions.

$\frac{X}{5} - \frac{X}{7} = \frac{6}{35}$ multiplying both sides by 35:

$\frac{35}{1}\left(\frac{X}{5} - \frac{X}{7}\right) = \frac{6}{\underset{+1}{\cancel{35}}}\frac{\overset{+1}{\cancel{(35)}}}{(1)}$: cancel on the right side, now distribute on the left side:

$\frac{+35X}{5} - \frac{35X}{7} = \frac{6}{1}$ cancel on the left side:

$\frac{+\overset{+7}{\cancel{35}}X}{\underset{+1}{\cancel{5}}} - \frac{\overset{-5}{\cancel{35}}X}{\underset{+1}{\cancel{7}}} = \frac{6}{1}$: cancel

$+7X - 5X = 6$ combine, add the like terms numerical coefficients or factors:

$+2X = 6$ isolate X, divide both sides by 2:

$\frac{+\overset{+1}{\cancel{2}}X}{\underset{+1}{\cancel{+2}}} = \frac{\overset{+3}{\cancel{+6}}}{\underset{+1}{\cancel{+2}}}$: cancel

$X = +3$, Checking using substitution:

$\frac{X}{5} - \frac{X}{7} = \frac{3}{5} - \frac{3}{7} = 0.6 - 0.428\underline{6} = 0.1714\underline{3} = \frac{6}{35}$: checks

Ex. The formula relating Fahrenheit (F) and Celsius (C) temperature is given below. Solve for variable F. If water normally boils at 212° Fahrenheit, then at what corresponding Celsius temperature does it boil?

$C° = \frac{5}{9}(F° - 32°)$ after multiplying both sides by 9 and canceling:

$9C° = 5(F - 32°)$ dividing each side by 5 and canceling:

$\frac{9C°}{5} = F° - 32°$ after transposing (-32) by adding the negative of (-32) = -(-32) = (+32) to each side, and afterwards, switching sides:

$F° = \frac{9C°}{5} + 32°$ or $F° = 1.8C° + 32°$

Notice that for every degree change in Celsius temperature that the corresponding Fahrenheit temperature changes not by 1 degree, but by 1.8 (almost 2) degrees. As to the boiling point of water:

$C° = \frac{5}{9}(212° - 32°)$

$C° = 5\frac{(180°)}{9} = 5(20°) = 100°$: Celsius temperature scale, boiling point of water. (At 0° C = 32° F , water freezes)

Ex. Show that $\left(1 + \frac{1}{x}\right)$ = one plus the reciprocal of x, is equivalent to: $\left(\frac{x+1}{x}\right)$ or = $\frac{(1+x)}{x}$

$\frac{x+1}{x} = \frac{x}{x} + \frac{1}{x} = 1 + \frac{1}{x}$: after putting each term in the numerator over the common denominator. You can also show they are equal by combining fractions in the first expression given for this example.

Ex. If x = 2: $1 + \frac{1}{2} = 1 + 0.5 = 1.5$ and:

$\frac{2+1}{2} = \frac{3}{2} = 1.5$

Ex. If x = 100: $1 + \frac{1}{100} = 1 + 0.01 = 1.01$ and:

$\frac{100+1}{100} = \frac{101}{100} = 1.01$

Ex. If: $a = b + c$ this can be mathematically expressed as:

$a = b + c$ dividing each side by a:

$\frac{a}{a} = \frac{b + c}{a}$ which can be expressed as:

$\frac{a}{a} = \frac{b}{a} + \frac{c}{a}$

$1 = \frac{b}{a} + \frac{c}{a}$ we see that (b) and (c) essentially represent a fraction or percent of (a):

$1 = 100\% = \left(\frac{b}{a}\right)\left(\frac{100}{1}\right)\% + \left(\frac{c}{a}\right)\left(\frac{100}{1}\right)\%$

Ex. $5 = 3 + 2$

$1 = \frac{3}{5} + \frac{2}{5} = 0.6 + 0.4 = 60\%$ of 5 + 40% of 5 = 100% of 5
: 3 and 2 are expressed as relative values with respect to the sum = 100%=1

When the variable being solved for is part of a radicand, rationalize the radical by raising it, and also the other side of the equation (to keep their balance and equivalence), to an indicated power equal to the index (indicated root of the radicand), and then convert the radical expression to its equivalent exponential form for easy simplification.

Ex. $2\sqrt{+X+5} = 7$ first, squaring both sides of the equation:

$(2\sqrt{+X+5})^2 = (7)^2$ placing the radical form into exponential form:

$((+X+5)^{(1/2)})^2 = +49$ power to a power, distribute the power:

$(+X+5)^{(2/2)} = (+X+5)^1 = +49$

$(+X+5) = +X+5 = +49$ T. +5:

$+X +5 -5 = +49 -5$ combine terms:

$X = +44$

Be sure to check this result in the original equation since raising values to powers, though algebraically correct, can possibly introduce some extraneous (extra, and usually undesired) results. As a simple verification, consider this:

$10 - Z = 0$ after solving for Z we find:
$Z = +10$

If both sides are squared, the solution of Z should still be the same since the equation is still in balance:

$Z^2 = 10^2$ or:
$Z^2 = 100$ Solving for Z by taking the square root of both sides, we now find:
$Z = \pm 10$: the solution of (-10) will not satisfy the original equation, and it is therefore an extraneous root.

Below is an example where understanding a problem can be more difficult than mathematically solving it, and the problem was not even intentionally written to be difficult.

50 workers belong to a machine shop. Some of them can make nuts, and some can make bolts. Some workers are known to be able to make both. If 35 workers said they can make nuts, and 40 workers said they can make bolts, how many workers make both nuts and bolts? A **bolt** is much like a (machine, metal) screw (essentially a rod (ie., long cylinder shaped) with a spiral of thin metal "threads" along its outer length) of which a **nut** with matching threads on the inside surface of its cylinder ring shape can be twisted upon so as tighten and create a clamping force upon the surface(s) between the larger head structure of the bolt and the nut.

The total sum of nut makers (N), and bolt makers (B), where some of these people can make both:

Total = N + B
75 = 35 + 40 : total "virtual" number of makers or "jobs" possible, where only 50 are actual people and makers

However, for each given day only 50 real or actual workers out of this total of 75 (nut or bolt makers, which include dual (both) makers) work at the machine shop making either nuts or bolts, but not both. That is, regardless of the actual number of workers who are making nuts or bolts that day, this sum is always 50 workers. Subtracting this value of 50 will leave the number of people who can make both nuts and bolts.

75 = N + B + workers who can make both nuts and bolts
75 - (N + B) = workers who can make both nuts and bolts
75 - 50 = virtual workers - actual workers = both
both = 25 workers

Even though the problem was solved using a simple equation, it may need some clarification. First, consider the possibility that none of the workers can make both nuts and bolts, then the total "possibilities", "jobs" or "positions" (nut makers or bolt makers) is always 50 (instead for example of the 75 shown above), and cannot be any less since there is always the same 50 workers at the machine shop. Now, if any workers do both, the total "possibilities" will then exceed 50, and this excess above 50 can only be those who do both. The subtraction shown will find this excess or people who can make both nuts and bolts. Note also that if every one of the 50 workers can make both nuts and bolts, that the maximum "positions" or "possibilities" is: 50 people can make nuts, and 50 people can make bolts = 100 people can make both.

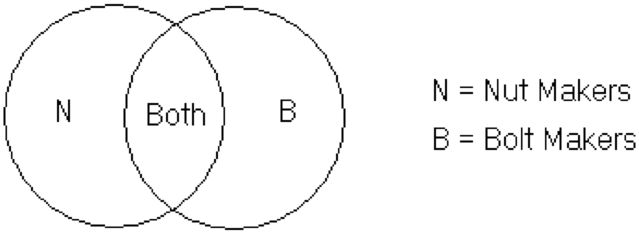
As a simple verification of the results of this problem, consider just 2 workers belonging to the machine shop, and each will either make nuts or make bolts during their work at the machine shop, that is, both workers are known to be a nut maker and a bolt maker. How many workers are both nut makers and bolt makers?

Total = N + B
4 = 2 + 2 : total possible or virtual "positions"

Since only 2 people are at the machine shop:

Both = Total - 2 : 2 workers at the machine shop
Both = 4 - 2
Both = 2 : 2 workers can do both (make nuts or bolts)

Though not discussed much further in this book, problems like the above can be represented and analyzed graphically with the aid of what are known as Euler (Leonhard Euler) or Venn (John Venn) diagrams. These diagrams represent sets (similar things) by using simple geometric figures, and their relationships and relative values are seen by observation and-or by using a special mathematical notation for sets. A simple Venn diagram of the above example might look like this: [FIG 23]



N
Both
B
N = Nut Makers
B = Bolt Makers

GRAPHING AN EQUATION TO VIEW AND SOLVE IT

Sometimes an equation cannot be solved easily using normal algebra. By graphing the equation you can get a close estimate of the solution. A graph of the relationship of variables is also very powerful and a useful visual tool for quickly understanding the numerical values and relationship between two variables over a wide range of possible values. For example, to view if one variable is increasing or decreasing and-or at what rate (ie. "how fast") as the other variable changes (increases or decreases) in value. Once an equation is graphed by making many calculations with it and plotting the results or points, it also then effectively becomes an automatic visual calculator or computer that can quickly solve for a corresponding value of either the independent or and-or dependent variable. It is even possible to make a mechanical computer with the curve drawn, and such as using the intersection of two movable or user adjustable lines, one vertical (for the x or independent value) and one horizontal (for the y or dependent value).

Solve for (x) in : $2x + 4 = -2$

Though algebra can be used to easily solve this equation for x, it will be only used to check or validate this demonstration of using a graph to solve an equation. To solve this equation, you are to find what value of (x) will make the left side equal to the right side of -2.

By transposing (-2), the equation can be algebraically expressed as:

$2x + 4 + 2 = -2 + 2$
$2x + 6 = 0$: x can be mathematically solved here, but also we want to solve this equation graphically Expressed this way, we can see that there is a certain or specific value of x that will make the expression on the left side equal to 0.

Here, we are to find the value of (x) that will make the left side equal to the right side of 0, still, the value of (x) that solves this equation will also solve the original equation since the new "derived" equation was derived (ie., created directly from) from the original equation. It is simply another mathematical expression of that original equation. This can easily be verified after solving for (x) mathematically. When the equation is expressed this way (set equal to 0), the value of (x) that satisfies or solves this equation is called the "root" of the equation, although don't confuse this concept with that of radicals.

Since the equation given is a linear (has a line-like graphing, of the proportional mathematical variable relationship) or "first-order" equation (where the exponent of the variable is only one = first = 1st), there will only be one root or solution. In general, if the power of the variable is 1, it is a linear equation. Linear equations always graphically plotted (ie. scribed, indicated , graphically expressed locations (ie., address) of corresponding variable values) as marks or points of a straight line.

To plot or graph an equation, there must be a mathematical relationship between two variables. In this discussion, the relationship is a mathematically proportional or linear ("one to one" or "balanced") type of relationship. As one "independent" variable changes in value by some factor (ie. a multiplier applied to the variable), then the other "dependent" variable will then change at the same constant rate since its value is essentially multiplied by that same constant factor value. Consider:

$y = 1x$: this is the same as: $y = x$, and this will actually graph as a horizontal line as long as the multiplying factor or coefficient to x is 1, but if it changes to another value, then it will no longer be horizontal, but will have a vertical part, either upward if the coefficient is positive, or downward if the coefficient is negative. The greater this multiplier, the "steeper" the line, because the rate of change of the y values with respect to the x values is mathematically more such as for : $y = 5x$

We can also set the entire equation, or its equivalent result, as equal to another variable such as (y) for plotting purposes. Rather than just expressing a mathematical relationship between (x) and the result or numeric "output" of the expression, and we will now have a mathematical relationship between two expressed variables such as (x) and (y). (x) can be thought of as the input or "independent" variable, and (y) can be thought of as the output or "dependent" (dependent or depending upon the value of x) variable.

$2x + 6 = 0 = y$ or by switching sides:
$y = 2x + 6$

By setting the equation equal to 0, the root or solution will actually be where the graphical line (considered as a special instance of a curve, or curve plot on a graph) of the equation crosses the (x) or horizontal axis which is where the (y) value, of that corresponding point or part of the curve, is always 0. When finding corresponding values of (y) and (x), that is, finding the coordinates (corresponding values which define a points location) of each point on the line, it is best to find points both above and below the (x) or horizontal axis so that a smooth line (or curve) can be drawn (by hand, with the aid of a straight-edge drawing guide or a ruler) through or across the axis when using the points as a drawing guide. To draw a line, at least two points on it must be known, and a third or more points gives some verification that the two other points and line is accurate. You could begin by selecting random-like values for (x), and then mathematically finding (solving for, using the equation) each corresponding (y) value:

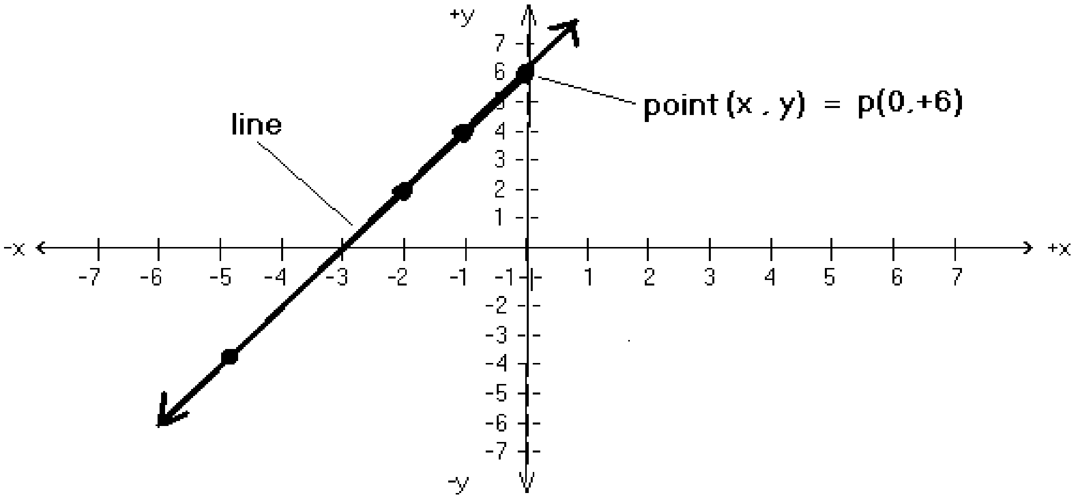
Make a list of several corresponding values of the (x) and (y) variables to be graphed or expressed visually as the (coordinate, or coordinated) location of points on a (flat) plane or rectangular (square-like) coordinate (location) system. These points are identified by that corresponding pair of values for the variables such as: (x , y). The coordinates (corresponding locations) are fundamentally in reference to an arbitrary point chosen as the starting or reference point, usually identified with coordinates (x=0,y=0), and which is sometimes called the "axis center point" of the coordinate system. The horizontal and vertical dimensions are called the axis (lines) of the system, and these are numerically scaled for values and measurements of each variable.

x	y = 2x+6
0	+6
-1	+4
- 2	+2
-5	-4

: each pair of corresponding values of the variables can be represented graphically as a point whose location, address or coordinates is identified as point(x,y) = p(x,y)

Plotting the points:

[FIG 24]



The solution (visually, and by the chart or list of the corresponding values of the variables) appears to be about: $x = -3$. Let's check by substituting this value into the original equation:

$2x + 4 = -2$
$2(-3) + 4 = -2$ distributing:
$-6 + 4 = -2$ combining;
$-2 = -2$: checks

The point where the line crosses the x-axis is called the x-axis intercept. Here, the corresponding value of y is always 0. If not already done, solve the equation for y, and then set this equation and y equal to 0. This is important since it will create a completely solvable equation with only one variable in it.

$y = 0 = 2x + 6$: setting y equal to zero, to find the corresponding value of x. Solving for x we have:

$x = \frac{-6}{2} = -3$: after transposing +6, and dividing both sides by 2
The x-intercept, or x-axis intercept, point is: P(x,y) = P(-3,0)

Likewise, given $y = 2x + 6$, we can solve for variable x and set its value equal to 0. Then we can solve for y since there will be only one variable in this equation since variable x will be essentially eliminated (by using a constant or numeric value for it, such as 0). y is then solvable, or is said as being "completely solvable" since it will have a numeric value:

$x = \frac{y - 6}{2}$ setting x=0 for the purpose of finding its corresponding y value:

$0 = \frac{y - 6}{2}$ when x=0, solving for y so as to find the corresponding y value of that point:

$y = 2(0) + 6$

$y = 0 + 6 = +6$: The y-intercept point is: P(x,y) = P(0,+6) as seen in the graph above.
The intercept points also can be used to draw the line, and-or to verify if a previously plotted and graphed (drawn) points or line is correct. Any more points should also be plotted on that same existing line.

SOLVING EQUATIONS CONTAINING MULTIPLE VARIABLES

If an equation contains multiple variables, a specific variable and its value can still be solved for if all the other variables can be placed on the other side of an equation and be expressed "in terms" of the given variable . This is known as algebraic substitution (as opposed to substituting actual numeric values for numeric substitution). The overall method is to produce a new equation which will have only one unknown or variable of which it will then be solvable.

Ex. In a certain animal sanctuary, there is a total of 60 animals consisting of cats and dogs. There are twice as many cats as dogs. How many cats, and how many dogs are there?

We see that we have a problem with one known value: 60 animals, and two unknown values: the number of cats and the number of dogs. From the given statement, creating a simple algebraic equation:

60 animals = number of cats + number of dogs

Let's let variable D represent the number of dogs, and variable C represent the number of cats.

Notice that the number of cats was stated in terms of the number of dogs. For each (1) dog, there are two (2) cats. There are twice as many cats as dogs.

First, it is incorrect to state or express this situation mathematically as: 1 dog = 2 cats or $1D = 2C$ or $1D/2C$ ("one dog per two cats") as a ratio. If used that way, dog, D, and cats, C, are being incorrectly used as units of measurement, rather than as variables or numeric values that can change in value. Saying, that there is one dog per two cats is normally acceptable, but if you actually express or divide the values: $1D/2C = 0.5(D/C)$, hence the units would be (D/C), and again, D and C are to be variable here, rather than units. It would be better to express the ratio as: 1 dog/2 cats.

The actual number of cats: (C) equals the number of dogs times two, hence the number of cats depends on the number (D) of dogs, well mathematically anyway:

$C = 2D$: C depends on D, and C can be called a dependent variable whose value depends (is mathematically related to, depends upon, and is determined by) on the value of an independent variable, here D.

$C = 2D$ can also be expressed as: $D = C/2$

$60 = C + D$ since $C = (2D)$, and using algebraic substitution for C:
$60 = 2D + D$: hence, now a solvable equation (because it has just one unknown value, here variable D)
$60 = 3D$ isolating D by dividing each side by 3 :
$D = 20$: number of dogs

$C = 2D$: original equation
$C = 2(20)$: using (numeric) substitution for the value of D
$C = 40$: number of cats

OR:

$60 = C + D$ after solving for C:
$C = 60 - D$
$C = 60 - 20$
$C = 40$: number of cats.

If you used algebraic substitution for $D = C/2$, you would also arrive at this value:

$60 = C + (C/2) = 40 + (40/2) = 40 + 20 = 60$

Ex. A box contains 75 coins consisting of pennies and nickels with a total sum of $1.75. There are twice as many pennies as nickels, how many pennies and how many nickels are there?

Let P = value of a penny = (0.01)
Let N = value of a nickel = (0.05)

Let X = number of pennies
Let Y = number of nickels
Total coins = X + Y = 75

Total monetary sum due to pennies + total monetary sum due to nickels = 1.75

$X(P) + Y(N) = 1.75$ substitution the monetary values:

$X(0.01) + Y(0.05) = 1.75$

Since there are twice as many pennies as nickels, Y must be multiplied by 2 to equal X: $X = 2Y$

Now, X can be algebraically substituted or replaced by 2Y, therefore producing a solvable equation which has only one unknown (variable):

$2Y(P) + Y(N) = 1.75$
$2Y(0.01) + Y(0.05) = 1.75$ distribute:
$0.02Y + 0.05Y = 1.75$ combine like terms (add their numerical coefficients):
$0.07Y = 1.75$ isolate Y:

$$Y = \frac{1.75}{0.07} = 25$$: there are 25 nickels

Since $X + Y = 75$
$X + 25 = 75$
$X = 75 - 25$
$X = 50$: there are 50 pennies

Or: $X = 2Y = 2(25) = 50$: as noted above

Checking, using the original equation:

$X(0.01) + Y(0.05) = 1.75$
$50(0.01) + 25(0.05) = 1.75$
$0.50 + 1.25 = 1.75$
$1.75 = 1.75$: checks

Here is another way, perhaps a simpler way of solving this problem, and which uses only the number of coins involved, and it's very similar to the previous example:

We were given:

$X + Y = 75$ and as stated in the original problem:
$X = 2Y$ by algebraic substitution:
$2Y + Y = 75$ combining like terms:
$3Y = 75$ solving for y, isolate it by dividing both sides by 3:

$Y = \frac{75}{3} = 25$: number of nickels

$X = 2Y = 2(25) = 50$: number of pennies

Check: $X + Y = 75$
$50 + 25 = 75$
$75 = 75$: checks

SIMULTANEOUS EQUATIONS

One method to solve multiple variable equations that are all related to a particular situation or instance is referred to as the "addition and subtraction" method. The basic requirement is to have N equations for N unknowns (variables). These initial equations must be independent of one another, that is, none can be algebraically derived or created from another because that would essentially be expressing the same equation as just another way.

Things that happen together or function together, and sometimes at the same exact time or "instantaneously together", are called simultaneous and their (numerical) relationship is that they behave and change simultaneously or together, and may be dependent on the values of each other. A set or group of related multiple variable equations is often called "simultaneous equations" when the solution for each variable is also simultaneous (ie. the same) for all of the given equations. After solving any equation in a set of simultaneous equations for a particular variable(s), its value will satisfy all the other equations..

Here is a system of simultaneous equations that has only one unknown (variable):

Equation 1: 5 + N = 8 : N is a placeholder (ie. a variable) for some unknown value yet to be found
Equation 2: (7.9)(N) = 23.7
Equation 3: 3N + 2 = 11
Equation 4: N^2 - 2 = 7

Find the value of N. Since the system of equations shown contains only 1 variable, solving for the value of the variable can be done using just one equation, and with or without the assistance of any of the other equations. This will also solve all the equations of the system of equations shown.

5 + N = 8 T. (5), add the negative of it to each side = -(+5) = -5
5 + N - 5 = 8 - 5 combining:
N = 3

Checking using equation 4:

N^2 - 2 = 7
3^2 - 2 = 7
9 - 2 = 7
7 = 7 : checks

Before a multi-variable example is shown, some verification or practical proof of the "addition and subtraction" process often used comes from the basic fact that adding, subtracting, multiplying, or dividing both sides of an equation by the same value still keeps the equation in balance or "true". For instance, given these two equations:

Eq. 1: (3+2) = 5 and Eq. 2: (4+6) = 10 Adding 10 to each side of the first equation:

$(3+2) + 10 = 5 + 10$ but since $(4+6) = 10$, and substituting this expression for it:

$(3+2) + (4+6) = 5 + 10$: which is effectively the same as adding both corresponding sides of the original equations (Eq. 1, and Eq. 2) horizontally. Simplifying:

$5 + 10 = 5 + 10$
$15 = 15$: checks

But now take note:

$(3+2) + (4+6) = 5 + 10$ clearing grouping symbols:
$3 + 2 + 4 + 6 = 15$ since addition is associative, we can regroup some other terms:
$(3+4) + (2+6) = 15$
$7 + 8 = 15$ showing this vertically, we can visualize adding both sides or the entire equations together:

$$\begin{array}{rcl} (3+2) & = & 5 \\ +\underline{(4+6)} & = & +\underline{10} \\ 7+8 & = & 15 \end{array}$$

here, the left sides were combined, and then the right sides were combined:

: $15 = 15$ checks

Perhaps an expressed pseudo-algebraic (algebraic-like) verification can also help explain this concept:

left side eq. 1 = right side eq. 1 : eq. = equation
left side eq. 2 = right side eq. 2

Taking the first equation, and then adding anything to both sides of it, even if its the left side of the second equation, still keeps the equation in balance:

left side eq. 1 + left side eq. 2 = right side eq. 1 + left side eq. 2

However, since: left side eq. 2 = right side eq. 2, and then substituting this into the above equation:

left side eq. 1 + left side eq. 2 = right side eq. 1 + right side eq. 2 : horizontally adding the equations
sum = sum

Showing this vertically:

$$\begin{array}{rcccl} & \text{left side eq. 1} & & & \text{right side eq. 1} \\ + & \underline{\text{left side eq. 2}} & & + & \underline{\text{right side eq. 2}} \\ & \text{sum} & = & & \text{sum} \end{array}$$

: vertically adding the two equations

Ex. You purchased some fruit at a grocery store on several occasions, but have forgotten the price for each piece of fruit. You have receipts of your purchases showing the amount and type of fruit purchased, and the total purchase price:

6 apples + 8 pears = \$ 1.10 : a receipt (of a purchase, receiving and payment record) total from one purchase
3 apples + 2 pears = \$ 0.35 : a receipt total from another purchase several days later

How much is an apple? How much is a pear? (also assuming their prices did not fluctuate (change) between the two purchases shown, and perhaps since then).

Let A = cost of each apple
Let P = cost of each pear

Optionally considering each value with units of cents, rather than dollars. Therefore:

Eq. 1: $6A + 8P = 110$ cents
Eq. 2: $3A + 2P = 35$ cents

Before the addition (or subtraction) of these two equations, you must first multiply (or divide) either or both equations by some value so that when they are either added or subtracted that one variable will essentially be eliminated from the new equation formed, hence producing a solvable equation which has only one variable or unknown value. Whenever you multiply or divide both sides of equations by the same value, this actually creates a (derived) "equivalent equation" in the sense that the solution will be equivalent or the same for both. Related equations where the solution is the same for both are also called simultaneous equations as mentioned previously.

Ex. Eq. 1: $2x + 3 = 7$ multiplying both sides by 2 :
$2(2x + 3) = (2)(7)$ we have created an equivalent equation of:

Eq. 2: $4x + 6 = 14$

For both Eq. 1 and Eq. 2 directly above, the solution is the same value of $x=2$.

Extra: If you were to graph (plot or place, and draw) these two (line or linear) equations (as discussed previously, and ahead in this book), they would intersect (cross, meet, join) at a single point. Since the second equation was created from the first, the solution here is actually a point on the "x" (horizontal or independent variable) axis, and which is also the "x" axis intercept (where $y=0$) for both lines. Algebraically re-arranging the equations for plotting:

From eq. 1, we get: $2x - 4 = 0 = y$: let $y = 0$ (and the eq.), and then plot this relationship.
From eq. 2, we get: $4x - 8 = 0 = y$: let $y = 0$ (and the eq.), and then plot this relationship.

Note however, that if an expression, not an equation, such as these is added by a value, that the new expression will yield a line that is parallel to the original line expression. The reason that it will be parallel is that this added in constant value will essentially shift the line (or curve) vertically (up and down) in reference or respect to the original line. The vertical steepness (or "slope") will still be the same for both lines. Consider:

Ex. $2x + 3$ after adding 5:
$2x + 8$

Setting both expressions equal to (y) for plotting:

Eq. 1: $y = 2x + 3$
Eq. 2: $y = 2x + 8$

Since parallel lines do not intersect at some point, there is no (simultaneous) solution to this system of equations.

Continuing the original example and equations:

Multiplying the second equation by 2 since $6A/3A = 2$, or simply $6/3 = 2$ after canceling A in the num. and den.

Eq. 2: $2(3A + 2P) = 35(2)$ distribute:
New Eq. 2: $6A + 4P = 70$

$6A + 8P = 110$ Eq. 1

$\underline{-(6A + 4P = 70)}$ New Eq. 2. Subtracting (or adding the negative of each term) the equations:
$0A + 4P = 40$: The result is one equation with one unknown (here P) which can be solved for.
Or by first distributing the (-1) to both sides to clear grouping symbols, and then combining terms (instead of actual subtracting) we would have this for the new Eq. 2:
$\underline{-6A - 4P = -70}$ Now combining (adding) instead of subtracting:
$0A + 4P = 40$ Variable A was effectively eliminated, and we now have an equation that has only one variable, and we can solve for the value of that variable.

$4P = 40$ isolating P, by dividing both sides by its multiplying factor of 4, we have:

$P = \frac{40}{4} = 10$: The price of each pear is 10 cents.

By substituting the value of P into any of the original equations, you can solve for A.

$6A + 8P = 110$
$6A + 8(10) = 110$
$6A + 80 = 110$ transpose the non-A terms:
$6A + 80 - 80 = 110 - 80$ combining:
$6A = 30$

$A = \frac{30}{6} = 5$: The price of each apple is 5 cents.

Checking these results in an original equation, by using substitution:

$3A + 2P = 35$
$3(5) + 2(10) = 35$
$15 + 20 = 35$
$35 = 35$: checks

Another possible method to solve simultaneous equations is by equating similar variables. That is, at the solution to the set of equations, each particular variable in question will have the same solution or value, and the expressions for them can therefore be equated. It can also be said that the difference between similar variables is 0 at the solution. For example:

Eq. 1: $a + 2b = c1$: here, identifier (c) is some constant numeric value, and not a variable value
Eq. 2: $3a + b = c2$

We could have also used subscripts (to identify two or more different instances and their values) for variables (a) and (b), but at the solution, both values of (a) are identical, and both values of (b) are identical. Therefore, for now, we can identify both as just (a) and (b) rather than for example (a_1) and (a_2).

From Eq. 1: $a = c1 - 2b$: variable (a) in terms of variable (b)

From Eq. 2: $a = \frac{c2 - b}{3}$: variable (a) in terms of variable (b)

At the solution: $a = a$: or $a - a = 0$

Therefore: $c1 - 2b = \frac{c2 - b}{3}$ transposing the right hand side:
(Could also begin to solve for (b) by multiplying
both sides by 3, and then canceling.)

Or: $c1 - 2b - \left(\frac{c2 - b}{3}\right) = 0$ with some distribution:

$c1 - 2b + \frac{-c2 + b}{3} = 0$ combining fractions on the left hand side:

$\frac{3c1 - 6b - c2 + b}{3} = 0$ multiplying each side by 3 and canceling:

$3c1 - 6b - c2 + b = 0$ combining like terms:

$3c1 - c2 - 5b = 0$ transposing (-5b), and then dividing each side by 5, and switching sides:

$b = \frac{3c1 - c2}{5}$:since c is a constant and there are no other variables in
the expression, the numeric value of (b) is solved for

In a similar manner to the above process, variable (a) could have been found. Since (b) is now known, (a) can be found by substituting this value of (b) into one of the original equations and then solving for (a).

There are a few other methods to solve a system of equations besides the last two methods shown. For example, there is the "graphical method" discussed previously where the solution is the point of intersection (crossing) of the graph (plotting, drawing) of the equations. However, the result is usually only a good approximation since it's a non-algebraic (ie. non-exact) method that does not produce a specific or exact numeric result. Still, don't underestimate graphs since for instance they have the power to quickly show the relationships of variables over a wide range of possible values and can be used for quick estimates.

Problems involving percentages might seem to be awkward at first, but if you can write some simple equations, the problem usually resolves to one of basic algebra.

Ex. If 5% of N is 30, what is 15% of N ?

Writing equations with the information given:

1) $N(0.05) = 30$: note that the percentage rate is expressed here in (strict numeric) decimal form for the equations
2) $N(0.15) = X$

By algebraically solving for N in the first equation, we can algebraically substitute its equivalent value into the second equation that has two unknown values, and therefore make that equation solvable with only one unknown value:

From the first equation: $N = \frac{30}{0.05} = 600$ substituting this value for N into the second equation:

$N(0.15) = X$
$600(0.15) = 90$: hence $X = 90$ and 15% of 600 is 90

An alternate approach to finding X is to use the concepts of (equal or similar) proportions, and which will be discussed shortly ahead, but that method can simply be thought of as an equivalent fractions concept where if one value is magnified (basically by a multiplying factor, greater or less than one [ie. technically, demagnified]), all the other corresponding values (between the two systems or magnifications) will have the same (ie. equal or similar) value of magnification.

A basic example of proportions could be if you were using a basic recipe where half (50%) of something (ex. weight, mass, volume, some other ingredient, cake, batch) is water. If you were to make more or less of that entire recipe, still, half (50%) of that something (whatever size it is) should still be water. It will be more or less (as for this example, less water) than used in the original recipe, but it is still half of that something. It could be said that the proportions, relative amount (here, with respect to the previous instance), fractional part value(s), or even corresponding ratio values among its other ingredients, are still the same value.

Given the original equations above, here is where the proportions type of equation shown below comes from:

$N(0.05) = 30$ and $N(0.15) = X$ Solving for N in both equations:

$N = \frac{30}{0.05}$ $N = \frac{X}{0.15}$ Equating the two expressions for N, we have a "proportions" type of equation, or "equivalent (in value) portions":

$\frac{30}{0.05} = \frac{X}{0.15}$: can be read as: "If 30 is 5%, then X is15%"
or: "30 is to 5%, as X is to 15%", or: "30 is to 0.05 as X is to 0.15",
or: "5% of some value corresponds to 30, as 15% of that value will correspond to X",
or : "5% is to 30, as is 15% is to X". (etc)

Clearly, if you increase the percentage, or fraction of something, you should have more of it, so X should be greater than 30.

You can also invert the fractions since their new (reciprocal) values will still be identical:

$\frac{0.05}{30} = \frac{0.15}{X}$ as mentioned above, for example: "5% is to 30, as is 15% is to X"

First, solving by using the equivalent fraction concepts:

since: $\frac{0.15}{0.05} = 3$, multiplying both the numerator and denominator by this value to create the equivalent fraction:

$$\frac{30(3)}{0.05(3)} = \frac{X}{0.15}$$

Note above that (3/3)=1, and that multiplying any side of an equation by 1 will not unbalance the equation.

$\frac{30}{0.05} = \frac{90}{0.15} = \frac{X}{0.15}$ hence, by simple observation:

$$X = 90$$

Now using the concepts of proportions, and of which are expressed as equations and usually solved as such:

$\frac{30}{0.05} = \frac{X}{0.15}$ after multiplying both sides by 0.15 and canceling :

$$X = \frac{30(0.15)}{0.05} = 30(3) = 90$$

N can also be found using a proportion type of equation.

Since 100% = 1.0 = 1

$$\frac{90}{0.15} = \frac{N}{1} \quad \text{or} \quad \frac{30}{0.05} = \frac{N}{1}$$

$N = 600$

Ex. In a bag, there are some marbles. Of the total number of marbles, 25% (of the total) are red, 10% are white, and exactly 13 are blue. What is the total number of marbles?

Notice that the number of red and blue marbles was not given, however their values were indirectly stated in terms of the total number of marbles, and more specifically, a portion or percentage of the total number of marbles.

Let us represent the total number of marbles with the letter or variable M, then we have:

Total Marbles = red marbles + white marbles + blue marbles or:
$M = \text{red} + \text{white} + \text{blue}$
$M = (25\% \text{ of } M) + (10\% \text{ of } M) + 13$ which can be expressed as:
$M = 25\%M + 10\%M + 13$ expressing the percentages as their decimal number equivalent:
$M = 0.25M + 0.10M + 13$ combining like terms on the right side:
$1M = 0.35M + 13$ transposing +0.35M, add the negative of this term to each side:
$1M - 0.35M = 0.35M + 13 - 0.35M$ combining like terms:
$0.65M = 13$ after dividing both sides by 0.65 we have:
$M = 20$:a total of 20 marbles in the bag

Note that the total percentage of red and white marbles in the bag is: 25% + 10% = 35%. The percentage of blue marbles in the bag is therefore the remaining (of 1.0 = 100%) percentage of the marbles left:

100% - 35% = 65% of all the marbles are blue. : or $1.0 - 0.35 = 0.65$

checking: (Total Marbles)(0.65) = (20)(0.65) = 13

$$\frac{\text{blue marbles}}{\text{Total marbles}} = \frac{13}{20} = 0.65$$ and the problem could have been solved using:

$$\frac{13}{M} = 0.65$$ solving for M:

$$M = \frac{13}{0.65} = 20$$: total marbles

The number of red marbles is therefore: 25% of 20 = (0.25)(20) = 5
The number of white marbles is therefore: 10% of 20 = (0.10)(20) = 2
red marbles + white marbles + blue marbles = 5 + 2 + 13 = 20 marbles

Ex. The sum of two numbers is 198, and their difference is 48, what are the two numbers?

equation 1: $a + b = 198$
equation 2: $a - b = 48$

From equation 2, we find: $a = 48 + b$, [or: $b = a-48$] , and using substitution of this into the first equation:

$(48 + b) + b = 198$ combining like terms:

$48 + 2b = 198$ after transposing 48:
$2b = 198 - 48$ after combining:
$2b = 150$ after dividing each side b 2:
$b = 75$

$a + b = 198 = a + 75 = 198$, after transposing 75, $a = 123$. and $a + b = 123 + 75 = 198$: checks

The solution for one variable was made by placing it in terms of the other variable, so as to have a solvable equation. As an extra note, there are many two number pairs that can sum to 198, and many two number pairs that have a difference of 48, but only one pair does both, and for this example , that pair is only 123 and 75.

ALGEBRAICALLY VERIFYING THE LOG RULES

Below are algebraic verifications of the fundamental log rules.

Given: N1 = b^x and N2 = b^y : power equations, therefore:

N1 N2 = b^x b^y = b^(x+y) by the log definition:

$\log_b (N1\ N2) = x + y$ the equivalent expressions for x and y are:

From N1 = b^x, we have by the log definition: $x = \log_b N1$.

From N2 = b^y, we have by the log definition: $y = \log_b N2$.

Using substitution in:

$\log_b (N1\ N2) = x + y$

$\log_b (N1\ N2) = \log_b N1 + \log_b N2$: LOG PRODUCT RULE

Ex. Given log (X + Y) , factor it to where the log product rule can be used:

Factoring out X from each term of the given binomial, we now have two factors:

$\log (X (1 + Y/X)) = \log X + \log (1 + Y/X)$:

Letting N = N1, and given: $\log N + \log N + \log N$

Since repeated addition of any value can be represented using multiplication of that value, we have:

$1 \log N + 1 \log N + 1 \log N = (1+1+1)\log N = 3 \log N$

By treating (log N) like a variable and adding the numerical coefficients of each of the like variables, we can let a variable (such as x shown below) represent this sum of numerical coefficients (c) of (log N). Unlike for repeated addition as shown above, the numerical coefficient(s) need not be 1. Expressing this as an algebraic equation, we have:

$x \log N = (c_1 + c_2 + c_3 + \ldots) \log N = c_1 \log N + c_2 \log N + c_3 \log N + \ldots$

Note, you can also consider this as factoring (log N) from each of the terms, leaving a sum of the numerical coefficients.

Ex. $x \log N = \log N + \log N + 0.3 \log N = (1 + 1 + 0.3) \log N = 2.3 \log N$: x = 2.3

Now, the concept of the log product rule will be used on the following equation:

$x \log N = \log N + \log N + \log N + \ldots$

Using the log product rule in reverse (ie. a "log factor [of a product] rule") on the right hand side:

x log N = log (NNN . . .) : x equals the (integer) power of N
x log N = log N^x : (form of) LOG POWER (OR EXPONENT) RULE

The equation above almost verifies the log power rule, but since all the coefficients of log N were (1), (x) is always an integer and not a real (possible integer plus a possible fractional value) value. Here is a derivation when (x) can be any (ie. real) value:

Eq. 1: N = b^a raising each side to the x power:
N^x = (b^a)x using the power to a power rule, this can be expressed as:
Eq. 2: N^x = b^(xa)

Using the log definition on the two equations above:

$\log_b N = a$ and:

$\log_b$ N^x = xa substituting the above expression for (a):

$\log_b$ N^x = x $\log_b N$: LOG POWER (OR EXPONENT) RULE

Now, the log quotient rule will be algebraically verified, and it also uses the exponent rules for dividing like variables:

$\left(\frac{N1}{N2}\right) = \frac{b\text{^}x}{b\text{^}y} = b\text{^}(x - y) = b\text{^}(\log_b N1 - \log_b N2)$: with both logs having a base of (b).

Using the log definition, or by taking the log (base b) of both sides and simplifying with the log power or exponent rule:

$\log_b \left(\frac{N1}{N2}\right) = \log_b N1 - \log_b N2$: LOG QUOTIENT RULE
Also: $\log_b$ (N1/N2) = $\log_b$ [(N1) (N2)^-1] = (log(b) N1) + (log(b) N2^-1)
= log(b) N1 -1 log(b) N2
= log(b) N1 - log(b)N2

If the base of an indicated power is the same as the base of the logarithm:

$\log_b$ b^x using the log power rule:

x ($\log_b b$) since b^1 = b, $\log_b b = 1$ therefore:

x (1) = x therefore:
x $\log_b b$ = x by the log exponential rule:

$\log_b$ b^x = x : "SPECIAL" log rule. If the log base, and the base of N are the same, then the log expression is simply equal to the indicated power of N.

The number in a log expression, can also be an expression.

Ex. ln (a + 1) = 3.218875 solve for a: Using the log definition, and N = number = (a+1):

$\ln N = \ln_e N = \log_e N$, e is a special number in mathematics, like PI is special.
e is about 2.71, and PI for a circle is about 3.14
When e is used for logarithms, it is called the
"natural logarithm (nl = ln) base"
$\log_e (a+1) = 3.218875 = \ln (a+1)\ 3.218875$

e^3.218875 = (a + 1) = a + 1 Solving for a:
a = e^3.218875 - 1 Using a calculator which can easily calculate powers of (e):
a = 25 - 1
a = 24 : A calculator can easily check this if it can calculate natural logarithms.
$\ln (a + 1) = \ln (24 + 1) = \ln_e 25 = 3.21887\underline{6}$

SOLVING FOR THE BASE OF A POWER

Ex. Solve for x, the base of an indicated or expressed power, given:

x^(2/3) = 10 raising each side to the 3/2 power, we can isolate x as: x^1 = x :

(x^2/3)^(3/2) = 10^(3/2)

x^(6/6) = 10^(3/2)

x^1 = x = $\sqrt[2]{10^3}$ = $(\sqrt[2]{10})$^3 or $\sqrt[2]{10^3}$ = $\sqrt[2]{1000}$ = 31.62

x can also be solved using logarithms:

x^(2/3) = 10 taking the log (use same base) of both sides:

log x^(2/3) = log 10 using the log exponent rule:

(2/3) log x = log 10 solving for log x by dividing by its multiplying factor:

$\log x = \frac{\log 10}{(2/3)} = \frac{\log 10}{0.67}$ from the definition of logs (here x = N, the number):

x = 10^((log 10)/0.67) = 10^(1/0.66667) = 10^1.5

x = 31.62 and 31.62^(0.67$\underline{7}$) = 10

Note, you could also begin to solve for x by first simplifying its fractional exponent as:

x^(2/3) = 10
x^0.6666$\underline{7}$ = 10 and after solving for x: x = 10^1.5 as shown above.
If you were to also take the 0.66667 root of both sides of: x^0.66667 = 10^1, the result would also be the same value for x.

SOLVING FOR AN EXPONENT VARIABLE

Solving for an exponent generally involves using a logarithm expression. Most of this topic has already been discussed previously in the topics of logarithms and solving for exponents, however, here is a more complex example in purely algebraic terms:

Solve for x given:

$\frac{a}{b} = \frac{c^x}{d}$ multiplying both sides by d and canceling:

$\frac{a d}{b} = c^x$ taking the logarithm (can use any base) of both sides:

$\log c^x = \log \left(\frac{a d}{b} \right)$ using the log of an indicated power rule:

$x \log c = \log \left(\frac{a d}{b} \right)$ dividing both sides by log c :

$$x = \frac{\log \left(\frac{a d}{b} \right)}{\log c}$$

Ex. Given $5^x 7^x = 1225$, solve for x.

$5^x 7^x = 1225$ multiplying the bases of similar indicated powers and keeping the exponent:

$((5)(7))^x = 1225$

$35^x = 1225$ taking the log (use any base) of both sides:

$\log 35^x = \log 1225$

$x \log 35 = \log 1225$ isolating x:

$$x = \frac{\log 1225}{\log 35}$$

$x = 2$

Ex. $2^{(5-x)} = 8$ Solve for x: Two methods will be shown.

Method 1:

$2^{(5-x)} = (2^5)(2^{-x}) = 8$: factoring the left hand side

$\log ((2^5)(2^{-x})) = \log 8$ using the log product rule:

$\log 2^5 + \log 2^{-x} = \log 8$ using the log exponent rule:

$5 \log 2 - x \log 2 = \log 8 = (5 - x) \log 2$ if terms factored. isolating the term that contains the x variable, use transposition (transpose):

$-x \log 2 = \log 8 - 5 \log 2$

$x = - \frac{\log 8 - 5 \log 2}{\log 2} = 2$: this is easily solved here when you use a base of 2 for the logarithms

Method 2:

$$\log 2^{(5-x)} = \log 8$$

$$(5-x) \log 2 = \log 8$$

$$5 - x = \frac{\log 8}{\log 2}$$

$$x = 5 - \frac{\log 8}{\log 2} = 5 - 3 = 2$$

Ex. Solve for x:

$$2 = 4^x$$

$$\log 2 = \log 4^x$$
$$\log 2 = x \log 4$$

$$x = \frac{\log 2}{\log 4} = \frac{\log 2^1}{\log 2^2} = \frac{1 \log 2}{2 \log 2} = \frac{1}{2} \quad : = 0.5$$

Note $4^{(1/2)} = 4^{0.5} =$ square-root(4) $= \sqrt[2]{4} = 2$

Note also that this is an example where if you can express the numbers (N1 and N2) as indicated powers having the same base (2 in this example), then the result is simply the quotient of those indicated powers.

Ex. Find x given: $5^x + 6^x = 61$

A more advanced analysis will be discussed, and you may skip over this discussion for now if you want. Since the (x) variables cannot be combined, the method below solves for one instance of (x) in terms of the other instance. Of course you cannot (immediately) solve for a variable when that same variable is also part of the solution for itself. To overcome this limitation, a guess, calculated or not, for the value of (x) is first used with the hope that by repeatedly using the formula, that a very close value of (x) will gradually and eventually be found. When this happens, it is said that the result is converging (becoming closer to, approaching (a certain final value or "limit"), "focusing" or "zeroing in on" and becoming equal) to the true value of (x), and the difference between each new value of x approaches 0, hence continue this process till this difference is as close to 0 as needed. This method of solving for a variable is called successive approximation with recursion (reusing the same formula over and over with each new closer approximation of x to be used in it). More examples of successive approximation will be shown throughout this book. Successive approximation will not always work as shown below:

First, as a very simple example to help consider the above described method:

Find x in the equation: $5 + x = 8$. Rather than mathematically solve and express the equation in terms of, and equal to x, you can take an initial guess, of say, 1 for x. $5+x = 5+1$, and since this left side equals 6 and does not equal the right side of 8, the difference with respect to, or compared to the right side is: $(8-6)= 2$. Therefore, the difference in the sides is not 0, and you can keep increasing the value of x and comparing the left side to the right side of 8. This comparing is done mathematically by taking their difference. If the difference between both sides is 0, they are therefore equal and the actual value of x has been found, and that is 3.

$5^x + 6^x = 61$

$6^x = 61 - 5^x$ taking the log of both sides:
$\log 6^x = \log(61 - 5^x)$ using the log of a power rule:
$x \log 6 = \log(61 - 5^x)$ isolating (x) by dividing by log 6:

$x = \frac{\log(61 - 5^x)}{\log 6}$: The result of (x) here is a better approximation of (x). log 6 is also a constant for this problem and therefore it needs to be calculated only once. After substituting an initial guess for (x) into this expression, a new and closer value to the true value of (x) will result. Continue to use these closer values of (x) until you are satisfied with the result. The value for(x) will converge to 2. Checking using substitution:

$5^2 + 6^2 = 61$
$25 + 36 = 61$
$61 = 61$: checks

The other equation that you can derive from the original equation above for finding the solution for (x), as shown below, will not converge to a single value when using the computer program shown ahead in this book. The solution is still 2:

$$x = \frac{\log(61 - 6^x)}{\log 5}$$

Even though the value of (x) is not initially known, we can find a rough value by noting that if x=0:

$5^0 + 6^0 = 1 + 1 = 2$: since 2 is less than 61, clearly, x must be larger than 0

If x=1:

$5^1 + 6^1 = 11$: since 11 is less than 61, clearly, x must be larger than 1

If x=3:

$5^3 + 6^3 = 125 + 216 = 341$: x must be less than 3 since 341 is greater than 61

For the maximum value of (x), consider that logs are only defined for positive numbers. Since 0 is considered as the smallest positive number:

$0 = 61 - 5^x$: 0 ensures 5^x will be at it's maximum possible value; when x is at maximum
$5^x = 61$
$\log 5^x = \log 61$
$x \log 5 = \log 61$

$x = \frac{\log 61}{\log 5} = \frac{1.785329835}{0.698970004} = 2.554229543$: maximum value possible for a guess of x
Note, this is not the solution to the original equation.

If (x) were larger, the result would be a negative number for (61 - 5^x). 5^x was used instead of 6^x since division by log 6 would result in a slightly lower value. The true solution of (x) is 2. See A METHOD TO SOLVE DIFFICULT EQUATIONS in the APPENDIX section for a computer method that can be used to solve equations such as that shown above.

SOLVING FOR AN INDEX VARIABLE

The easiest way to solve for an index (the indicated root of the radicand in a radical expression or root operation) is to first rationalize the radical by raising it to an indicated power equivalent the index, then convert the radical to its exponential form and simplify, or vice-versa. This effectively transforms the problem into one of solving for an exponent.

Ex. What "root" of 1024 is equal to 4 ?

Expressing this mathematically:

$\sqrt[x]{1024} = 4$ raise each side to the (x) power:

$(\sqrt[x]{1024})^x = (4)^x$ convert the radical to exponential form:

$(1024^{(1/x)})^x = 4^x$ using the power to a power rule:

$1024^{(x/x)} = 4^x$

$1024 = 4^x$: This could have easily been found by inspection by considering:
"What is the exponent of a base of 4 so that the power would equal 1024".
OR:

$\sqrt[x]{1024} = 4$ expressing the radical with its equivalent exponential form:

$1024^{(1/x)} = 4$ raising each side to its x power:

$(1024^{(1/x)})^x = 4^x$ using the power to a power rule, multiplying exponents:

$1024^{(x/x)} = 4^x$ simplifying:

$1024 = 4^x$: the same equation as shown above
Taking logs of both sides:

$\log 1024 = \log 4^x$ using the log exponential rule:

$\log 1024 = x \log 4$ dividing each side by log4:

$\frac{\log 1024}{\log 4} = \frac{x \overset{+1}{\cancel{\log 4}}}{\underset{+1}{\cancel{\log 4}}}$: isolating x

$x = \frac{\log 1024}{\log 4} = \frac{3.0103}{0.60206}$

$x = +5$, hence $\sqrt[5]{1024} = 4$, and $4^5 = 1024$

If you were to write a simple formula for the above process, it would look like this:

$i = \frac{\log \text{radicand}}{\log \text{root}}$: **FORMULA FOR THE INDEX , THE INDICATED ROOT OF A RADICAND**

Also note the similarity of this formula, and the actual values used, to that of the formula for solving for an exponent shown below. The only thing different is the wording or description for the values. This is due to the close relationships of the power, root, and log concepts and expressions, as shown previously in this book. Using the last example:

From: $1024 = 4^x$

$$x = \frac{\log 1024}{\log 4} = \frac{3.0103}{0.60206} = 5$$

$$x = \frac{\text{log power}}{\text{log base}}$$: **FORMULA FOR THE EXPONENT OF AN INDICATED POWER**

EQUATING RADICALS (Solving For A Radicand)

As mentioned previously, the easiest method to solve for variables involved with radicals is to first place the radicals into exponential form.

Ex. $\sqrt[2]{100} = \sqrt[3]{N}$ placing radicals into exponential form:

100^(1/2) = N^(1/3) taking the logarithms of both sides of the equation, use any base (b) and use it consistently in a problem.

log 100^(1/2) = log N^(1/3) using the "log exponent rule":

$$\left(\frac{1}{2}\right) \frac{\log 100}{1} = \left(\frac{1}{3}\right) \frac{\log N}{1}$$

$\frac{\log 100}{2} = \frac{\log N}{3}$ solving for log N, and switching sides of the equation:

$\log N = \frac{3 \log 100}{2}$ since the right side is essentially the exponent of the base to equal N, and choosing a base of 10:

N = 10^((3 log 100)/2) : after expressing the anti-logarithm or "removing or reversing the logarithm" (here, from N) using the basic definition of logarithms. Now, after simplifying the exponent:

N = 10^(6/2)

N = 10^3 = 1000

hence: $\sqrt[2]{100} = \sqrt[3]{1000}$
checking: 10 = 10

Writing a general formula for the above procedure:

$\sqrt[i1]{N1} = \sqrt[i2]{N2}$: i1 and i2 are the indexes of their corresponding or associated radicals

N2 = b^((i2 $\log_b$ N1) / i1) : EQUATING RADICALS (RADICAND FORMULA)

EQUATING RADICALS (Solving For An Index)

Ex. $\sqrt[2]{100} = \sqrt[x]{1000}$ converting both sides to their equivalent radical form:

$100^{(1/2)} = 1000^{(1/x)}$ taking logarithms of both sides, be sure to use the same base:

$\log 100^{(1/2)} = \log 1000^{(1/x)}$ after using the log exponent rule:

$\frac{\log 100}{2} = \frac{\log 1000}{x}$ after solving for x:

$x = \frac{2 \log 1000}{\log 100} = \frac{6}{2} = 3$

hence: $\sqrt[2]{100} = \sqrt[3]{1000}$

checking: $10 = 10$

Writing a general formula for the above procedure:

$i2 = \frac{i1 \log N2}{\log N1}$: EQUATING RADICALS (INDEX FORMULA)
N1 and N2 are the radicands of the radicals.

Some other observations and derivations can be made here. Considering the above formula, we then have:

$\frac{i2}{i1} = \frac{\log N2}{\log N1}$: when two radicals are equal, the ratio of the indexes is equal to the ratio of the logarithms (with the same base) of the numbers. N1 and N2 are the radicands of the radicals.

Some of the following may, or may not, appear obvious according to the logarithm and radical definitions. We know that the log of a value is an exponent (here of any base that is used consistently in a problem), hence:

$\frac{i2}{i1} = \frac{\text{exponent2}}{\text{exponent1}} = \frac{\log N2}{\log N1}$: base^exponent2 = N2 and base^exponent1 = N1

EQUATING A POWER OF A NUMBER TO THE LOG OF THAT NUMBER

Here, the base of a power of (N) is the same as the number (N) of a logarithm and we are to find the proper exponent that will make that power value of (N) equal to the logarithm of (N).

$$N^x = \log_{b1} N$$

Taking the log of both sides (can use any base (b2) as long as you use it on both sides): Note that the base for the logarithm on the right hand side can also be any value. It could be 10, 2, 7, (e) or any other value.

$$\log N^x = \log (\log_{b1} N)$$

using the log of a power rule:

$$x \log N = \log (\log_{b1} N)$$

isolating x, by dividing both sides by (log N):

$$x = \frac{(\log (\log_{b1} N))}{\log N}$$

: note, log N in the numerator is not a common factor of the entire numerator, and therefore it cannot be canceled out by the denominator. (Log N) in the numerator is the Number value of another logarithm. Note that (Log N) in the numerator might even have a different base than (Log N) in the denominator, but it depends on how it was expressed in the original problem.

Here is a solved example where x = about 0.1505

$$100^{0.1505} = \log_{10} 100 = 2$$

: Another way of solving for x is to first simplify the right hand side as shown to a value of 2, hence this example would then become: $100^x = 2$, and then of solve for exponent x in the normal manner using a logarithm of both sides.

EQUATING A ROOT OF A NUMBER TO THE LOG OF THAT NUMBER

Here, a radical is set equal to the logarithm of the same radicand value, and we are to find the proper indicated root (index) of that radicand.

$\sqrt[x]{N} = \log_{b1} N$: any base for the logarithm. Expressing the radical in exponential form:

$N^{1/x} = \log_{b1} N$: taking the log (with any consistently used base) of both sides:

$\log N^{1/x} = \log(\log_{b1} N)$ using the log "exponent" or "(indicated) power" rule:

$\frac{\log N}{x} = \log(\log_{b1} N)$ solving for x:

$$x = \frac{\log N}{(\log(\log_{b1} N))}$$

Observe that this value for (x), the index of a root, is the reciprocal of the value for (x) as just shown above as for the indicated power when equating the power of a number to the log of the number. When you compare $N^{1/x}$ to N^x, or a power of N to the same root of N such as in the above two formulas, you will see that the exponents and their values are reciprocals of each other, and this leads to the reciprocal-like results of the two formulas.

Here is a solved example for the index (x), where N=100, and x=6.644:

$\sqrt[6.644]{100} = \log 100 = 2$: again, simplifying the right hand side, as shown to a value of 2, is the easiest way to solve this equation, as: $\sqrt[x]{100} = 2$

As an extra note, when the index of a radical is less than one, it actually represents an indicated power greater than one for that radicand.

Ex. Here is the half-root (1/2 = 0.5) of N, and it's actually equivalent to a larger value than that base of N:

$\sqrt[0.5]{N} = N^{(1/0.5)} = N^2$ Ex. $\sqrt[0.5]{10} = 10^2 = 100$

Of course, if N is less than one , a (proper) fractional value, then the expression would actually represent a value less than N since repeated multiplication of a fractional value is essentially a fraction of that fraction, and which results in a lesser value. For example,
$\sqrt[0.5]{0.3} = 0.3^{(1/0.5)} = 0.3^2 = 0.3^2 = (0.3)(0.3) = 0.09$

SIMPLE EQUATIONS CONTAINING RECIPROCALS

Given: $\frac{1}{G} = c\,G^x$ Here, G and cG^x are reciprocals of each other. (c) is a constant. The expression of: (1/G) is the reciprocal of G. The expression of: $c\,G^x$ is a multiple of G^x since (c) is multiplying factor to G^x. (c) and G can have any value except 0. Solve for c, G and x:

$\frac{1}{G^1} = c\,G^x$: note here that $G^x = (1/c)(1/G^1) = (1/cG^1)$, multiplying both sides by G:

$1 = cG^{(x+1)}$ dividing both sides by $G^{(x+1)}$, and switching sides:

$c = \frac{1}{G^{(x+1)}}$ For example, if x = 1: $c = \frac{1}{G^2} = \frac{1}{G^1}\ \frac{1}{G^1}$

Ex. Given: $\frac{1}{5} = c\,5$, $x=1$, $c = \frac{1}{G^{(x+1)}} = \frac{1}{5^2} = \frac{1}{25} = 0.04$: $G=G^1=5$

Note also that $1/cG = G^x$, here,for this example: $1/((0.04)(5)) = 1/0.02 = 5$

After mathematically solving for $G^{(x+1)}$, such as by taking the reciprocal of both sides::

$G^{(x+1)} = \frac{1}{c}$ taking the (x+1) root of both sides:

$$\sqrt[(x+1)]{G} = \sqrt[(x+1)]{\frac{1}{c}} = \frac{\sqrt[(x+1)]{1}}{\sqrt[(x+1)]{c}} = \frac{1}{\sqrt[(x+1)]{c}}$$

Given:

$c\,G^x = \frac{1}{G}$ solving for x:

$C^x = \frac{1}{cG}$ taking the log of both sides:

$$\log c^x = \log\left(\frac{1}{cG}\right)$$

$$x \log c = \log\left(\frac{1}{cG}\right)$$

$$x = \frac{\log\left(\frac{1}{cG}\right)}{\log c}$$

From the initial equation this can also be had:

$1 = cG^x\,G^1 = c\,G^{(x+1)}$ switching sides:

$c\,G^{(x+1)} = 1$

$G^{(x+1)} = \frac{1}{c}$ taking the logarithm of both sides:

$\ln G^{(x+1)} = \ln(1/c) = -\ln c$

$(x+1)\ln G = \ln(1/c) = -\ln c$

$x + 1 = \frac{\ln(1/c)}{\ln G} = \frac{-\ln c}{\ln G}$

$x = \frac{\ln(1/c)}{\ln G} - 1 = \frac{-\ln c}{\ln G} - 1$

If $G^x = \frac{1}{c}$ solve for x. Taking the log of both sides:

$\ln G^x = \ln\left(\frac{1}{c}\right) = -\ln c$

$x \ln G = \ln(1/c) = -\ln c$

$x = \frac{\ln(1/c)}{\ln G} = \frac{-\ln c}{\ln G} = -\frac{\ln c}{\ln G}$

SOME EXAMPLES OF ALGEBRA WITH GEOMETRIC FORMULAS

Geometery is a word that means the measure (meter, metery, metric) and analysis of earthly (geo), physical (real) or virtual (as if real) things or ideas.

Since this book has a trigonometry section, the first example will be directed towards finding the formula for the area of a triangle.

Ex. What is the formula for the area of a triangle?

Previously in this book, some basic concepts about area have been discussed in the topic of Powers. Below are some more fundamental details about the concept of area.

Distance is a measurement of how many units, or "long" (ie. length), something is, or the length between two points or locations, hence it is a measure of the amount of separation, which is therefore a difference, between things. Distance or length is a linear or line-like concept. The length or distance between two points is found by measurement and-or the difference between those two points having a known linear value. In short, linear (having a line-like quality or relationship) means one-dimensional which basically means having only a single direction for its structure and measurement. Lines are one-dimensional geometric concepts. Lines are infinitely thin, that is, in theory or concept, they actually have no thickness, and are infinitely long, and each extends infinitely outwards in one specific direction. Being one dimensional, a line and its can graphically represent one dimension and its concept. Likewise, one dimensional concepts are therefore often associated with lines and are said as being linear. A line can also be considered as being composed of an infinite number of infinitely small points, all being side by side or next to each other.

One dimensional means that something can only be measured, so as to quantify it, in only one way, such as the length of a line segment that is a small part of a line. A line segment is a defined or (length) bounded region, section or segment of a line.

Two dimensional basically means that something can be measured, so as to quantify it, in two ways, such as a length (dimension) and width (dimension) of a defined or bounded area that is part of the infinite area of a plane. Planes are essentially infinitely "flat surfaces" that have only two dimensions: a length dimension and width dimension, also known as the first and second dimensions, but no thickness or third dimension. Two dimensional measurements will naturally build upon and use the one dimensional concept of length. Some examples of two dimensional structures are squares, circles and triangles which are a small defined or bounded (having defined boundaries) part of an infinitely large plane. A plane can be thought of as an infinite number of side by side parallel lines so as it creates a width, thickness, second dimension. Parallel lines will never intersect or cross each other. Each of the two dimension of a plane are defined and understood as being perpendicular (90° of rotation apart, right-angle, exactly "sideways" or "cross") to each other.

Three dimensional means that something can be measured in three ways such as the length, width, and height (or "thickness") of a bounded or defined volume, space or solid structure that is part of the larger and infinite volume of space. Three dimensional measurements will be done using the concepts of two dimension measurement of which are based on the linear or one dimensional concept. Therefore, it is possible to conceive a solid or volume as being a bounded or defined segment, section, or region of an infinite number of side by side parallel planes. The third dimension of a volume is defined and understood as being perpendicular to the other two dimension of a plane.

A drawn horizontal (left to right) line can be thought of as graphically representing the first dimension, and a vertical (up and down) line can be thought of graphically representing the second dimension. A line extending straight through the paper can be thought of as graphically representing the third dimension.

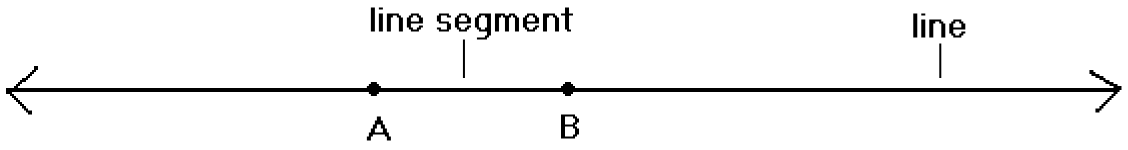
The perimeter (the bounding and defining sides, and-or its corresponding length values) of a triangle or the circumference of a circle, both two-dimensional objects, can still considered as a single (total) length value even though it is not a single (straight) line or segment but rather the sum of them, and that the objects are two-dimensional. This total distance or sum of various lengths can then be thought of and represented as one single line segment.

Again, a distance or length concept is considered as a one-dimensional concept. A distance or length value is a measurement of just one-dimension that is bounded or defined. Because the second and third dimensions are based on the concept of one-dimension, one-dimensional measurements and values of distance or length will also be used to bound, define and-or measure areas (ie., surfaces) and volumes (ie., space).

One of the most fundamental or basic concepts of geometry is the point. A point can be thought of as both an infinitely small object and-or a location for it. Hence a point is either physical (object), and-or logical (a location, address, numeric). A line can be thought of as composed of an infinite number of points. How do you then locate or identify a point on a line or line segment? It is very difficult without another known or agreed upon point that can be used as a reference of measurement or addressing point for all other points. Like numbers being in reference to some value, often 0 as for the common counting numbers, a location is always in reference to some other known (reference) location which can be even considered as 0 (or having a address of 0). A location of something can be described or represented as a numeric address or distance value (using some standard unit of measurement) from a reference address, point or location. The units of (distance or length) measurement used are a defined length unit. It takes two points to create or define a line segment. These points can be thought of as side by side or separated by some distance, with an infinite number of points between them. The number of points possible on a line segment of any size of length is infinite (unending, uncountable), and the definition of a line can then be thought of as one continuous (unending) line segment. The smallest, least, or shortest distance between two points is equal to the length of a line segment between those two points.

[FIG 25]

line , the arrows indicates it extends infinitely, and therefore it cannnot be measured to express its length. It's length is therefore said to be infinite.

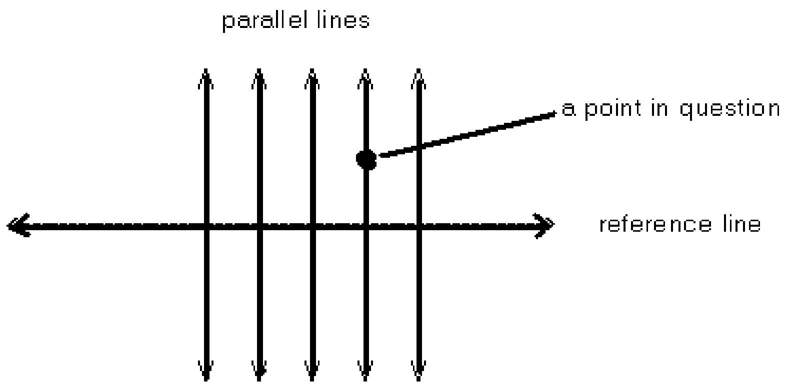


line segment, a (bounded or defined) part or portion of a line that can be measured to express its specifc or definite length

line segments can be identified with two defining end-points, here labeled or expresed as point A and point B for line AB = $\overline{AB}$

All points (or locations) on a plane can be identified (ie. its numerical distance or location) by two perpendicular distances from any point chosen as a reference point of measurement and-or addressing for the system. This distance and-or its (address) location is the point's linear (distance in each dimension of a plane or surface) coordinates in a rectangular coordinate system of measurement. Coordinates is a term used to describe a point's two corresponding (or "coordinating" or "coexisting") location values. Point (0,0) is usually used to indicate the common and starting (measurement and location) reference point for all dimensions or axis of the measurement system. Why perpendicular? First, all points on a line are unique to that line only, that is, they can only be identified as a distance from another reference point on that one specific line. To identify or locate a point on a plane or surface would require that you know which particular line (of an infinite number of parallel lines), so perhaps from a line chosen as a reference line, and the distance to that point along that line from a "base" or reference point on that line. Since there is an infinite number of parallel lines that are uniform to each other, it is best to make all the reference points of these parallel lines uniform also, hence placing them all along a common fixed "reference" line in this (location) system. Still, a problem now would be identifying a line among an infinite number of parallel lines, and that is not practical. This reference line need not be perpendicular to these parallel lines, but it is usually set perpendicular (a "right-turn" or "right-angle" = a quarter of a full 360° circular turn = ninety degrees = 360°/4 = 90°) since it is essentially the least parallel-like of all possible parallel lines. It is also done in order to create a rectangular coordinate (measuring) system. Rectangular (which means "right-angular") is a term that is used to describe something that is: "square-like", where each dimension or side is rotated 90 degrees in reference to each other.

Some initial concepts for creating a coordinate system on a plane. [FIG 26]



As mentioned, finding the location of a point on a plane using this system, shown in the above figure, is still difficult since there is an infinite number of parallel lines to identify so as to locate a specific parallel line, and then to locate the specific point in question along that specific line. To overcome this problem of identifying and-or address a line, you could assign a particular parallel line as a reference (of measurement) line and then identify each line by its practical (and not the infinite and hence undefinable line number) length or distance from this reference line using a standard (agreed upon) unit of measurement. The outcome of all this is that a points location on a two-dimensional plane or area is identified by it's two perpendicular distances (which could be represented as dotted lines) from two reference lines.

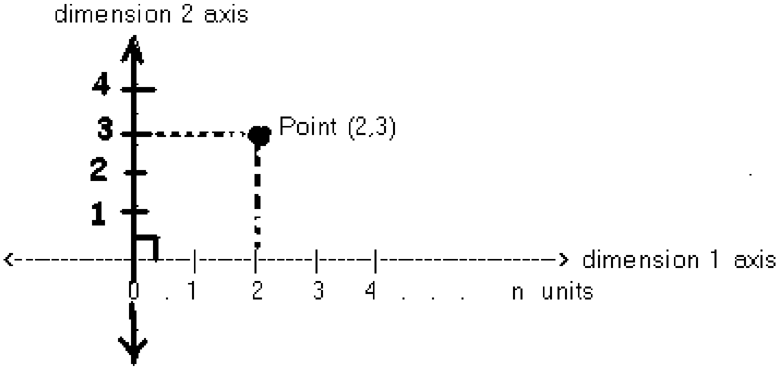
Each point on a plane or surface is at a unique (only one instance of) intersection of two specific lines in a rectangular measuring and addressing system. This perpendicular system is the simplest and most practical method to locate (give an "address" to, or identify and refer to) a point on a plane or surface. The location or point where the two reference lines (of measurement in this system) intersect or cross is called the reference point (that the location of all other points on that plane will be in reference or respect to) or **origin** ("original", source, reference, or starting) point of the system, and it is therefore has an address, "offset" or distance value of 0 with respect to the two reference lines of the system. The location of this point, and any other points in that system, is typically written as a pair of coordinates (its two corresponding location values). The location of the origin of the system is written as: (0,0) or p(0,0) which can be read as: "point zero comma zero". The two perpendicular reference lines drawn through the origin are commonly called **axis lines** of the coordinate system. Axis is a word based on "axel" and "center" location such as of a wheel. These two lines represent the reference lines of measurement for each of the two each dimensions of a plane or rectangular the coordinate system. Each of the two coordinates of a point are effectively the (perpendicular) distance to (or from) the other coordinates axis line of reference. If given an address of (x,y), the x-coordinate is the points distance from the y-axis, and the y coordiante is the points corresponding distance from the x-axis.

The coordinates of a point (p) are often expressed using the basic format of:

p**(**length or position in dimension1 **,** length or position in dimension2**)**

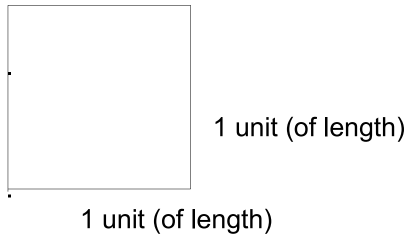
Examples: p(x , y) , p(horizontal, vertical) p(left and right, up and down)
p(variable1,variable2) , p(independent variable, dependent variable)
p(time, temperature) , p(age,weight) , p(day,sales)

[FIG 27] A Rectangular Coordinate System



For an analogy (a similarity or likeness) of this addressing scheme, consider this: If a plane represented a city, the origin would be the town-square or center, the (x) co-ordinate (distance in dimension 1) would be the street location from the town-square, and the (y) co-ordinate (distance in dimension 2) would be the location along that street.

Since plane or flat surfaces are now defined as two-dimensional, the basic unit of measurement of a plane surface (area) cannot be in length units alone - which are used to measure only one-dimensional lines. The obvious choice is to have a reference piece of surface as the basic unit of measurement of areas (bound, defined regions) of a plane, and this is similar to the method of measuring one dimensional distances by using a standard reference piece of length as the unit of measurement or reference to compare and quantify all other lengths to. Other surfaces or portions of surfaces can therefore be measured (comparing and counted) in reference or with respect to this special piece or unit of reference or measurement surface. Since a measurement for each dimension will be in reference to the (hopefully similar) units being used for each dimension, this basic unit for area or surface measurement should then also include both dimensions and the units used for both dimensions. Since dimensions are at right angles, this reference piece or unit of surface area will have the shape below which is called a square. A square is a bounded or defined piece, segment, or "area" of a plane, and can therefore be used as a common reference or measuring unit to measure and-or represent the size of other areas. [FIG 28]



: basic unit of surface measure
: 1 square-unit

Like a scaled (marked with several equivalent unit distances) ruler line is to measuring distances, these special squares are to measuring surface areas. Since the shape is a square with each side having a length of 1 unit (feet, inches, meters, centimeters, etc), it is common sense to call this unit of measurement a "square unit" or "unit square". A square-unit is the basic unit of measurement for measuring surfaces. In mathematical notation:

1 square unit = 1 unit square = 1 sq. unit = (1 unit) x (1 unit) = (1)(1)(unit)(unit) = 1^2 unit^2 = 1 unit^2 = unit^2

Consider the algebraic notation when width = length, as for a square: (length)(width) = (length)(length) = length^2
Also, if that length was just one unit long, that length unit squared is also the unit of area measurement:
length^2 = unit^2 = squared unit

The actual measured size of a portion of a plane or surface is called the surface's area, area of surface, or just area. The word "area" is sometimes loosely used as meaning surface itself, instead of a measurement of it. Since a surface is measured in reference to a square-unit, the actual number of units of a measured surface or "area" will be equal to a specific quantity or number of those square-units of measurement.

If you had 4 separate surfaces, each with an area of 1 unit^2 = 1 square-unit, their total area would be:

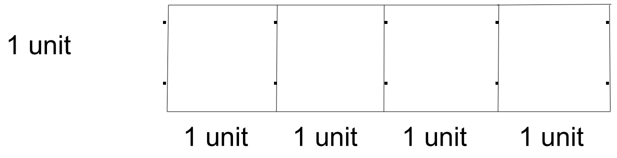
Total Area = (1 unit^2) + (1 unit^2) + (1 unit^2) + (1 unit^2) adding like units:
Total Area = (1 + 1 + 1 + 1) unit^2 = 4 unit^2 : "4 units square" = 4 units^square = "4 square units"

If the reference length units used to define a reference square-unit were feet units, the units of surface measurement must therefore be expressed with those same units:

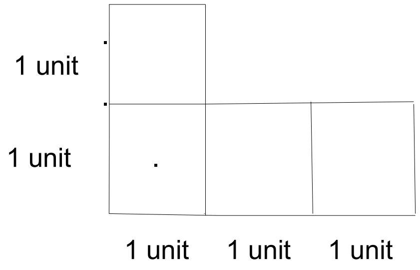
Total Area = 4 unit^2
Total Area = (4)(1 ft x 1 tt) = (4)(ft^2) : the word feet is actually the multiple or plural of foot (ft)

= 4 feet^2 = 4 ft.^2 : note, this expression: units^2 , is not a mathematical operation, and it is
= 4 square-feet just the mathematical notation used for these types of units of measurement since it was defined this way from two linear units: (1 unit)(1 unit) = 1 unit^2 = unit^2 . That is, the unit of area reference is an area that is bounded or defined as a square, 2 dimensional shape, and the unit of reference is therefore not just a line or one dimensional unit only.

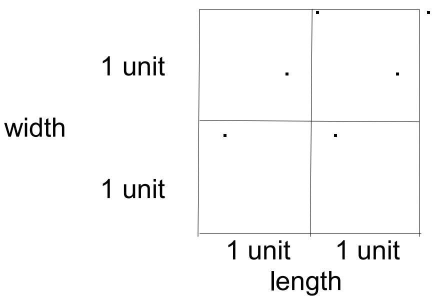
These different shaped surfaces shown below can be measured as a sum of unit areas, and the total area is equivalent to any other possible surfaces having the same total area of 4 ft.^2. This can easily be seen when these separate surfaces are joined together, particularly when the entire shape becomes a rectangle and the area can be easily calculated.
[FIG 29]



: total area = 4 square-units =
= 4 units-square = 4 units^2



: total area = 4 units^2



: total area = 4 units^2

The first and the last surface shapes shown above can help verify an important concept. When a bounded or defined surface has straight (or linear) sides that are set at a right (or "square", 90 degree) angle with respect to each other, and remain constant throughout the surface, the corresponding sides (or "lines") of that surface are said to be parallel and "opposite (across from) from each other", and the shape or structure of this surface is called a rectangle. First, the word "**angle**" is an old French word that means a "corner" where two sides, such as two walls, intersect, meet or join at. A rectangle ("**rect**" is an old Latin word that means a "right" turn, bend or direction, hence 90° like that of a square shape) is essentially a square surface that has been elongated (in one direction or dimension) by increasing the distance between one pair of parallel sides. The longest or largest side of a rectangle is commonly called it's "length side", and the shortest or smallest side is commonly called it's "width side". The word "width" is similar to the word and meaning of the word "wide". The expression for the total area of any rectangle shape will becomes one of repeated addition (of square units), which as we know, can be expressed simply or more compactly as multiplication:

To find the area of a given rectangle, divide the entire rectangular surface into rows or columns of square units, where each division or part is 1 unit long for each of the length and width dimensions or sides (a side is a portion of the entire boundary or perimeter of the surface or object) of each square unit. If the side of the rectangle is (n) units long, there will be (n) such rows of square units, and the total area (A) of that rectangle (r) can then be expressed as:

Ar = area of row 1 + area of rows 2 + area of row 3 + . . . + area of row n

Since each row of a rectangle is equivalent in area, to say the area of row 1, and there are (n) such rows, by algebraic substitution, we have:

Ar = area of row 1 + area of row 1 + area of row 1 + . . . + area of row 1

Expressing this repeated addition with a multiplication expression:

Ar = (n)(area of 1 row)

Since the area of each row is equivalent to length (L, of the row) square units, of which each unit automatically includes a unit of width (W), or a width length units, and that (n), the number of rows, is equivalent to the numeric value of the rectangle's width, that is, it is the number of width (W) units:

Ar = (W)(L units^2) By multiplication:
Ar = (LW) units^2 : **AREA OF A RECTANGLE = (length units)(width units)**

We see that the formula is equivalent to multiplying the number of length (L) units by the number of width (W) units:

Ar = (L units)(W units) = LW units^2

For a similar check, if there are L squares, or L square units per row, and there are (W) rows, the total number of squares in a rectangle is just a matter of repeated addition or multiplication:

Ar = (L squares)(W) = (LW) squares

If each square with sides 1 unit long is the unit of measurement for area, that is, each is a square-unit:

Ar = LW square-units = LW units^2

The same formula for the area of a rectangle is also naturally used if the area being measured also has or includes a fractional part of a square unit. For example if a rectangle is measured to be 5.2 centimeters long, and 2 centimeters wide, the total area of that rectangle is: Ar = LW units^2 = (5.2 cm)(2 cm) = (5.2)(2) square-centimeters = 10.4 cm^2

As a final description of (two-dimensional) area, the corresponding change or increase in the amount of area is not a linear (balanced, direct, one-to-one, matching, same, constant portion or ratio) concept when its (one-dimensional, or linear) sides change in size or value. The formula for area in relation, respect or in reference to its sides is not a linear expression or resulting value. When a line has or will be increased in length by some factor, you can find its new or resulting length value by adding repeatedly or multiplying a value to the old length and value. If you add a length to itself, you double its length and value. This is the same as multiplying that value by 2. However, if you were to double the sides of a square, it's corresponding area does not just double, but actually increase by the square (the second power) of this (increasing) factor. The area will then increase by the (multiplying) factor of: (the increasing or multiplying factor of its side length)^2. For this example, where the side length of a square increased by a factor of 2, the corresponding area will increase by a factor of = 2^2 = 4 The new area is 4 times more or bigger. It could be said that the area has been magnified or multiplied by a factor of 4. Here is an algebraic or symbolic mathematical verification:

A = (s)(s) square-units : s = side length of a square, where length=width,
A square is actually a special or unique instance and form of a rectangle

A = s^2 square-units : **FORMULA FOR THE AREA OF ANY SQUARE** = **(side)(side)**

Since the variable does not have an exponent equal to just 1, this
mathematical relationship of (s) and A, will not graph as a line.
Their mathematical relationship is said to be non-linear.

Doubling each side of a square we find::

A = (2s)(2s) units^2 = A1 =
A = (2)(2)s^2 units^2 = 2^2 s^2 units^2 = 4s^2 units^2 : when each side of an area is increased by a factor, that area increases by: (factor^2).

A2 = ((factor)(s))^2 = (factor^2)(s^2) = (factor^2)(area) = (factor^2) A1

Dividing this new or second area A_2 by the older or original area A_1 that was initially shown and expressed above as just variable A, we can find the number of times that A_2 is bigger than A_1, or the number of times that the original area A_1 has been magnified (a multiplicative or factor increase = increased by a multiplying factor value, rather than being just a simple linear increase by adding some value).

$$\frac{A_2}{A1} = \frac{4\,\cancel{s^2}}{\cancel{s^2}} = 4$$

: the new area is four times bigger or larger than the old area, such as is the result when that old area has been increased by a factor or four after doubling (2) its sides.

If the side length of an area tripled (increased by 3 times), the area will increase by: (increasing factor)^2 = 3^2 = 9 times more.

A = (3s)(3s) units^2
A = (3)(3)s^2 units^2 = 3^2 s^2 units^2 = 9 s^2 units^2 , hence A2 = 9 A1

The mathematical relationship between area and length is said to be a non-linear relationship, and specifically, it is an exponential relationship. Area grows or increases in value much more rapidly than the side lengths of that area. As the sides length changes or increases, the change in the areas increases by an exponential rate. This is due to the squared value: side^2 = s^2 in the formula for area. Consider this small chart below, and the descriptions on the right side as a more advanced analysis of the mathematical relationships of side length and area, and may be skipped over for now.

Side length of the square	Area of that square	
1	1 sq. units	
2	4 sq. units	: the side increased by 1, and the area increased by a value of 3 1 is the difference between the new and old side lengths values. 3 is the difference between the two area values At this point, as the side increases by 1, the area increases by 3. At this point, the areas is increasing by 3 for each 1 increase in the side. The rate of a change in area to a 1 unit change in a side is 3. (change in area) / (change in side) = 3 : rate of changes or (difference in areas) / (difference in sides) = 3/1 =3 : rate of changes Generally, a rate should rather be thought of as a multiplicative increase, magnification, or factor, rather than a difference. This value of 3, or the rate is not a fixed or constant value but depends upon the specific value of the side length and area.. When the mathematical relationship of: area with respect to side is graphed, the higher the rate, or mathematical relationship, the more "steeper" the curve becomes as the side increases in value. In a linear relationship, this rate, depending on the equation, would be a constant value. For example y=2x, and no matter what value x is, if x changes by 1,the corresponding change in the value of y will always be 2. (change in y) / (change in x) = 2, therefore: (change in y) = 2 (change in x). The mathematical relationship between and y and x is said to be a constant or linear mathematical or numeric relationship. This rate (of changes) value of 2 is also the mathematical expressed steepness or "slope" value of their graphed relationship or "curve" that shows all the corresponding values of those two variables, here, x and y, as points on the graph.
3	9 sq. units	: again, the side increased by 1, however, the area now increased by a value of 5 square units. Clearly area is increasing at a faster rate than the sides, and therefore their numeric relationship is not linear or proportional. 1 is the difference between the new and old side lengths values. 5 is the difference between the new and old area values. At this point, as the side increases by 1, the area increases by 5. At this point, the areas is increasing by 5 for each 1 increase in the side. The rate of a change in area to a change in side is 5: (change in area) / (change in side) = 5 or: (difference in areas) / (difference in sides) = 5 This value of 5, or the rate of changes, is not a fixed or constant

		constant value but depends upon the specific values of the variables being considered. Previously, when the side increased by 1, the area only increased by 3.
4	16 sq. units	: the side increased by 1, and the area increased by 7
5	25 sq. units	: the side increased by 1, and the area increased by 9

Notice that when the side length increase or changes by 1, a constant value, that the area increases or changes (ie. a difference) not by a constant value (which would make the relationship between area and length a linear mathematical relationship), but by a variable and growing (not constant) value.

Likewise, if the area of a square is only doubled, the corresponding sides are, or were not actually doubled either, as would be the case for some kind of linear or direct relationship, but they are only increased by a (multiplying) factor of:

$\sqrt{2}$ which is about 1.414, and here is the verification:

$A = s^2$: formula for area of any square. Solving for the side variable (s) given the area:

$s = \sqrt{A}$: **FORMULA FOR THE SIDE OF A SQUARE SHAPE OR AREA**

Given: $A = s^2$ multiplying each side of the equation by 2, so as to double the area:

$2A = 2s^2$ factoring 2 (here, for its two sq. root factors):
$2A = \sqrt{2}\,\sqrt{2}\,(s)\,(s)$ by the associative law :
$2A = (\sqrt{2}\,s)\,(\sqrt{2}\,s)$: each side or dimension of a square must have the same length
$2A = (\sqrt{2}\,s)^2$: if area of a square doubles, the sides only increase by the square root of 2 (about 1.414), and which is lesser value than 2.

In general, if some area and value is said to change by a factor of N, the formula for the sides of a representative square that has the same equivalent area is:

From: $s = \sqrt{A}$ If area increases or is magnified by some factor N:

(Note, we cannot use: $s = N\sqrt{A}$, since this is actually only a multiple of $\sqrt{A}$ or= s, and this is not equal to the area value = A)

$s = \sqrt{NA}$ which can be expressed as:

$s = \sqrt{N}\,\sqrt{A}$: If area increased by a factor of N, the corresponding sides of that (equivalent square shaped) area will only increased by the factor of: $\sqrt{N}$, and not N. Shown above, when the area doubled (2), the side length of the square increased by the (multiplying) factor $\sqrt{2}$ = about 1.414

If it is said that the side length of an area (being thought of, represented or considered as a square) changed by a factor of N, a general expression for area would be:

From: $A = s^2$ if the side length changed by a factor of N:

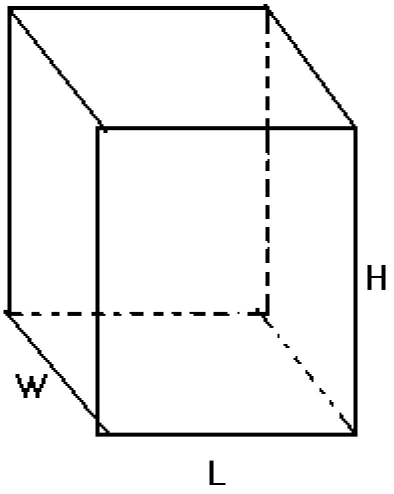
$A = (Ns)^2$ which could be expressed as:
$A = N^2 s^2$: we see that when the sides of a square change by a factor of N, that the area of that square will actually change by a factor of: $A / s^2 = N^2$

Much of the reasoning that went into the discussion about area can also be applied to the concept of volume or spatial (spaces) measurement. Volume is considered as a three-dimensional concept and measurement. The standard unit of measurement or reference of a volume is a cube shape, and since it is defined so to have sides of 1 unit of length long, it is called a cube unit = cubic unit.

A cube or "square-block" is essentially constructed from a square plane shape that is moved a unit distance that is perpendicular to the (planar) square's two (ie., length and width sides) reference lines or dimensions. For the volume (V) of a cube:

V = (Length units)(Width units)(Height units) : volume of a cube , and where all the units are identical
V = ("Base Area" units^2)(Height units^1) : Base or "Bottom" square area will be moved Height units.
V = LWH cubic-units = LWH units^3 : a cube is the reference (unit) of measuring volume [FIG 30]

A 2 dimensional visual representation of a 3 dimensional cube.



L = W = H = 1 unit long

Cube = (base) x height = (1 unit x 1unit) x 1 unit = 1 unit^3 = 1 cubic unit

Ex. An irregular shaped container is said to contain a volume of 100 cubic units of some liquid. If this liquid is put into a (uniform, equally sided) cubic shaped container, what would the length of each dimension be?

First: volume = unit^1 x unit^1 unit^1 = units^2 x units^1 = units^3 , taking the third or "cubic" root of each side:

$\sqrt[3]{\text{volume}} = \sqrt[3]{\text{units}^3} = \text{units}^1$

The side length of a cubic structure having a volume of 100 cubic units is:

$\sqrt[3]{100} = 4.64\underline{2}$ units long : the length units are usually those indicated with the original volume (ex. feet, inches, meters, centimeters, etc)

Checking: Using the above value, the total volume of the corresponding container is:

Volume = length x width x height = $4.64\underline{2} \times 4.64\underline{2} \times 4.64\underline{2} = 4.64\underline{2}^3$ cubic units = 100 cubic units = 100 units^3

If each linear dimension of a volume is increased a factor of (n) times, the volume will increase by a factor of n^3 times:

New Volume = (n) old_length x (n) old_width x (n) old_height : n = linear magnification or factor
New Volume = n^3 (old_length x old_width x old_height)
New Volume = n^3 old_Volume

For example if the 3 dimensions of a volume, space or solid object are doubled (2), such as after a object and-or size magnification, the old volume is increased by:

n^3 = 2^3 = 8 times.

Another related concept is that the mass and-or weight of a 3 dimensional object will also increase by (linear_magnification)^3 = the cube of the linear magnification of the volume ("or size") of an object.

new_mass = (linear magnification)^3 old_mass and new_weight = (linear magnification)^3 old_weight

If any one factor or physical dimension of a volume changes by (n), either multiplied or divided by that factor of (n) such as its size decreasing, the volume will likewise decrease by that same factor of (n). Here is a verification for when the height is half:

V1 = (length)(width)(height) = LWH if the height is now half, or divided by a factor of n=2:

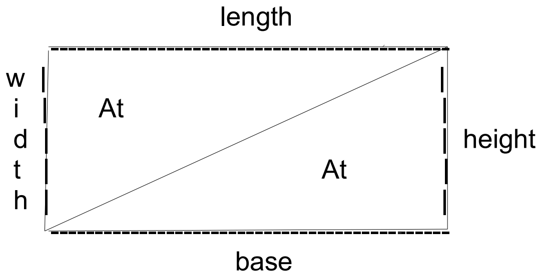
$$V2 = (\text{length})(\text{width})\frac{(\text{height})}{2} = L\,W\,\frac{H}{2} = \frac{LWH}{2} = \frac{V1}{2}$$

:the volume is divided by that same factor of n=2
If the height was rather doubled, V doubles:

V2 = (length)(width)(2 height) = L W (2H) = 2 LWH = 2 V1

Due to the previous discussions, we now have more information to help us develop the formula for the area of a triangle.

First, the area of a rectangle is: Ar = (length)(width) , the units of measurement for length and width must also be the same so that the area's units of measurement resolve to square units = units^2 of measurement. Now, if you diagonally (corner to opposite corner, that is, being not on the same side or line itself) divide any rectangle in two, and the result is two identical (same = congruent = identical or "exact same size") triangles. Hence, each one of those two triangle's is equivalent to half the area of a rectangle that it was or can be derived from. Expressing this as a mathematical expression we have the formula for the area of any right triangle:



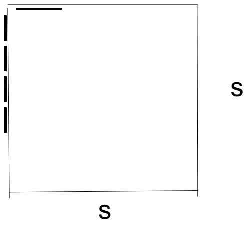
[FIG 31]

$$At = \frac{(\text{base})(\text{height})}{2}$$: **AREA OF A RIGHT TRIANGLE**

Here, base (side of the triangle) is equivalent to the length of the rectangle, and height (side of the triangle) is equivalent to the width of the rectangle. This formula is essentially that of half (divide by 2) the area of a rectangle which contains "square corners" or "right-turn" angles (90 degrees in value). All right-triangles will have a 90 degree internal angle = 90° angle.

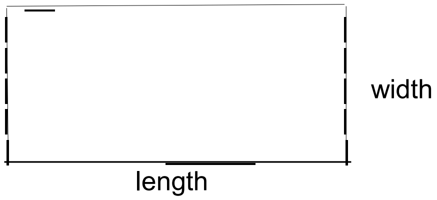
Now we will derive the formula for the area of a parallelogram in order to create a more general formula for the area of any triangle that may or may not contain a right angle so as to be a right triangle of which the above formula can only be applied to.

A square, a figure having four equal sides at right ("square", "corner", "exactly right or left", "exactly (vertical) up and down", or "ninety-degree") angles to each other, is actually a special case or instance of the geometric figures called rectangles. For a square or "square rectangle", the length of each pair of parallel sides, happens to be the same value. [FIG 32]



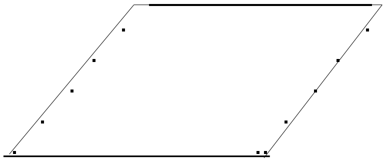
: a square

Rectangles have all sides at right angles with respect to each other. Parallel (ie. sides directly opposite each other, "side by side", "next to", "along side") sides must be the same length, but the pair of adjacent parallel sides (at a right angle to the parallel sides) can vary in length unlike that for a square where they must all be the same length. **Rectangles are actually a special case or instance of the geometric figures called parallelograms.** [FIG 33]



: a rectangle

A **parallelogram** has 2 pair of opposite sides which are parallel and equal in length, however, the non-parallel or adjoining sides can be at any angle with respect to each other rather than be perpendicular (90 degrees or right-angle) only. [FIG 34]



: a parallelogram

The formula for the area of the square is based on that of the area of rectangles:

A = length x width   For a square, the length and width sides (s) are always equal, therefore:
A = s x s
A = s^2   : area of a square

What is the general formula for the area of a parallelogram? It's very similar to that of a rectangle:

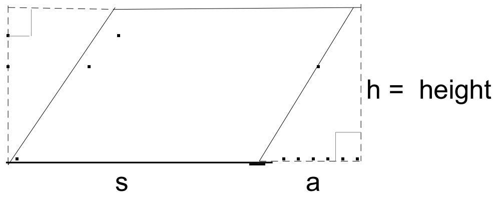
Ar = length x width : area of a rectangle

Below, the sides of the given parallelogram are extended to construct a rectangle whose length dimension is (s + a), and whose height dimension is (h):

The area of the indicated rectangle below in which the parallelogram resides is:

Ar = length x width
Ar = (s + a) x (h) : here h = height of parallelogram = width of rectangle. Distributing :
Ar = sh + ah

[FIG 35]



The area of the parallelogram (Ap) can be found if the area (At) of the 2 identical small triangles is subtracted from the total area (Ar) of the rectangle:

Ap = Ar - 2 At using substitution:

$Ap = [(s + a) \times h] - \cancel{2}\frac{(ah)}{\cancel{2}}$: canceling like terms, then using distribution:

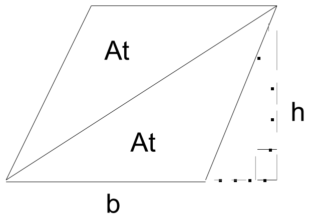
Ap = sh + ah - ah combining like terms:
Ap = sh letting s= b= base of the parallelogram :

Ap = bh : AREA OF A PARELLELOGRAM

As the parallelogram is tilted away from where the sides intersect, one pair of diagonal angles will decrease, and the other pair will increase by the same angle. The more the sides of a parallelogram are "tilted", the more its height will decrease, and therefore its area will decrease. The parallelogram becomes "flattened".

If you draw a diagonal within the parallelogram you will create two identical (exactly the same or congruent) triangles, and then it is easy to see the general formula for the area of any triangle, and not just for right-triangles, and that it is one-half of the area of the corresponding parallelogram: [FIG 36]

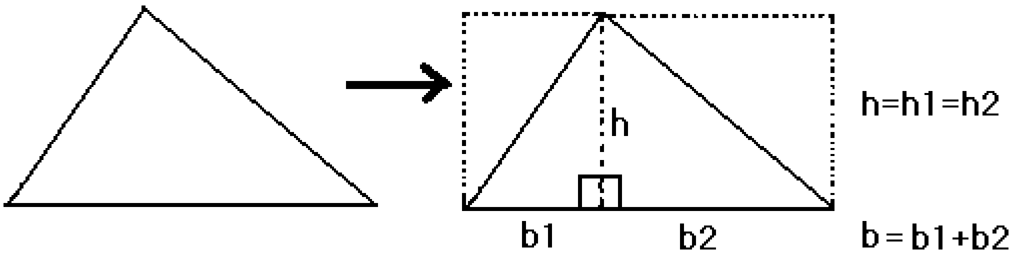
$At = \frac{Ap}{2} = \frac{bh}{2}$



: AREA OF ANY TRIANGLE

Note, the base (b), and height (h) lines and-or indicated extensions, are defined as perpendicular to each other. This is obviously the same formula for the area of a right triangle.

Consider this alternate analysis and derivation of the area of any triangle: [FIG 37]

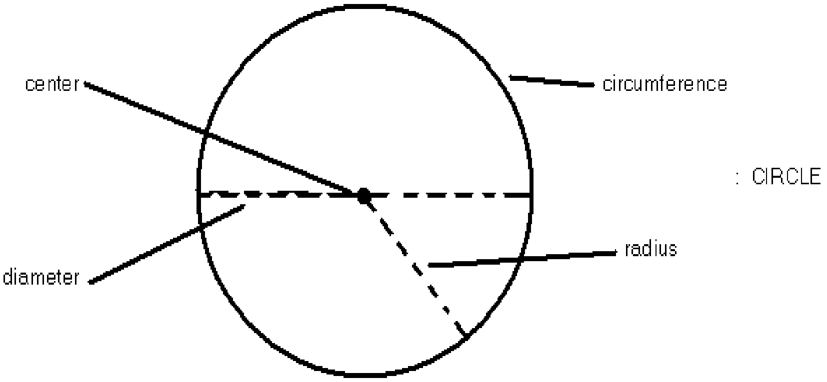


Let :   h = h1 = height of left rectangle = h2 = height of right rectangle

$$\textbf{At} = \frac{\text{area of left rectangle}}{2} + \frac{\text{area of right rectangle}}{2} = \frac{(b1\ h)}{2} + \frac{(b2\ h)}{2} = \frac{(b1\ h) + (b2\ h)}{2} = \frac{h\ (b1 + b2)}{2} = \frac{h\ b}{2} = \frac{\mathbf{b\ h}}{\mathbf{2}}$$

Here are some formulas concerning circles, or that which is circular-like:

A **circle** is a defined area of a plane. A **circle** is a set of points where each point is exactly the same distance (called the **radius** = r or R) from a common (reference) point and-or location called the center or center point of the circle. This set of points is called the **circumference** (C) of a circle and is essentially the perimeter (defined border, boundary) of a circle. The **diameter** or greatest length within or across a circle, and it is equal to twice the radius length: (D = 2R). One concept of a circles circumference is that it is like a line segment that was bent or curved so that the end points meet. A similar concept is that a circles circumference is composed of an infinite number of infinitely small line segments joined together and are set or positioned at an infinitely small angle, nearly 0°, with respect to the previous one. If that circle then "grew" or increased to a very large size, a small portion of its circumference would begin to appear as if it were a straight (non-curved), unbent or "flat" (level) line segment. A circles area can be closely approximated using a large number of these infinitely small line segments as a base of identical triangle with a height equal to the radius (r) of that circle. [FIG 38]



If the circumference (C) of a circle is C=10.75ft., what is the radius and area of that circle?

The formula (standard expression) for the circumference (C) of a circle in relation to its radius (R) is:

first, $\mathbf{C = \pi D}$: π is the pi (pronounced as "pie") symbol, and you may sometimes see this expressed using a simple text symbol as (p) or (pi), as in this book. For example: C=pD
Pi is an abbreviation for the Greek word "periphereia" (periphery, ie., perimeter), and its modern use for the circle is generally credited to mathematician Leonhard Euler in about 1750.

p , (("pi") or PI), is not a variable but is a symbol for a numeric constant that has a value of about 3.141592654. The appendix section of this book contains a derivation of pi, area, and the circumference of a circle. The value of p is equal to the circumference (C) of any circle divided by its corresponding diameter (diagonal or across measurement) (D) which is the greatest distance across the circle. **p = C / D**. Mathematically, (p or pi) is the ratio of a circles circumference to its diameter. It is how many times longer that the circumference is than the diameter. Pi is a strict numeric value that does not have any associated units such as for length, and is simply a plain, numeric factor value. Given any circle, its circumference is always larger by a factor of about 3.14 times more than its diameter. The diameter, when considered or represented as a line segment, always passes though the center of the circle from and to the circumference. The radius (R, or r) of a circle is the distance from the center of a circle to its outer perimeter, hence it is equal in length of half the circle's diameter. The word "radius" is rooted in the word "ray", such as a ray of light that extends outward from a source.

For a specific given circle that remains a constant size, the radius, diameter, and circumference are not variable in value, but are constant (specific, unchanging) values for that circle. All circles are similar, but are not identical (the same) if they are of different size and-or have different values or parameters (radius, circumference, diameter, area) in their construction.

$R = \frac{D}{2}$ hence: $D = 2R$

therefore, $\mathbf{C = pD}$: **CIRCUMFERENCE OF A CIRCLE** (in terms of its diameter)

$C = 3.1415\underline{9}\ D$: a simplified, approximate formula for the circumference of a circle

$C = p2R$: Rearranging the values to express a more standard form so that the decimal
$\mathbf{C = 2pR}$ number comes first as a typical numerical coefficient of a term.
: This is the circumference of a circle in terms of its radius.

$C = 2(3.1415\underline{9})R = 6.283\underline{2}\ R$: a simplified, approximate formula for the circumference of a circle

From $C = 2pR$, after solving for R:

$\mathbf{R = \frac{C}{2p} = \frac{D}{2}}$: **RADIUS OF A CIRCLE**

$R = \frac{C}{2(3.1415\underline{9})} = 0.15915\underline{5}\ C$: a simplified, approximate formula for the radius of a circle. This indicates that the radius is about 16% of the length of the circumference.

Substituting the values given in the example:

$R = \frac{10.75\text{ft.}}{2(3.14159)} = \frac{10.75\text{ft.}}{6.2832} =\sim 1.71091$ ft.

Also, since $C = pD$, $\mathbf{D = \frac{C}{pi}}$ **: DIAMETER OF A CIRCLE** , pi = about 3.1415$\underline{9}$

$D = \frac{C}{3.1415\underline{9}} = 0.3183\underline{1}\ C$: a simplified, approximate formula for the diameter of a circle. This indicates that the diameter is about 32% =~ (1/3 = 0.3333...) of the length of the circumference, or that the circumference of a circle is slightly more than 3 times its diameter length.

The following example may be too advanced, involved or lengthy for some people, and they can just skip it for now, and consider viewing it at another time.

Ex. The orbit of Earth around the Sun is circular-like. Since the Earth is about 93 million miles away from the Sun, how many miles does it travel in its orbital path around the Sun in the following periods of time : In 1 year, in 1 day, in 1 hour, in 1 minute, and in 1 second? Here are some useful formulas:

distance = speed x time **: DISTANCE FORMULA** (the units of distance are length units)

This will find the distance that a moving object has traveled or moved. Distance is directly related to speed and time. The faster you travel, and the longer the time you travel will increase the distance you traveled. "speed" is sometimes called the "rate" (ie. intensity) or velocity of travel. **velocity = (change in distance) / (change in time)**
If 0 is the initial values for distance and time, the equation reduces to:
speed = distance / time : this is much like an average velocity

An object that can or is moving will travel a distance or length from its starting and reference (ie. 0) position. The total distance or length it will travel depends on how fast it is going. The word "fast" used in this way, is equivalent in meaning to the word "speed". If something is moving greater or faster per, or for each, unit of time, such as a second or an hour, the greater the distance it will have moved after that amount of time.

Ex. If you traveled at 50 miles per hour (50mi/1hr) for 2 hours total time, the total distance you traveled is:

$$\text{distance} = \text{speed x time} = \frac{50\text{mi}}{\underset{+1}{\cancel{1\text{ hr}}}}\ \frac{\overset{+2}{\cancel{(2\text{hr})}}}{(\ 1\ )} = 100 \text{ miles}$$

Mathematically, from the distance formula, we can derive the formulas for its associated variables:

$$\text{speed} = \frac{\text{distance}}{\text{time}} \quad \text{and} \quad \text{time} = \frac{\text{distance}}{\text{speed}}$$

Notice that for a fixed distance value, that speed and time are inversely related. In short, as time increase, speed decreases, or vice-versa. If speed is higher than a previous speed, the time to travel a given (fixed value, constant) distance will be lower.

The distance of 93 million miles = (93)(10^6)mi. is actually Earth's radius (R) of orbit or path about the Sun. Hence:

Circumference of orbit about the Sun = 2pR = 2p(93)(10^6) miles = 584,336,233.6 miles

Since the orbit takes 1 year to complete, Earths speed is therefore: 584,336,233.6 miles/year.

Since there are close to 365 days in 1 year (1 year = 365 days), we can find the orbit speed or distance traveled per day if we divide the yearly orbit distance by 365, essentially creating an equivalent fraction.

$$\frac{584{,}336{,}233.6 \text{ miles}}{365 \text{ days}} = \frac{1{,}600{,}921.188 \text{ miles}}{1 \text{ day}} = 1{,}600{,}921.188 \text{ miles/1 day} = 1{,}600{,}921.188 \text{ miles per day}$$

: 1 year is actually 365.25 days

We would also get this result if you simply canceled out the denominator (ie. set it equal to 1) by dividing the numerator and denominator by 365 without actually creating the equivalent fraction.

Since there are 24 hours in 1 day, (24h = 1d), we can find the orbit speed or distance traveled per hour if we divide the daily orbit distance by 24:

$$\frac{1{,}600{,}921.188 \text{ miles}}{1 \text{ day}} = \frac{1{,}600{,}921.188 \text{ miles}}{24 \text{ hour}} = \frac{66{,}705.04949 \text{ miles}}{1 \text{ hour}} = 66{,}705.04949 \text{ miles/1hour}$$

Since there are 60 minutes in 1 hour, we can find the orbit speed or distance traveled per minute if we divide the hourly orbit distance by 60:

$$\frac{66{,}705.04949 \text{ miles}}{1 \text{ hour}} = \frac{66{,}705.04949}{60 \text{ minutes}} = \frac{1{,}111.750825 \text{ miles}}{1 \text{ minute}}$$

Since there are 60 seconds in 1 minute, we can find the orbit speed or distance traveled per second if we divide the minute orbit distance by 60, and to keep the fraction in balance or equivalence, it must also be done to the numerator:

$$\frac{1{,}111.750825 \text{ miles}}{60 \text{ seconds}} = 18.52918042 \text{ miles/second}$$

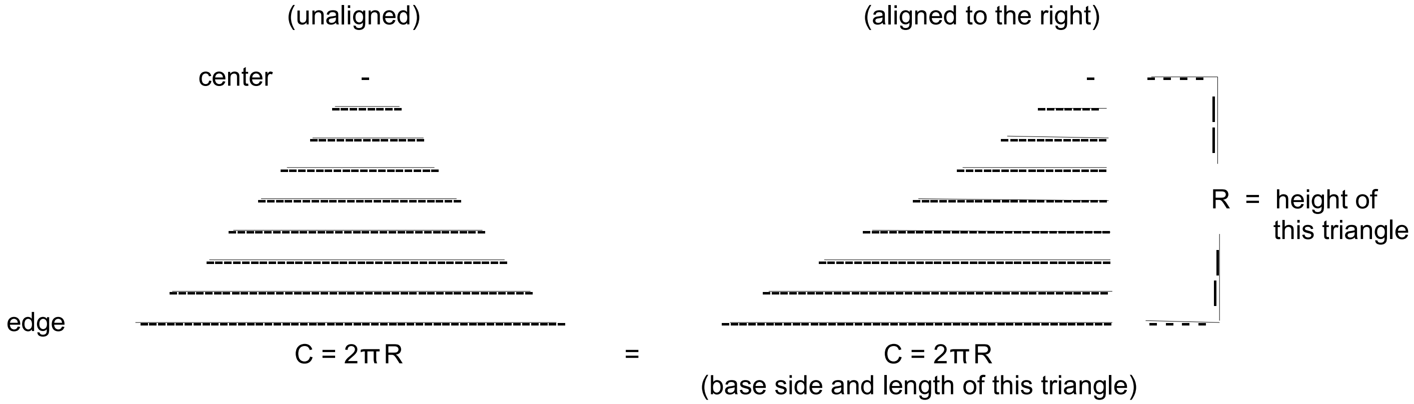
We don't notice this speed since we are relative (in relation to) to Earth's speed. That is, we are also going a distance of 18.53 miles per second around the Sun so there isn't any new accumulated distance between us and the Earth so as to even notice this speed. The difference between our speed and the Earth's speed is practically 0.

The formula or standard equation for the area (A) of a circle or disk surface in relation to its radius is derived below:

Given a circle, and creating an infinite number of concentric (all having the same center point) circles, "rings" or "shells" within it, the width of each ring will approach a thin width close to 0 (but never actually reaching 0 since there would not even be a possible ring to consider). The length (ie. circumference) of each ring will go from C=2(pi)R at the outer edge of the circle to 0 at the center point of the circle. The area of each ring will essentially be that of an infinitely thin rectangle. Here is the area of the outer ring:

-- = width : C = Circumference of the circle
C = 2πR = outer length : R = radius of the circle

Stacking all the rectangle areas and aligning them to the right, their combined width or height is obviously equal to the radius of that circle, and the structure has the shape of a triangle: [FIG 39]



The area of the circle is then equivalent to the sum of the areas of all the thin rectangles, or simply the area of the right-triangle created as seen above when all the rectangles are aligned to their right side. The triangle created is a right triangle and its area is therefore equivalent to the area of the circle from which it came from:

$$Ac = At = \frac{bh}{2} = \frac{CR}{2} = \frac{(2\pi R)(R)}{2} = \boldsymbol{\pi R^2}$$

: AREA OF A CIRCLE OR DISK
: b = base side of triangle , h = height of triangle

(The letters (c) and (t) are not variables, but are called subscripts (of the variable). Here, they are used to specifically identify what kind of area or what the area is in reference to. Here, (c) is used for circle, and (t) is used for triangle. Variables Ac and At are now unique variables, that is, they are not similar or "like" variables or terms, and they have and represent a unique thing and value each. If more than one circle was to be identified, a subscript or number would usually follow (c), for example: Ac1, Ac2, C1, C2, r1, r2, etc.).

This derivation of the area of a circle above is a good hint of what the branch of mathematics called calculus is about in general: the summing of the very small parts of the "whole" in order to find out what the "whole" actually is, or, it is finding a particular (the mathematical value, or equation of a) small part. The appendix contains another derivation of the area and circumference of a circle.

This derivation above is also a simple verification to the general formula for the area of any triangle: At = (bh)/2. Clearly a right triangle is half the area of a rectangle which also has the same dimensions, but as graphically shown above using two triangles, for as long as the base and the height of any two triangles are equivalent, their areas are always equivalent. Using this method, a formula for the area of parallelogram can be verified by using a square. The general formula for the area of a triangle will be verified in the TRIGONOMETRY section of this book.

Continuing the problem given previously:

A = πR^2

A = (3.14159)(1.71ft.)^2
A = (3.14159)(1.71ft.)(1.71ft)
A = 9.18632(1ft. x 1ft.) = 9.18632ft.^2 or=: 9.18632 square-feet

While on the topic of circular areas, here is a discussion of the size and comparison of circular areas, specifically when the diameter (or radius) is doubled or halved:

Ex: There are two circular areas, one with a diameter of 5 inches and the other with twice the diameter with 10 inches. How many times greater is the area of the larger circle? Since 10 is double or twice of 5, you might first assume the area is double (2), triple (3), or perhaps some value like 3.14. Since area is actually based on 2 linear dimensions, and if they are doubled, the result is that the area is 4 times greater, and this increase and factor will be shown algebraically below.

The area of a square (s) is: A=s^2 , with (s) being the side length of the square. Given a square with side (s), and when this length is doubled to (2s), the area of that square is:

As = (2s)^2 = 4s^2 : hence 4s^2 / s^2 = 4 times greater than that before doubling the side length

Likewise, if the side length is tripled, the area would be increased by 9. We have verified that when the sides of a square or rectangle increase by a factor, then the area increases by the square of that (linear) multiplying factor.

For the two circles mentioned in the example: r1 = d1/2 = 5/2 = 2.5 , r2 = d2/2 = 10/2 = 5 , and their areas are:

A1 = (pi)(r1)^2 A2 = (pi)(r2)^2 : the second circle, with area A2, has twice
A1 = (3.14159)(2.5^2 in^2.) A2 = (pi)(5^2 in^2) the diameter as the first circle with area A1
A1 = 19.635 in^2 A2 = 78.54 in^2

The (factor) increase (expressed as a ratio) of A2 in comparison, reference or respect to A1 is:

$$\frac{A2}{A1} = \frac{78.54\ \text{in}^2}{19.635\ \text{in}^2} = 4$$

Showing this in general terms algebraically if the radius (r) of a circle increases by a factor of N:

$$\frac{A2}{A1} = \frac{(\text{pi})Nr^2}{(\text{pi})\ r^2} = \frac{(\text{pi})N^2r^2}{(\text{pi})\ \ r^2} = N^2$$

: Area will multiply in value equal to the square or second power of the multiplying factor to the radius.

Using this information, it is now reasonably clear that if it is said that the diameter or radius of a circle is halved, then the area will be 4 times less:

$$A2 = (\text{pi})(r1/2)^2 = (\text{pi})(r1^2/4) = (\text{pi})(r1^2) / 4$$

:where r1 is the radius of the original circle. The area will be divided by 4, hence 4 times less.

Dividing by 4 is the same as multiplying by $(1/4) = 0.25$

r2 is noted at being half of r1: $r2 = r1/2 = 0.5\ r1$, Hence $r2/r1 = 1/2 = 0.5$

If r1 was changed by this factor value of 0.5, then area will change by this factor value squared:

$$\frac{A2}{A1} = N^2 = 0.5^2 = 0.25 = (1/4)$$

: A2 is a "fourth" of A1, as mentioned above

Extra: $\frac{\text{area of circle}}{\text{circumference of circle}} = \frac{Ac}{C} = \frac{(\text{pi})\ r^2}{2\ (\text{pi})\ r} = \frac{r}{2} = 0.5\ r$, mathematically: * $Ac = \frac{C\ r}{2}$, and $C = \frac{2\ Ac}{r}$

* : hence with this equation: Ac = **(**one semi-sphere length of the circle = C/2**)** **(** r **)** =
Ac = (Half the Circumference) (Half the Diameter) = (length) (width) units^2 . This can be seen by drawing a circle and "straightening" out the upper semi-sphere length, and then swinging the two radius lengths connected to that so as to be at a right angle to it. This rectangular area (which can be thought of as being constructed of many rectangles whose length is that radius value) is greater than the semi-sphere area due to that gaps (extra space) in that area were introduced by straightening the curve of the circumference. After overlaying the lower semi-sphere area, a solid rectangle is created whose area is equivalent to the area of that circle. A **sphere** is a three dimensional geometric structure and-or volume that is basically a **ball shape**.

$$\mathbf{Acircle = Arectangle = (length)(width) = (C / 2)\ (r) = (2\ (pi)\ r / 2\ )\ (r) = (pi)\ r^2}$$

$$Ac = (C / 2)\ (D / 2) = ((\ 2\ (\text{pi})\ r) / 2\ )\ (\ r\ ) = (\text{pi})\ r^2$$, also:

$$Ac = (C / 2)\ (D / 2) = CD / 4$$

Another derivation for the area of the circle is to consider it being composed of the summed area of a larger to infinite number (N) of thin triangles with their base (b) side along the circumference and whose height is the equal to the radius of that circle. $Ac = N\ (At) = N\ (b\ r / 2) = (Nb)\ r / 2 = C\ r / 2 = (2(\text{pi})r)(r) / 2 = (\text{pi})r^2/$
Note above that: $C\ r / 2$ = (area of a rectangle or parallelogram) / 2 = (area of a triangle)

Extra: From: $C = (\text{pi})\ D$ and $A = (\text{pi})\ (D / 2)^2 = (\text{pi})\ D/4 = (\text{pi})\ r^2$

$$(\text{pi}) = \frac{C}{D} = \frac{A}{r^2}$$, we have: $$r^2 = \frac{AD}{C}$$

It must be mentioned that the mathematical relationship between area (A) and perimeter (P) of any two objects is not always a corresponding or direct relationship. The relationship can be an inverse relationship, that is, It is possible for the area of an object-1 to be smaller than the area of object-2 even though the perimeter of object-1 is larger than the perimeter of object-2. Consider the simple example below where the units of measurement are considered the same for both rectangles: [FIG 40]

Ex.

From: Perimeter = sum of each side of an object:

P1 = 10 + 10 + 1 + 1 = 22　　　　P2 = 7 + 7 + 2 + 2 = 18

From: Area of a rectangle = (length)(width):

A1 = (10)(1) = 10　　　　A2 = (7)(2) = 14

The mathematical conclusion of this example can be expressed as:

$P1 > P2$: > means "greater than". Arrow points to the smaller value. "Perimeter 1 is greater than perimeter 2."

$A1 < A2$: < means "less than", still, the arrow points to the smaller value. The larger or "open" end of the arrow indicates the larger value. These symbols and their use are discussed next. "Area 1 is less than area 2."

When the length and width of a rectangle are the same value, the ratio of the length and width of the perimeter of a rectangle are 1, and the rectangle will have the largest possible area, and this shape is that of a square which is a special instance or case of all the possible rectangles. When the length or width are not equal, one side, usually the width, is a fractional of the length, the longest side.

More about expressing mathematical differences or relationships will be discussed next in the topic of inequalities.

INEQUALITIES

An inequality is when two or more things are not the same or mathematically equal. An inequality can be considered as an equation that is out of balance and-where the left and right sides are not equivalent (=). The way to determine if things are equal is to simply subtract their values, and if the result is 0, there is no difference among them, and they are therefore equal. If they are not equal in value, there is a difference between those two values, and one value will be greater than the other value, and one value will be less than the other value. < and > are symbols which are examples of what are known as relational or conditional syntax (grammar, notation). This syntax is used to show or express a mathematical or numerical relationship of the actual values, or a supposed (conditional) relationship as for a some kind of question ("if such and such") or test (performed mathematically, usually by subtraction, such as for computers) or determination of a value or relationship so as to simply express, or to do, or not do something.

The mathematical expression of a mathematical relationship is called a (mathematical) statement. A statement is sometimes noted as being a (mathematical) "sentence". Here is a symbolic, general format of a mathematical statement:

(expression) (mathematical relationship) (expression) : statement

Statements where the mathematical relationship is not one of equivalence (ie. equals) are often called inequalities. Here are the common mathematical relationship operators and what they mean:

relation or condition	meaning, or read as:
>	"greater than", ex: a>b is read from the left to the right as: "(a) is greater than (b)"
<	"less than"
= or: ==	"equivalence" : used in statements called equations, there is no inequality here
>=	"greater than or equal"
<=	"less than or equal"
≠ or: !=	"not equal" or: /=/ series of standard text characters as sometimes used in this book.
~ , ~= or =~	"approximately equal to", "about equal to", "equals about" ex. 5.1 ~= 5

Ex. Express all values of (x) being greater than five.

$x > 5$: This can be read as "x is greater than 5"

Here, (x) can be a specific value greater than 5, or it is a general representation for all values greater than 5. This can also be expressed as:

$5 < x$: This can be read as "5 is less than x",
Expressed this way, it gives more of a significance to 5, such that
it makes it like the focus of the statement, or reference value.
The statement also indicates: "x is greater than 5":

Hence: $x > 5$ or= $5 < x$: again, the tip of the arrow points to the smaller value or side

Ex. a /=/ c : "a is not equal to c"

Ex. Express the quantity of (x+1) being greater than or equal to 5.

$x + 1 >= 5$

To solve for values of (x) that satisfy this relationship, solve the inequality just like solving an equation:

$x + 1 >= 5$ T. +1, so add or combine -1 to each side :
$x + 1 - 1 >= 5 - 1$ C. and we find that:
$x >= 4$

If you multiply or divide each side of an inequality by a negative signed value, the direction (or "sense") of the inequality sign must be changed. The example below will illustrate and verify this:

Ex. We already know by common sense, or according to a number line, that both of the following statements are true:

$5 > 4$ and $-5 < -4$: both statements are right, correct, true

```
      -8 <--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|---------> +8          : [FIG 41]
 (lesser)  . . . - 5     -4      -3      -2      -1       0      +1      +2      +3      +4      +5 . . .   (greater)
```

If this number line was a road, this is what some direction signs located at any point on it would look like:

(greater -->) : values that are greater, are in the rightward direction, (regardless of your current position)
(<-- less) : values less are in the leftward direction, (regardless of your current position)

Multiplying each side of both of the inequalities expressed above by (-1), but not changing the "sense" or relationship:

$5 > 4$ and $-5 < -4$
$(-1)(5) > (4)(-1)$ $(-1)(-5) < (-4)(-1)$
$-5 > -4$ $5 < 4$: both relationships are wrong, incorrect, false

According to the number line, both of these statements are now false. To true these statements, simply change the direction of the relationship indicated between the members (expressions) or sides of each statement. The results will then be equivalent to the true statements shown at the beginning of the example.

HOW A COMPUTER MAKES DECISIONS

After considering the previous discussion, the same mathematical grammar, notation or syntax is often used with modern electronic, digital computer programming languages to make decisions on what to do next, such as displaying a value on the screen or adding some values, or perhaps what not to do next - such as even jumping-over (skipping-over, not-processing) some computer code (program, steps) statements. You can skip over this section if you are not currently interested in this topic and-or computer programming. Since the syntax and it's corresponding meaning was already defined before computers, their is no need to replace it with something else for computer use. To determine if the computer should do something, some condition (essentially a test, or determination) must be met (be satisfied or true) by determining that a certain mathematical relationship is true. This is accomplished with some appropriate computer code (a piece or part of the entire computer program that instructs the computer to do things). This particular type of code is formally called a conditional statement. When the computer is processing or "running" a program, it will process the mathematical (relational) statement part in the conditional statement. The computer (or even you can) determines if a conditional statement is true by subtracting the two values (operands) on either side of the conditional symbol. For example, to determine if two variables, or perhaps a variable and a constant, are equal, their difference must be 0. As another example, to determine if one variable or value is less than or greater than another, their difference will be checked to be either positive or negative in sign. In short, a computer makes decisions by the mathematical comparison (comparing) of two or more values by essentially using subtraction to find their difference.

Ex. Using a basic, generic or "pseudo" computer programming instruction, language, or code:

if (a=b), then do (this) : "if a equals b then do this" , "this" could be for example, incrementing the value of a variable, going to another part of the program, make a sound, display some text, a print command, or to do something else. "do this" means process the following command(s) and-or other statement(s) if the stated relationship (here (a=b) is true.

When a = b, they both have the same value and therefore, there is no change or difference (separation, change) from one to the other. The computer will subtract b from a, and if the result is 0, they are equal, and the "do this" part of the computer program will be processed since the expressed relationship is true, otherwise, the "do this" will not be processed since the conditional (or test) statement is false, and will be skipped over to the next line of the computer instructions (ie., computer program). For C-language computer programs, since (=) is used to set a value of a variable, the notation or "syntax" of: (==) is used to check or determine an equivalence, and the above pseudo conditional statement would be: if(a==b){ then do this; };

Ex. if (5 > 10) :Check and determine if 5 is greater than 10 , or= is 10 is less than 5 , since: (5 > 10) = (10 < 5)

To find out if this condition stated is true, subtract that which is considered, or assumed, as being truly less from that which is assumed more or greater, as indicated by the conditional symbol. Since 5 was the first value expressed, it is the reference value for this statement which asks if 5 is greater than 10. Performing a subtraction operation to find out:

$$\begin{array}{r} 5 \\ -\underline{\ 10} \\ -5 \end{array}$$

or: $(+5) - (+10) = 5\ (+)\ (-1)10 = +5\ (+)\ -10 = -5$

: the negative sign of the difference indicates that 5 is not greater than 10, and the condition, test or question of: is (5>10)? , = is false = 0 : Computer systems often use a binary number that is physically or electronically represented using a voltage value of 0 for false and 1 for true. true (1) and false (0) are logic (truthiness, "truth" and-or deciding "decision") values.

Here, for the question (if) and (logic, truthfulness = truth) condition and mathematical relationship (5>10)? , that the actual value of the result, other than 0, does not matter and has no further use here, but what does matter is the sign of the result since we are looking to see if the relationship is true or false only. The negative sign indicates that the mathematical relationship is not possible, hence the relationship cannot be true, and therefore the conditional statement evaluates to false = untrue = not-true. As a simple illustration, it is false that you can physically give away 10 apples if you (only) have 5 apples. It is true that you can give away 3 apples if you have 5 apples since you will have +2 apples leftover or remaining. A computer has a special memory (data or information storage implemented via electronic circuitry) location that indicates ("flags") the mathematical sign (pos. + , = 1 , or neg. -, = 0) of the result of an arithmetic operation after performing it. Another memory location indicates if the result's value is 0 which means no difference. This will allow for conditionals such as: "equivalence", and the "greater-than-or-equal" dual-conditional where both the "sign" and "zero" flags are then both checked after the subtraction, and both need to be set to 1 for that conditional statement to evaluate (or result, "return") as true = 1 to the computer program being used to control or direct the computer system to do things. If a certain bit at a memory address or location, such as a "flag register" and "flag bit" is set to 1, it is sometimes said as that bit or location is "set", otherwise if is 0, it is said as "not set". The word "**bit**" has its origin in the word of "bite", and that a bit is the piece of the entire object or food that was bitten. Later, a grouping of 8 bits was called the word "byte" in digital and-or computer terminology. Interestingly, the word "bit" could also be considered as based on the ancient word of "cubit" which is unit and-or measure of an amount of length.

As an example consider this pseudo-code (generic code expressed with literal statements, generally adaptable for any computer language) of a conditional statement, and the possible syntax for it:

```
 if (condition is true) then do something     or:   ?(condition) then (do something)  ,  Ex:  if ( P2  <  P1) then do something
```

The "do something" in the above statement is computer program code (coding, instructions, statements, "steps", commands, often written in plain text) to perhaps change the value of a variable, or code to branch (go to) to another portion of the program to do something else, or to evaluate the logic (truth or falseness) of another conditional statement. If the condition that the relationship stated is true, it will be "flagged" (remembered or indicated) as 1=true, then the "do something" code will be processed by the computer. If the relationship stated is false, it will be "flagged" as 0=false, then "do something" will not be performed and that portion of computer code will simply be ignored by "ignored", "jumped over", or "skipped over", and the program will then continue processing ("running") at the next computer code.

With modern-day "high-level" (plain text) computer programming languages, the eventual and actual computer (strict numeric) code (steps) to find the difference and branch to the "do something", or not, is then converted and written as an equivalent machine language program. Machine language and programs are a "low-level", fundamental computer language which is strictly a numeric (digital, binary) code language so as to be compatible with the electronics of the computer, and specifically the CPU which is the "Central Processing Unit" to execute (ie., "run") programs, usually built as an integrated circuit ("chip") inside the computer system. Higher level languages such as BASIC convert the much more mentally easier to understand, more readable (as ASCII text and understandable words) programs into machine code.

A plain text, readable "high-level" computer language that the computer programmer types in will later be processed with the aid of another general computer program called a compiler program that gathers and compiles (ie., combines to a single piles) together the "readable" program parts (variables, values address, etc.) and transform it into its equivalent, low-level, machine program that an electronic machine, such as a computer, can effectively understand or work with, and which is very much like (logically to physical electronic voltages) controlling, setting and resetting, many on-off switches of that machine. Note that it is still possible for a programmer to initially write (faster) actual machine code or language programs, and a helpful program to do this is with a program called an "assembler", of which itself often has its own (minimal) syntax called "assembly language", and these programs are then called assembly (language) programs. In pure (digital, numeric input, control) machine language, "strict (ie., only)" numbers that are input and stored as digital, binary numbers in its memory would be used for commands and-or data to process (ie., use, work with). For example, 00000100b = 4d might be the documented instruction (ie., command, or "opcode" = operation code = machine code) to add the values (ie., the operands of the addition operation) in two memory locations and-or (operand) "registers" and place the output or result in another memory location, and the equivalent for the assembly language program would use a mnemonic (pronounced as "nuh-maa-nik", and is associated with the word memory, and is another word, abbreviation, or symbol(s) so as to represent and be easier to use) for that instruction or command such as ADD, and this helps the programmer understand what is being done in the program and makes it easier to write and-or edit later. In a high level language such as C, we can more easily read and write (for example, using more common English language) expressions and-or program statements (much like a complete set of instructions or a sentence) for what we want done, and the compiler program will quickly create all the corresponding machine code from that for us. Here, the machine is the computer's central processing unit (CPU, digital circuit, on chip(s)) and the rest of the computer system that will run (ie.

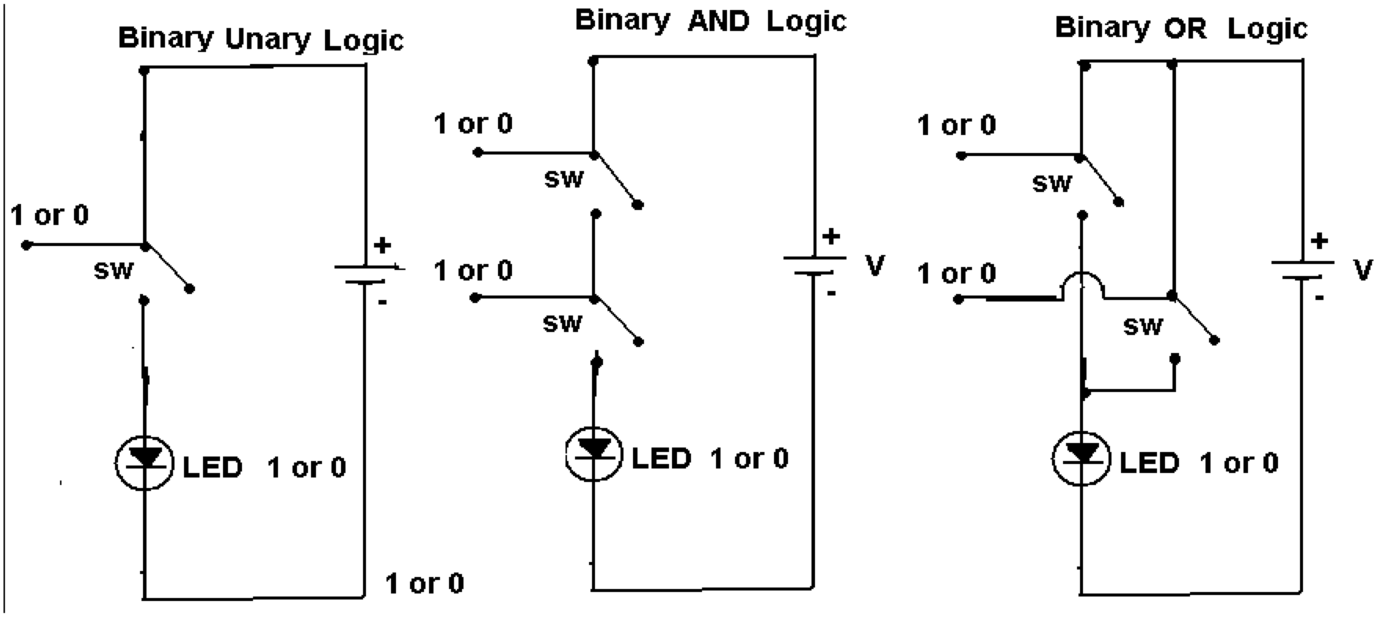
process, execute, utilize) that computer program. For example, the C statement: c = a + b; will add the operands (a) and (b) that are each stored at a memory location that is identified and accessed by the program as (a) and (b) respectively, and the result is assigned to variable (c) that it and-or its value is assigned to another memory location to hold (numeric, digital) data.

Finally, if something or some process is to be performed depending upon the truth (ie. the logic or logic state) of more than one conditional statement, a special syntax is often used. The symbols of this syntax are called logical operators. The operands of a logical operation where truth (numerically represented as 1), or falseness (numerically represented as 0) is to be determined are conditional statements used to determine the truth of a mathematical relationship. The two most common logical operators are called the AND and OR operators. The AND symbol is usually something like: &&, and the OR symbol is something like: ||, however for some programming languages (such as BASIC), or a generalized pseudo-code language, they may be simply noted as: AND and OR. AND is used when all the conditional statements must evaluate (result) to true for a logically true result. OR is used when either or both conditional statement must evaluate to true for a logically true result.

if (condition1) AND (condition2) then do something : This logical operation uses the logical operator: AND Logical operations operate on the results of conditional statements whose results are either true (which can be mathematically represented as a value of 1), or false (which can be mathematically represented as a value of 0). Electronically, a condition could be considered as an input of a 1 or 0 value or result.

Ex. if ((P1 < P2) && (A1 < A2)) then do something
The English translation is typically something as the following:
"If P1 is less than P2, AND if A1 is less than A2, then do something."

Because the logical AND operator is used, for something to be performed, both of the two (logical, true or false) conditions shown must first evaluate to be logically true (1). For OR logic or an OR Gate, if either input is 1 or set, the output is 1. [FIG 41B]



SW = switch, here shown as a mechanical on-off (ie., on or off) switch, but it could also be an electronic switch or "current valve" such as a transistor. Connected to each switch is a logic or data, input control line or pin which can electronically open or close the switch, and that if it set at a high enough voltage (often 5V standardized), which can be described as a binary 1 value or set, then the switch will also be set or closed so as to allow current to flow and the LED will be lit, on or set which can also be described logically as binary 1, logical 1 or digital 1 when lit, or 0 when off or not set or lit. In binary, unary logic, only one binary (either 0 or 1) and-or logic value (true=set=1, or false=notset=0) at the input will determine the binary and-or logical output of either 0 or 1. Simple binary logic or binary **unary** or single logic can be thought of as a **single switch** that can be ON=1 or OFF=0 and have the same corresponding logical output of 1 or 0. Negative or inverse logic is when a binary value is converted to its opposite value where 1 becomes a 0, and a 0 becomes a 1. A single transistor can be used to create either a switch (ie., a gate) to control current flow, much like a relay, or to be an "inverter" which is also called a "not gate" or "(binary) complement" of which will invert the logic or state (ie., logic status) of a binary value. The above circuits are also called "logic gates" for it can be said that it is the input logic (truth, binary on, or binary off, open or closed, set or not-set, or logical 1 or 0) and (logic) gate (ie., like a "logic or binary filter", here implemented as circuits) that determines output (ie., 0 or 1) which is based on the input values. Note for example that it is possible to construct an AND gate with more than two or more inputs, and that all would have to be set to 1 so as to produce a 1 output. A NAND gate is a Negative-AND gate of which inverts the logic of the output of the initial AND gate. If the logic result of the AND section is 1, it will be inverted by an inverter and sent to the output as a 0.

Before the invention of the modern-day electronic, digital or binary computers, there were mechanical, analog computers. These often contained gears and rods. One of the oldest found mechanical, analog computers is known as the **Antikythera mechanism** which is a (hand cranked powered, turned) mechanical computer having thin, fine bronze gears and which could calculate and-or predict many astronomical events in the past or future. It was made by the ancient Greeks and has been scientifically estimated to have been made around 75BC to 100BC, due to the carbon dating of wood pieces, and other items having a known antiquity date. The device was found in a submerged shipwreck in 1901 near the Greek island Antikythera in the Mediterranean Sea, and it is considered as an incredible discovery. The delicate device was encrusted by debris and had to be x-rayed so as to find much further details about it. An obvious speculation is what other mechanical computers, metallurgy, machine and-or **gear** (a rotational disk [cog or cogwheel] that is a part of a mechanical [ie. force and-or power] transfer method, and having teeth or protrusions about its circumference so as to interconnect [without slipping in their motion] with another gear) knowledge and technology was available at its time and that which came before this, and was the production of such devices very limited, and were there many less complex, and less costly mechanical devices available to the general public. Later, similar fine metal gear work would be found in the clocks made in the 1500's. Surely, hundreds of years of astronomical observations, calculations and knowledge had to be already known so as to produce a **automatic computing** device such as the **Antikythera mechanism or calculator**. By 1000AD, the Arab civilization of the middle-east made further progress in the sciences, including mechanical devices, most likely assisted by the decimal, positional numeric system first invented in India and then refined and used by the Arabs so as to express formulas and make calculations. Numeric counters and-or displays before the electronic digital age used gears and-or wheels. The Antikythera mechanism is a "hard coded" computer, that is, it is a (mechanically) pre-programmed (by using specific gear sizes, etc) device to do only specific (astronomical) calculations that it was designed to do. Many computer processes are repetitive and-or cyclic, and a wheel or gear is a mechanical device that can be used to do and-or control such processes. As for electronic computers, at the core of their repetitive and or cyclic processes is a (high speed) electronic oscillator (ie., creates repetitive vibrations or pulses having a uniform clock-like timing, that which causes oscillations, "back and forth" motion) which for its specific use here in a computer, it effectively replaces the older, slower and larger sized technology, mechanical rotating wheels or gears, springs, cams, etc. of a mechanical oscillator and-or clock which needs to be regularly adjusted and-or reset. An electronic computer is not analog (analogue, analogy, similarity or representation) in nature, but rather digital (ie., discrete steps, approximation) and capable of being very fast, especially in terms of numerical calculations and data processing.

[This space for edits.]

RATIOS

A ratio is a value and-or numerical expression for the numerical relationship of two values. This (ratio) numerical relationship and value is created when the two values are expressed in fractional form and-or divided form, and then calculated to find the resulting value or ratio. In "simple terms" (ie., a simple explanation), it is how many times (like a multiplying factor) larger that the dividend or numerator value is with respect to the divisor or denominator value. Likewise, the denominator value could be said as being that many times smaller. Hence a ratio value it is much like a quotient or result value of a division problem. It must also be noted that even though quantities with unlike units are often (mathematically, numerically) compared like a ratio, true or formally defined ratios will have quantities with the same units so that the resulting ratio value is unitless and only a simple numeric value that is how many times that the numerator value is greater than (more, magnified) or less than the denominator value. Ratios and their concepts are very important and useful, for example, for magnification values, and for an equivalent portion ("ration") or fraction of something that is bigger or less than another similar thing of reference.

In terms of true fractions representing a value less than 1, a (fractional) ratio can be thought of as a simple numerical representation of an expressed fraction, and that ratio value will always be between 0 and 1 after dividing the numerator by the denominator. Here, two fractions are shown to have and represent the same ratio or portion of something, and therefore both have the same ratio value and are therefore equivalent fractions: 3 / 4 = 0.75 and 4.875 / 6.5 = 0.75
The numerical value of a fraction can be thought of as a relative value or percentage that the numerator is part of the denominator. A value between 0.0 and 1.0 in percentage form is a value between 0% and 100%

First, here is a short and practical discussion of why ratios are used.

We can compare two values, and can do it first with words that simply say or express that one value is less than, equal to, or greater than another value. We can express these states or conditions mathematically with the relational operators of: (<, = and >). If the values are different, we can mathematically quantify and express how different they by finding their difference with a subtraction operation. This is one way to compare two values. This is not practical if the values are not in relation or respect to the same thing, for example: If there is 5 objects in one box, and 8 objects in another box, the number of objects is different in each box, and their difference is (8 objects - 5 objects) = 3 objects. However, if there is 5 houses and 8 total people in all the houses, we cant compare people to houses and express it as a difference of either houses or people because it just doesn't make much practical sense: 8 people - 5 houses? , or 5 houses - 8 people? What we can do is create, express and quantify their numerical relationship as a ratio:

8 people/5 houses or 5 houses/8 people : "8 people per 5 houses" , or "5 houses per 8 people"

Note that with ratios, the parts of a numerical relationship don't need to have the same units of measurement. Here, the amount of people, and amount of houses are not even fractional parts of the same thing as would be for example: 5 objects out of 10 objects expressed as: 5 objects/10 objects, and even then, the result is strictly a numeric value, here 0.5 = 50%. Since the units were the same, it can be said that 5 objects is 50% of 10 or all the objects being considered. With the ratios of people and houses, the ratio can be expressed as a (non strict) numeric value or ratio, or perhaps even expressed with a new named unit that is a composition of the specific units used:

The ratio of people to houses is: 8/5 = 1.6 : This result is expressed as a strict or pure numerical quantification, and the result is to be considered more like a numerical average or possibility only , rather than the actual number of people in each and every house.

8 people / 5 houses = 1.6 (people/house) = "one point six people per one house"

The ratio of houses to people is: 8/5 = 0.625
5 houses / 8 people = 0.625 (houses/people)

Ex. If you have two apples and five oranges, the ratio of apples to oranges (meaning the quantity of apples compared with, or with respect or in reference to, the quantity of oranges) is said to be "two to five", which is mathematically expressed as: 2/5 = 0.4/1 ("zero point four, to one", or simply 0.4) after reducing the fraction to lower terms. It is incorrect to convert this decimal value to its equivalent percentage and say that 40% of all the fruit is apples. NOTE: This value of 0.4 really means that the quantity of apples only is 0.4 times larger than the quantity of oranges only. The value of "all the fruit" is actually the number of both apples and oranges, and which is (2+5) = 7 fruits.

The ratio of apples to oranges is: $\frac{\text{apples}}{\text{oranges}} = \frac{2}{5} = 0.4$: apples and oranges, being different fruits, cannot be physically or mathematically compared or combined to produce more of either. The expressions here just represent the quantities of the apples or oranges. The words of: "apples" and "oranges" are being used here like mathematical variables that are only numeric in value.

Mathematically the number of: apples = 0.4 oranges

If the number of apples equaled the number of oranges, their ratio would be 1. For the result value of 0.4, it can be said that, for every 1 orange, there are 0.4 apples. That's almost half an apple, or 0.5 apples for ("per") each orange

As mentioned, tt is incorrect to convert this decimal value to its equivalent percentage and say that 40% of all the fruit (both apples and oranges) is apples. This value of 0.4 really means that the quantity of (only) apples is (only) 0.4 times larger than the quantity of (only) oranges. Since 0.4 is less than one, it is a fraction, hence the number of apples is only a fraction and will be less than of the number of oranges. The can be clearly seen since 2 is less than 5, and therefore, 2 is only a fraction or part of 5.

The ratio of oranges to apples is: $\frac{\text{oranges}}{\text{apples}} = \frac{5}{2}$: "five to two", or by canceling:

$\frac{\text{oranges}}{\text{apples}} = \frac{2.5}{1}$: "two-point-five to one", or simply 2.5 times more oranges
This form is an expression for a "fundamental or unit" ratio.
Mathematically: oranges = (2.5) apples

Clearly with the numbers shown that for every 1 apple, it can be said that there are 2.5 oranges. Likewise, it can be said that there are 2.5 oranges per 1 apple. Note that 0.4 and 2.5 are reciprocals of each other and that these two corresponding ratio's may sometimes be noted as being "reverse" or "inverse" ratios. If you converted both of these ratios to their corresponding percentages, their combined percentage is: 40% + 250% = 290%. Clearly, this is incorrect since the total quantity of fruit cannot exceed its whole or entire self = 1 = 100%. Since apples is part of the total quantity of fruit, to find the percentage of (all) the fruit that is apples only, the quantity of apples must be mathematically compared, by a division by the total quantity of fruit, hence by taking the ratio of apples with respect to the total quantity of fruit (and not just oranges):

$\frac{\text{apples}}{\text{fruit}} = \frac{\text{apples}}{\text{apples + oranges}} = \frac{2}{2+5} = \frac{2}{7} = 0.2857...$: The ratio of apples to, or of, all the fruit is 0.2857... "~ 28.6% of all the fruit is apples", and the ratio of apples to oranges is 0.40 = 40%

The remaining fruits' (oranges in this example) percentage can be found by:

Whole = Sum of parts and for this example:
Whole = (part apples) + (part oranges) algebraically:
part oranges = Whole - part apples
part oranges = 1.0 - 0.285714285 : can optionally use percentages: 100% - 28.57%
part oranges = 0.714285714 : "71.43% of the fruit is oranges"
As a check:

$\frac{\text{oranges}}{\text{fruit}} = \frac{\text{oranges}}{\text{apples + oranges}} = \frac{5}{2 + 5} = \frac{5}{7} = 0.714\underline{3} = 71.43\%$: 5 parts of 7 total parts

PROPORTIONS

The concept of proportions (same, "similar", proper or equal portions) is a concept of having the same portion or fraction of the whole or entirety as that of a similar reference has. When two things (items, parts, portions) are mathematically compared to each other as a fraction, portion or rate, and then if two other things are compared and have that same exact value, then the mathematical relationship between those to fractions, ratios or portion values is said to be proportional (ie. having the same or portion, "within proper proportions"). The word "portion" which means: "a part or fraction of". The word proportion, as a noun, is a combination of the prefix "pro", which means: "for", "in favor of", "consistent with", or "similar". **Proportional** or "**proportional in value**" means having and keeping a consistent or constant mathematical portion and-or relationship (among the parts of the whole). Since a portion of something is a fraction of that something, proportions also means equal portions or equivalent fractional parts, either physically and-or numerically. The concept of proportions has been briefly mentioned previously in this book.

Ex. ratio1 = ratio2

$\frac{2}{4} = \frac{5}{10}$ Since ratio1 = ratio2 , the numerator represent the same part or portion of denominator, and that ratio and equivalent portion of the whole is 0.5. These two equivalent fractions are proportional.

If you were to magnify (make larger, or possibly smaller - a demagnification) a construction such as a square or triangle to be smaller or larger, that construction is said to be a similar construction because it looks (and is mathematically, as in a certain measurements, such as the ratios of any two corresponding parts) the same as that of the source or initial reference construction. Given a source construction, and you magnify it by a value to produce a larger, new and similar shaped construction, all the individual parts (or portions) of the new construction will also be magnified by that same value. To magnify values mathematically, we can "grow" (increase, or possibly decrease) or change all those values by multiplying them by the same (factor) value. Note that adding the same value to a group of different values will not equally magnify all of them by the same value, and this was mentioned when creating equivalent fractions where multiplication by the same value must be used.

Lets look at some of the basic mathematics of proportions:

Given (a) and (b), perhaps two sides of one construction, we can "mathematically magnify" all of them so as to create a similar looking new construction, either bigger or smaller, by multiplying each by the same value of (n):

$a(n) = (an)$ and $b(n) = (bn)$: parenthesis are used around both (an) and (bn) to help show, or give clarity, that each values represents a different value than (a) or (b).

(n) is also the multiplying or "magnification" factor of the entire new construction in relation to the source or reference construction. It could be said that the second construction is "n times bigger" than the first construction. If (n) is not known, it can be found by dividing the two values of the corresponding (similar) parts of the two similar constructions, so as to find their ratio:

$\frac{(an)}{a} = n$ and $\frac{(bn)}{b} = n$

Ex. Construction2 is similar to, and larger than construction1. If a certain part, say part A1 of construction1 has a value of 5, and the corresponding part, say part A2 of construction2 has a value of 35, how many times bigger is that part and-or construction since all of its parts were also magnified by this same value so as to have a similar and larger construction?

$\frac{\text{part of construction2}}{\text{corresponding part of construction1}} = \frac{A2}{A1} = \frac{35}{5} = 7$: "seven times" bigger. All the parts, and and the construction, are n=7 times bigger.

This ratio value indicates that part A2 is seven times bigger than the similar (same) or corresponding part A1. Since the constructions are similar, each part has also been magnified or increased by the same (factor) value and the ratios of all corresponding parts will be this same value of 7. All the parts of construction2 can be said as being proportional or "of or with the same portion" to all the corresponding parts of construction1. Likewise, construction2 is therefore also said as being proportional to construction1. When constructions are proportional like this, even the ratio of any two parts of construction2 is equal to the ratio of the two corresponding parts of construction1, and these parts and-or their values are also said to be proportional or having the same portion (fraction of) or ratio value. In general, the ratio of any two parts within a single (unmagnified) construction does not necessarily have or need this same ratio value, however, this ratio of parts within one construction will be equal to the corresponding ratio of the two similar parts in a magnified or similar construction.

The reciprocal of (n) could be thought of as the "demagnification" factor. Given (an) and (n), to solve for (a), we divide (an) by (n), which is the same as multiplying by the reciprocal of (n), which is (1/n):

$a(n) = (an)$ dividing both sides by (n):

$\frac{a(n)}{n} = \frac{(a\cancel{n})}{\cancel{n}} = a$ or by indicating the reciprocal of (n) more clearly:

$$\frac{(1)\,a(n)}{(n)} = \frac{(1)\,(a\cancel{n})}{(\cancel{n})} = a$$

Ex. For the last example, the magnification factor was 7. If we multiply A2 by the reciprocal (here, 1/7) of this magnification (specifically here, by a shrinking, or reducing) factor, we will find A1.

Since $\frac{A2}{A1} = 7$, $A2 = 7\,A1$, $A1 = A2/7 = A2(1/7) = (A2)(0.1428\underline{6}) = 35/7 = 5$

We can take the ratio of the values of these two parts (a and b) of one construction before and after a magnification. One value will become the numerator, and the other value will become the denominator. This will essentially create two fractions that are equal since both the numerator and denominator have been multiplied by the same value. Expressing this mathematically:

$\frac{a}{b} = \frac{an}{bn} = r$ or perhaps a this subscript notation that indicates which construction that instance of the part, side or variable (value of that side) is in reference to:

$$\frac{a1}{b1} = \frac{n\,(a1)}{n\,(b1)} = \frac{a2}{b2} = r$$

(r) is the common or constant ratio value of all these and any other equivalent fractions, and similar (but magnified) constructions. Note, as shown above, (r) is not the magnification value that is to be (or was) applied or to all the parts of any one construction (so as to make a larger construction) since (n) is that value. (r) is sometimes called the "constant of proportionality" which indicates a constant (same value) numerical relationship among (with respect to) any two, or more, specific parts of any one construction, or of the same specific parts of a magnified (similar) construction.

Given a two parts of one construction, their mathematical relationship (ie. ratio), (r), may not be the same as that from another two of that same construction. Though the magnification (n) values between various sized similar constructions can be different, (r), the mathematical relationship of a specific set of parts of one construction, is always constant for all similar (magnified) constructions. Each part of a similar construction is numerically the same portion, fraction or percentage of that entire construction or other parts of that construction. Each part(s) is said to be of, or as having similar proportions as that of a similar reference or source construction.

Observe these equivalent fractions:

$\frac{2}{4} = \frac{4}{8} = \frac{6}{12} = 0.5$: r = 0.5, = ratio value of numerator to denominator for all similar fractions, and-or the ratio value of two parts of each similar construction

$\frac{2(2)}{4(2)} = \frac{4}{8}$: n = 2 = "magnification value" applied to an entire set of parts of one (reference) construction, or the "magnified value" within or of all parts of a similar construction. r=0.5

$\frac{4(1.5)}{8(1.5)} = \frac{6}{12}$: n = 1.5 , r = 0.5

$\frac{2(3)}{4(3)} = \frac{6}{12}$: n = 3. , r = 0.5 , with same values of (r), the portions are the same

We see that (n), the magnification factor of similar constructions can vary, and yet the ratio of any two parts of one construction is equal to the ratio of the two corresponding parts of all similar (magnified) construction.

When both numerator and both denominator values of two ratios differ in value by the same factor, those values and each expressed ratio are said to be proportional or in proportion to each other. In simple wording, when two ratios are equal in value, they are said to be (equally) proportional to each other. These ratios are equivalent fractions that represent, and are numerically equal to, the same portions or parts. Hence, two fractions with the same value can also be set equal to each other just like an equation (of two equivalent fractions) and solved just like one. This type of equation of two equal portions or fractional values is therefore often called "equivalent portions", "proportions" or a "proportion problem", and they are of great use when changing units or when something is grown (magnified, expanded) bigger or even smaller such as for the amounts to be used in, for example, a construction or a recipe or other mixture.

Proportional means having and keeping a consistent or constant mathematical portion and-or relationship (among the parts of the whole). Since a portion of something is a fraction of that something, proportions also means the same or equal portions or equivalent fractional parts, either physically and-or numerically. The concepts of equivalent fractions has been mentioned previously in this book.

In short, proportional means equivalent fraction parts or portions of the whole part. Two parts or entire constructions consisting of several parts, can only be said as being similar if all the corresponding parts of both constructions have the same portions with respect to each other, hence being proportional (same portions or fraction of). To magnify a given construction by a certain (magnification) value, so as to create a similar construction, you must also magnify each and every part by that same value or factor. The entire two constructions are then said to be similar in (visual) shape and function, and (mathematically) proportional since the ratio value of any two parts of one construction will have the same ratio value of the two corresponding parts of any similar construction.

The example below will verify the common mathematical constructions and methods of solving a proportion type of problem.

Ex. A certain mixture of metals is 15% copper and 85% tin. If 5 pounds are tin, how many pounds of copper are in the mixture?

First, since the percentage of tin is more than that of copper in the mixture, the weight of the tin in that mixture will be likewise be more than the weight of the copper in that mixture.

.

From the information given in the question, we can write some equations:

85% of total weight = 5 lb : can think of 85% from: part weight/total weight = 5lbs/total weight = 0.85,
15% of total weight = x lbs therefore mathematically: (0.85)(total weight lbs) = 5lbs

(total weight) (0.85) = 5lb : tin , 0.85 is the decimal equivalent of 85% , to be used for the calculations
(total weight) (0.15) = xlb : copper

From these, we algebraically have:

$$\text{total weight} = \frac{5\text{lb}}{0.85} \qquad \text{and:}$$

$$\text{total weight} = \frac{x\text{lb}}{0.15}$$

Equating the two (equivalent) expressions for total weight, we have a common expression of an equation for a proportion type of problem. With practice, this could be written just from the information given in such problems:

$$\frac{5\text{lb}}{0.85} = \frac{x\text{lb}}{0.15}$$

: This can be read as: "5lbs is to 85%, as xlbs is (equivalent or equal) to 15%".

Solving for xlb in the equation of (equivalent) proportions, or "proportion equation", we have:

$$x\text{lb} = \frac{(0.15)(5\text{lb})}{0.85} = 0.882\text{lb}$$

: pounds of copper in the mixture

The reciprocal of each side of the equation for the above proportion will also yield the correct result for xlb, if you happened to write the fractions and equation that way:

$$\frac{0.85}{5\text{lb}} = \frac{0.15}{x\text{lb}}$$

: This can be read as: "85% is to 5lbs, as 15% is to xlbs".
xlb = 0.882lb

Though the total weight could have been found from the original equations written, we can also find the total weight from the left hand side of the proportion equation by performing the indicated division:

total weight = 5lb/0.85 = 5.882lb : since (amount or weight of copper) = (total amount or weight)(0.85)

However, finding the total weight this way (with the specific right side expression known to be equal to the total weight) from the proportion equation may not of been intuitive (natural to you) that this was the only equation needed to solve the problem. As a check to this result, we can also create an expression for the total weight from:

total weight = (weight of tin) + (weight of copper)
total weight = 5lb + xlb = (5lb + xlb) = (x + 5)lb

Substituting this value into the original expressions:

(x + 5)lb (0.85) = 5lb : tin
(x + 5)lb (0.15) = xlb : copper

Let's solve for x, the weight of the copper, using the second equation:

(x + 5)lb (0.15) = xlb distributing:
0.15x + 0.75 = x transpose 0.15x:
0.75 = 1x - 0.15x combining like terms:

$0.75 = 0.85x$ dividing both sides by 0.85, and switching sides:

$x = \frac{0.75}{0.85} = 0.882\underline{4}$ lbs :checks

Given any other sized mixture or volume of the two metals, as long as 15% is copper and 85% is tin (as specified in the formula or recipe), the mixtures are said to be proportional ("within or having proper portions") to each other since they both contain the same portion, ratio or fractional part value of each metal used. Also, the "internal ratios" of each single construction or mixture, such as he ratio of copper to tin, or tin to copper, will also be a constant value. Those parts are also said to be proportional to each other in each instance of the mixture or construction..

From the previous equation:

$\frac{5\text{lb}}{0.85} = \frac{x\text{lb}}{0.15}$ From this we can derive and can mathematically express the ratio of the two ratios or parts percentages, and the ratio of their corresponding weight values:

$\frac{0.15}{0.85} = \frac{x\text{lb}}{5\text{lb}}$: ratio of portions = ratio of weights

$\frac{\text{copper}}{\text{tin}} = \frac{15\%}{85\%} = \frac{0.15}{0.85} = \frac{0.8824\text{lb}}{5\text{lb}} = 0.17648$: percentages and weights ratios of copper to tin, are equivalent

Note that the weight of copper is 15% of the entire weight of the mixture of the metals:

$\frac{\text{copper}}{\text{tin}} \;/\!=\!/\; \frac{\text{copper}}{\text{copper + tin}}$: these two expressions cannot be equal (have the same quotient or ratio) since the denominators are different. (copper + tin) = (total weight)

$0.17648 \;/\!=\!/\; 0.15$

Total Weight = weight of tin + weight of copper
Total Weight = 5 lbs + 0.8824 lbs
Total Weight = 5.8824 lbs

$\frac{\text{copper}}{\text{total weight}} = \frac{\text{copper}}{\text{copper + tin}} = \frac{0.8824}{5.8824} = 0.15 = 15\%$

Ex. In a mixture from a recipe, there are 2 cups of sugar, 3 cups of flour, and 1 cup of another ingredient. The ratio of sugar to flour can be mathematically expressed as:

$\frac{2 \text{ cups}}{3 \text{ cups}} = 0.667$: sugar/flour

However, it is incorrect to say that 66.7% of the entire mixture is sugar since the 1 cup of another ingredient was not even included in the calculation. Since there are more ingredients, the percentage of sugar in the mixture will then be less than 66.7%. To find the actual percent that is only sugar in the entire mixture is to have the ratio of the amount of sugar with respect to the total amount used for all the ingredients in the mixture. The units of each value must all be the same and consistent. For this example, cups are the units of measurement:

$$\frac{\text{amt. sugar}}{\text{amt. of all ingredients}} = \frac{2\text{ cups}}{2\text{ cups} + 3\text{ cups} + 1\text{ cup}} = \frac{2\text{ cups}}{6\text{ cups}} = 0.333 = 33.3\%\text{ sugar}$$

$$\frac{\text{amt. flour}}{\text{amt. of all ingredients}} = \frac{3\text{ cups}}{2\text{ cups} + 3\text{ cups} + 1\text{ cup}} = \frac{3\text{ cups}}{6\text{ cups}} = 0.50 = 50\%\text{ flour}$$

$$\frac{\text{other ingredient}}{\text{amt. of all ingredients}} = \frac{1\text{ cups}}{2\text{ cups} + 3\text{ cups} + 1\text{ cups}} = \frac{1\text{ cups}}{6\text{ cups}} = 0.16\underline{7} = 16.7\%\text{ other ingredients}$$

Summed together, we see that the sugar and flour comprise 33.3% + 50% = 83.3% of the mixture.
The sum of all the ingredients or parts portions is: 0.333 + 0.50 + 0.167 = 1.0 = 100% : the whole or entire mixture

If twice the amount of each ingredient is used to double (2) the amount or size of the mixture, there would be 2x2=4 cups of sugar, 3x2=6 cups of flour, and 1x2=2 cups of another ingredient. The percent of sugar, and flour in this mixture is then:

$$\frac{\text{amt. sugar}}{\text{amt. of all ingredients}} = \frac{4\text{ cups}}{4\text{ cups} + 6\text{ cups} + 2\text{ cups}} = \frac{4\text{ cups}}{12\text{ cups}} = 0.333 = 33.3\%\text{ sugar}$$

$$\frac{\text{amt. flour}}{\text{amt. of all ingredients}} = \frac{6\text{ cups}}{4\text{ cups} + 6\text{ cups} + 2\text{ cups}} = \frac{6\text{ cups}}{12\text{ cups}} = 0.50 = 50\%\text{ flour}$$

We see that the portion, or relative amount, of sugar in each mixture is always 33.3%, and the portion of flour in each mixture is always 50%. Each of the two mixtures is said to consist of the same fractional value or portion of a given ingredient. This is the basic essence of the concept of proportion - when the portions of something are always consistent regardless of the actual sizes or specific amounts (of units) being considered. Also, the ratio of the portions of sugar and flour in any one and all similar mixtures or "constructions" of the recipe (plan, steps, method, ingredients)) will always be the same value of:

$$\frac{\text{sugar}}{\text{flour}} = \frac{0.333}{0.50} = 0.667 \quad \text{: for any similar (magnified=increased or demagnified=decreased) batch or construction using that recipe}$$

Because of the portions (ie., percentages) of sugar and flour are to be always the same value, the actual amounts of sugar and flour used for any similar mixture of this recipe are also said as being proportional to one another. Since the ratio of the portions of sugar to flour is always 0.667, a constant, all similar ratios of sugar to flour in various sized mixtures or instances of this recipe will be equivalent, and these equivalent ratios are called (equal, same) proportions.

Using the actual amounts of each ingredient in a mixture, the amount of sugar will always be 33.3% of the mixture, and the amount of flour will always be 50% of the mixture, and the ratio of the amount of sugar to the amount of flour will always be 0.667

Checking: $\frac{2\text{ cups}}{3\text{ cups}} = \frac{2(2)}{3(2)} = \frac{4}{6} = 0.66\underline{7}$:66.7% sugar

Considering just the mixture of the sugar and flour, what percent of this mixture is sugar?

$$\frac{\text{sugar}}{\text{sugar + flour}} = \frac{2}{2 + 3} = \frac{2}{5} \quad 0.40 = 40\%\text{ sugar}$$

You will often read that a construction such as a model or "blueprint" (a type of photographic copy of a drawing, and where the background is a blue color due to a chemical reaction to light, and the subject or drawing is a white color) is "geometrically proportional" to the actual (reference) construction of something. What does this mean? The easiest way to answer this question is that by observation. They are proportional since they look exactly alike, except that one is larger or smaller than the other. This size, its "largeness" or magnification effect can even be achieved simply by viewing any one construction at different distances that are closer or farther from you. Now, the mathematics of constructions that are said to be proportional will be considered:

Ex. Now observe these two simple and similar constructions that have a triangle shape: [FIG 42]

construction 1 construction 2

In these similar constructions, sides (a) and (c) are corresponding sides, and (b) and (d) correspond to each other. Even though there are only two constructions, they are said to be (mathematically) proportional and are truly similar constructions if all the corresponding ratios of sides are the same.

Construction 1 and 2 are proportional if:

$\frac{a}{c} = \frac{b}{d} = r$: r = ratio value of each equivalent fraction

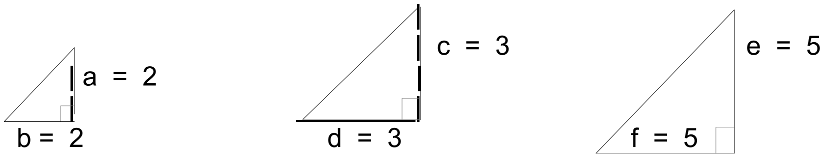
(n), the "magnification value" of each corresponding part is not indicated, but it is the value used to create any equivalent fraction and (magnified or indemnified) construction by multiplying all its parts by this same value of (n). In general (n) is a different value and concept than (r). Expressing this:

$\frac{a}{c} = \frac{a(n)}{c(n)} = \frac{b}{d} = r$: r = ratio value of each equivalent fraction or portion of all similar constructions
: n = magnification (factor) value used to created a unique similar construction

Given two corresponding sides of two similar constructions, you can find the magnification value. For example, since (c) is the magnified value and corresponding side to (a):

From: $a(n) = c$, therefore: $\frac{c}{a} = n$

Any two corresponding sides, or lengths, of any two geometrically proportional constructions will have a specific ratio. Note also that this ratio is not necessarily the same constant as shown for the two constructions in the example above. The specific value of the ratio of similar constructions, depends on the specific parts being considered. To help you understand this, consider all the infinite and different "magnifications" possible. As long as all the ratios of any sides or parts of one construction are equal to those of another construction, the constructions are still geometrically proportional or similar. For example, here are three constructions that are geometrically proportional. Basically, they are magnifications of one another: [FIG 43]



construction 1 construction 2 construction 3

$\frac{c}{a} = \frac{d}{b}$: ratios of corresponding parts of two similar constructions

$\frac{3}{2} = \frac{3}{2} = 1.5$

$$\frac{e}{c} = \frac{f}{d}$$

$$\frac{5}{3} = \frac{5}{3} = 1.6\underline{7}$$

Likewise, for example:

$$\frac{e}{a} = \frac{f}{b}$$

$$\frac{5}{2} = \frac{5}{2} = 2.25$$

Clearly, the ratios are different (due to the magnification value (n) applied to the values of all the parts of one construction, so as to create a similar construction), but still, the ratio (r) among specific parts of any one (similar) construction will always be the same as that of any another similar construction. Here, for example, one specific ratio of sides happens to be:

$$\frac{a}{b} = \frac{c}{d} = \frac{e}{f} = 1.0$$

: note for example that a and b are sides of the same construction, c and d are the corresponding (similar, or in reference to a and b) sides of another, such as the first construction.

It is important to note that we can mathematically derive ratios among corresponding sides of two similar constructions (here, in the example they happen to be triangles):

From: $\frac{a}{b} = \frac{c}{d}$

These are equivalent fractions and corresponding ratios of two sides of each construction. Here, each is an equal ratio value, this (before magnification is even considered) is the fundamental meaning of things or parts of a construction being proportional, or kept in proportion, among themselves. If a construction is magnified, all of its parts are automatically kept in proper proportion having the same fractional value of the whole. From this, we can mathematically derive other ratios between two constructions. From the above equation, if we multiply each side by (b), and divide each side by (c) we get:

$$\frac{a}{c} = \frac{b}{d}$$

or : $\frac{c}{a} = \frac{d}{b}$

: Ratios of corresponding sides of two similar constructions. Due to the various possible magnifications (n) possible for similar constructions, equations of their sides, as shown here, may not have the same values, as shown previously. The only thing that can be said here is that given any two specific similar constructions, the ratio of corresponding sides will be the same. This value is also the "magnification factor" (n, m, or f) for only these two specific similar constructions.

One method often taught for solving for a variable in an equivalent fraction or proportion type problem is to "cross multiply" the numerators to the denominators, effectively ridding the expressed fractions on both sides of the equation, but you should realize that this is essentially the result after proper multiplication and canceling has occurred.

Ex. Solve for (x) given: 2 is to 4, as 5 is to (x).

Mathematically, this can be expressed as:

$\frac{2}{4} = \frac{5}{x}$ this may also be expressed as: 2:4 as 5:x , 2:4 = 5:x , 2 to 4 = 5 to x
2 per 4 = 5 per x , 2 parts of 5 = 5 parts of x , and:

2 is to 4 as is 5 is to x

$$\frac{\overset{+1}{\cancel{(4x)}}(2)}{(1)\underset{+1}{\cancel{(4)}}} = \frac{(5)\overset{+1}{\cancel{(4x)}}}{\underset{+1}{\cancel{(x)}}(1)}$$

: C. clearing or canceling fractions by multiplying both sides by the LCD of the entire equation, and here it is 4x.

$2x = 20$: after D. distributing. This would be the same result after "cross multiplying" numerators and denominators together on opposite sides of the original equation

$$\frac{\overset{+1}{\cancel{2}}x}{\underset{+1}{\cancel{2}}} = \frac{\overset{+10}{\cancel{20}}}{\underset{+1}{\cancel{2}}}$$

: isolate x, so divide by its multiplying factor of 2

$x = 10$ Checking using the decimal equivalents of the ratios on both sides of the equation:

$$\frac{2}{4} = \frac{5}{10}$$

$$\begin{array}{r} 0.5 \\ 4\overline{)\,2.0} \\ \underline{2.0} \\ 0 \end{array} = \begin{array}{r} 0.5 \\ 10\overline{)\,5.0} \\ \underline{50} \\ 0 \end{array}$$

$$0.5 = 0.5$$

Ex. At an apple orchard, the workers picked 15 baskets of apples. They counted a total of 450 apples in all the baskets. The next day, they picked 24 baskets of apples. How many apples are expected or estimated to be in the 24 baskets without going through the long process of actually or physically counting each one?

This problem can be solved using an equivalent proportion or equivalent fraction equation such as:

450 apples is to 15 baskets, as (x) apples is to 24 baskets.

$$\frac{450 \text{ apples}}{15 \text{ baskets}} = \frac{x \text{ apples}}{24 \text{ baskets}}$$

Obviously, whenever the number of baskets of apples is larger, the total number of apples should likewise be larger. That is, the corresponding (such as the numerators, here apples, or the denominators, here baskets) numerical values that compose each equivalent fraction and ratio are said to be "proportional" or more correctly as: "directly proportional" or "directly related". If you increase (ie. magnify) or decrease the number of baskets by some factor, the total number of apples will correspondingly increase or decrease by this same factor. If the number of apples picked increases or decreases by some factor, the number of baskets needed to hold those apples will correspondingly increase or decrease by the same factor. The number or quantity of apples or baskets is said to be directly proportional. This keeps each physical portion or part of each new similar construction (here, apples or baskets) to have the same mathematical portion or fractional value with respect to the other parts of that construction. Mathematically, a proportion is essentially an equivalent fraction concept, and you can solve for the variable as if you were creating an equivalent fraction, otherwise, just solve it just like an equation.

First, in a true ratio form. the numerators and denominators are the quantity of similar things or quantities with the same or like units. The result (the ratio value) is a unitless or pure mathematical value:

$\dfrac{\text{new number of apples}}{\text{old number of apples}} = \text{a ratio} = \dfrac{\text{new number of baskets}}{\text{old number of baskets}}$: this ratio here is actually the magnification (n) value of similar (proportional) constructions

Mathematically, we can get another ratio from the above proportion:

$\dfrac{\text{old number of apples}}{\text{old number of baskets}} = \dfrac{\text{new number of apples}}{\text{new number of baskets}}$ = this a different ratio (r) and value than (n) is

Continuing the example:

Equation Method:

$\dfrac{450\text{ apples}}{15\text{ baskets}} = \dfrac{x\text{ apples}}{24\text{ baskets}}$ isolate x, here, we will multiply each side by (24 baskets):

$\dfrac{\overset{+1.6}{\cancel{(24\text{ baskets})}}(450\text{ apples})}{(\quad 1 \quad)\underset{+1}{\cancel{(15\text{ baskets})}}} = \dfrac{(x\text{ apples})\overset{+1}{\cancel{(24\text{ baskets})}}}{\underset{+1}{\cancel{(24\text{ baskets})}}(\quad 1 \quad)}$: c. cancel

$(+1.6)(450\text{ apples}) = x\text{ apples}$ d. distribute:

$720\text{ apples} = x$ or by switching sides:

$x = 720\text{ apples}$: 15 baskets is to 450 apples, as is, 24 baskets is to 720 apples , or
450 apples is to 15 baskets, as is, 720 apples is to 24 baskets

Equivalent Fraction Method:

$\dfrac{450\text{ apples}}{15\text{ baskets}} = \dfrac{x\text{ apples}}{24\text{ baskets}}$

The denominator on the right side of the equation is larger than the denominator on the left side by a factor of:

$\dfrac{\overset{+1.6}{\cancel{24\text{ baskets}}}}{\underset{+1}{\cancel{15\text{ baskets}}}} = +1.6$

To make a proper equivalent fraction, the numerator must also be changed (here multiplied) by the same factor.

$(450\text{ apples})(+1.6) = 720\text{ apples}$

$\dfrac{450\text{ apples}}{15\text{ baskets}} = \dfrac{(450\text{ apples})(+1.6)}{(15\text{ baskets})(+1.6)} = \dfrac{720\text{ apples}}{24\text{ baskets}}$

Note: Performing the indicated division on either side of the equation will give us the number of apples per basket (apples/basket). It also creates an equivalent fraction.

$\dfrac{450\text{ apples}}{15\text{ baskets}} = \dfrac{30\text{ apples}}{1\text{ basket}}$: or 30 apples/basket = "Thirty apples per basket" (a "unit ratio")

$\dfrac{720\text{ apples}}{24\text{ baskets}} = \dfrac{30\text{ apples}}{1\text{ basket}}$: or 30 apples/basket = "Thirty apples per basket" (same ratio)

This value of (30 apples/basket) which is common to both of the ratios shown, or any more that can be created for this proportional (equivalent portions or fractions) system, is known as a constant of proportionality of, or in each and every similar construction or instance. Hence, the total number of apples in the baskets can be simply found or predicted by multiplying the number of baskets by the number of apples known per basket.

$$(24 \text{ baskets})(30 \text{ apples/basket}) = \frac{(\overset{+24}{\cancel{24 \text{ baskets}}})(30 \text{ apples})}{(1)(\underset{+1}{\cancel{1 \text{ baskets}}})} = 720 \text{ apples}$$

If you like, you can substitute the word(s) of: "for", "for each", "for every", "to every", "in", for the "per" (/) symbol when reading the literary statements that contain it. Ex. "30 apples/1 basket", for example can be thought of as: "30 apples for every basket", or "30 apples to one basket". This may sometimes be simply spoken as "thirty to one", or mathematically expressed as : 30:1

Ex. 15 people is to 3 houses: 15 people / 3 house , We can create two equivalent fractions by dividing both the numerator and denominator by either the numerator or denominator so as to find the fundamental results for each unit of either people or houses:

1 people / 0.2 house or 0.2 house / 1 people, and 5 people / 1 house or 1 house / 5 people

Ex. A basic formula for some product might state that for each (that is, 1 mathematically) part or unit of substance A, there should be 3 parts of substance B. Note that here, A and B are not variables in an algebraic sense, but represent some physical materials. The word "part" as used in the context above means a general representation for any units of measurement used, for example, the parts could be ounces, pounds, kilograms, etc. The two parts might even be expressed as having two different units of measurement, for example: "Mix one gram of oil into every 3 liters of gas":

The ratio of A to B is 1/3 = 0.333333... (perhaps with units of "grams per liter" as: 0.333333 grams/liter)

$$\frac{\text{number of A parts}}{\text{number of B parts}} = \frac{1}{3} = 0.333333...$$

If you only used 0.75 parts of A, how many parts of B should you then use in order to ensure the parts have the same portions of the whole, or simply, so as to keep them proportional?

We know that the ratio of A to B is always a constant value of (1/3) = 0.333333 , regardless of the quantity of A and the corresponding value of B used for any instance or similar construction:

$$\frac{A}{B} = \frac{0.75}{B} = \frac{1}{3} = 0.333333 \qquad \text{solving for B:} \qquad B = 3\,(0.75) = 2.25$$

You could also solve for any quantity of A and B from the simple formulas of:

From: $\frac{\text{number of A parts}}{\text{number of B parts}} = 0.333333...$ we can mathematically or algebraically get:

$A = 0.333333\ B$ and:

$B = \frac{A}{0.333333} = 3A$: when given just two parts in a proportional system, the numerical coefficients of those values are reciprocals of each other

Here is a note about proportions:

Ex. You have the equivalent fractions or proportion of:

$\frac{X}{10} = \frac{1}{2}$, you can say that:

"X is one-half of 10" or = "one-half of 10 is X" : remember, "is" means "equals"

As a verification to these statements, consider this:

$\frac{X}{10} = (1/2) = 0.5$

Solving for X, we get: $X = (0.5)(10) = (1/2)(10) = \frac{10}{2}$: "X is one-half, or 0. 5, of 10". Any value divided by 2 is half of that value.

Ex. You have the equivalent fractions or proportion:

$\frac{5}{x} = \frac{1}{2}$: You can say that: "five is one-half of x" or = "one-half of x is 5"

Letting 1/2 = 0.5 be the quotient of 5/x,:

$\frac{5}{x} = 0.5$

Multiplying the divisor and the quotient to yield that dividend of 5, we see that the word "of" in "one-half of x is (equal to) 5" is mathematically expressed as a multiplication symbol, and the word "is" is expressed as the equals symbol:

$(0.5)(x) = 5$ after dividing both sides by 0.5:
$x = 10$

Ex. A cup of a liquid is defined as 8 fluid-ounces (oz.), which is actually a measure of volume. Weight measurements can also have units of ounces and is a measure of force. This similarity is due to that 1 fluid ounce volume of water is defined as having a weight 1 ounce. However, if the substance is not water, then 1 fluid ounce volume of that substance will no longer weigh 1 ounce of weight. How many (fluid) ounces are in 1/6 of a cup?

First, a more general or fractional approach:

Writing what we know about the relationship between cups and fluid-ounces of measurement:

1cup = 8oz. : 1 cup equals 8 ounces , this is an equation where each equivalent side is expressed as a quantity of different units.
1 is not equal to 8, but 1cup is equal to 8oz

1/6 ("one-sixth") of a cup implies a fraction of a 1 cup. (1/6) cup is one part of a cup divided into 6 equal parts = 1 part of 6 parts. (1/6) of 1 cup = (1/6) x 1cup. Which can be expressed as the following where a division (here of 1cup into smaller and equal parts) by 6 on both sides of the equation is used to express this fractional part:

$\frac{1\text{cup}}{6} = \frac{8\text{oz}}{6}$ simplifying the right side:

$\frac{1}{6}$ cup = 1.333...oz. : "one-sixth of a cup is (equivalent to) one point three, three ounces"

As an extra note, given that 1cup = 8oz., mathematically dividing both sides of this equation by either side, 1cup or 8oz., we can get:

$"1" = \frac{1\text{cup}}{8\text{oz}} = \frac{8\text{oz}}{1\text{cup}}$: since the numerators and denominators are equal (represent the same actual amount of substance, but with different units), the physical (not mathematical) volume ratio is 1. This can be read as "1 cup per 8 oz", and "8 oz per 1 cup".

Fractions like this are called "unity" (1) fractions or ratios. Here, the numerator and denominator represent the exact same amount or value of something, even though they are described differently using different values and units. Unity fractions will be discussed some more in the topic of changing units.

Now with the concept of proportions:

$\frac{8\text{oz}}{1\text{cup}} = \frac{X\text{oz}}{(1/6)\text{cup}}$ or=: $\frac{8\text{oz}}{1\text{cup}} = \frac{X\text{ oz}}{0.166...\text{cup}}$ solving for X oz.:

$X\text{ oz} = 1.33\text{oz.}$

Note also that: 1 cup / 8 oz , and dividing the num. and den. by 8: (1/8) cup / 1 oz or 1 oz / (1/8) cup = 1 oz / 0.125 cup

Ex. An objects true or actual height (H) is known to be 3.8 feet, and is measured to have a height (h) of 0.25 inches in a photograph. If the objects width (w) is measured to be 1.125 inches in the same photograph, what is a good estimate of the objects true width (W) ?

We can consider this a system with two similar constructions. One construction or instance is the real object, and the other similar and proportional construction is represented by an image on a photograph. These similar constructions are essentially magnified versions of each other, and the parts of each similar construction have the same mathematical portion of the whole part. One construction (here the photograph or image) is magnified or multiplied in value to create the larger construction. In a reverse type of manner, the larger construction is essentially demagnified" or multiplied by the reciprocal of the same value so as to create the smaller construction. It can be said that the larger construction is essentially divided by that same value (the magnifying or multiplication factor, n) to create the "demagnified" similar construction. We can solve this problem using proportions or equivalent fractions.

ratio in photograph = actual ratio of the reference construction or object

$$\frac{w}{h} = \frac{W}{H}$$

$H = 3.8\text{ feet} = (3.8\text{ feet})(12\text{ inches}/1\text{ feet}) = 3.8\,(12\text{ inches}) = 45.6\text{ inches}$: 1feet = 12 inches And used substitution, or by mult. both sides by 3.8

$$\frac{1.125\text{ in.}}{0.25\text{ in.}} = \frac{W\text{ in.}}{45.6\text{ in.}}$$

$$W\text{ in.} = \frac{(1.125\text{ in.})\,(45.6\text{ in.})}{0.25\text{ in.}} = \frac{51.3\text{ in.}\hat{}2}{0.25\text{ in.}\hat{}1} = 205.2\text{ in.}$$

$$W = 205.2 \text{ in.} = \frac{205.2 \text{ in. } (1 \text{ ft.})}{(12 \text{ in})} = 17.1 \,(1 \text{ ft.}) = 17.1 \text{ ft.}$$

: (1ft/12.in) is a "unity ("1") fraction"
Each inch is, (=), a fraction of a foot.
From 1ft = 12 in, equivalency or "unity":
Dividing both sides by 12 to solve for 1in:
1in = 1ft/12 = 0.083333ft, and to
have multiple inches, such as 205.2 here,
we multiply both sides of this by 205.2 to
have the equivalent number of feet.
From the expression above, we also get
these equivalent fractions:
(1ft/12in) = (0.08333ft/1in)
Here, the "magnification factor" is:
0.083333. Mathematically. from these
equivalent fractions. we can get:
(1ft/0.08333ft) = (12in/1in) = 12 which is
the reciprocal of the "magnification factor":
(1/0.083333) = 12

Checking: $$\frac{1.125 \text{ in.}}{0.25 \text{ in.}} = \frac{205.2 \text{ in.}}{45.6 \text{ in.}} = 4.5$$: the ratio of the width to the height in each similar construction

The similar construction magnification ratio (n) or factor is:

$$\frac{H}{h} = \frac{45.6}{0.25} = \frac{W}{w} = \frac{205.2}{1.125} = 182.4 \quad \text{or} \quad (1/182.4) = \text{about } 0.005482456 \text{ for demagnified constructions}$$

Up to now, the examples of proportions have been of the direct proportion type. Another type, perhaps not as common, is the inverse proportion type. With inverse proportions, a quantity is mathematically inversely related to another quantity. One way to think of an inverse relationship is to think of a quantity where getting "more when there is less" , or when getting "less when there is more". Algebraically, we know that a quotient (Q) is directly related to a numerator (N) value , and inversely related to the denominator (D) value:

$$r = Q = \frac{N}{D} \qquad : r = \text{ratio}$$

If the numerator increases, the ratio increases. If the numerator decreases, the ratio decreases. This is a direct mathematical relationship. If the denominator increases, the ratio decreases. If the denominator decreases, the ratio increases. This is an inverse type of mathematical relationship.

If an equation expresses the relationship between only two variables, and they are known to be inversely proportional or related to each other, then the numerator variable is not needed to express their relationship and it is replaced by (1), or changed to (1) using division if necessary:

$$B = \frac{1}{A}$$: essentially then, each variable is the reciprocal or "inverse" of the other. These variables are said to be (mathematically) inversely related to each other.

$$A = \frac{1}{B}$$ mathematically: $1 = AB$: the product of two corresponding reciprocals is 1.

Ex. It takes a (1) person to do a certain (1) job (such as make or repair something) in 1 hour. 2 people can work together and do that job in half the time or (1 hour / 2 =) 0.5 hours. Clearly, the variables of the number of people doing the work, and time to do that work, are inversely related. The more people working, the faster (less time) the job can get done. As we now know, this relationship cannot be expressed in the form of:

$\frac{N}{D} = r$ for example:

$\frac{1 \text{ people}}{2 \text{ people}} = \frac{1 \text{ hour}}{0.5 \text{ hour}}$: this is wrong since after canceling:

0.5 /=/ 2

Nor could this be expressed algebraically as something like:

$\frac{1 \text{ people}}{1 \text{ hour}} = \frac{2 \text{ people}}{0.5 \text{ hour}}$ since mathematically:

1 people/hour /=/ 4 people/hour : after canceling, or:

1 (people/hour) /=/ 4 (people/hour) : expressing or showing that (people/hour) is like a new unit of work

The proper form to use is that first discussed:

$r = \frac{1}{D}$ or $A = \frac{1}{B}$ using the variables stated in the example:

$\text{people} = \frac{1}{\text{time}}$ or mathematically:

$\text{time} = \frac{1}{\text{people}}$

Note, algebraically from each equation:

(people)(time) = 1 = 1(people)(time) = 1 (job completed) = 1 job = 100% job completed

(people)(hour) = 1

Checking that which was stated in the example:

$1 \text{ hour} = \frac{1}{1 \text{ people}}$

$0.5 \text{ hour} = \frac{1}{2 \text{ people}}$

If 4 people were all helping each other getting the job finished, it would take one-fourth the time: time/4 = time(0.25)

$0.25 \text{ hour} = \frac{1}{4 \text{ people}}$, or perhaps by using this equation:

1 job = 1 job : since 1 job = (people)(time), and using substitution of the problems values:

1 ((people)(hour)) = ((4 people)(x hours)) solving for x hours :

$$x \text{ hours} = \frac{1((\text{people})(\text{hour}))}{4 \text{ people}} = 0.25 \text{ hours} \quad \text{, or } = 15 \text{ minutes}$$

Note that for both instances:

(people) (time) = 1 : = 100% , one job completed

(people A) (time A) = 1 = (people B) (time B) = 1 job completed : here, A=of job A, B=of job B
(4 people)(0.25 hours) = (2 people)(0.5 hours) = (1 people)(1 hour) = 1 = 1 job finished or completed

We can now make ratios which will then express the problem as an inverse proportion or inverse equivalent fractions:

From: (people A) (time A) = 1 = (people B) (time B) we mathematically have:

$$\frac{\text{people A}}{\text{people B}} = \frac{\text{time B}}{\text{time A}}$$: A BASIC FORMAT EXAMPLE FOR AN INVERSE PROPORTION

Notice that the ratios are inverted, instead of having corresponding units in their numerators and denominators. In more general terms, if A is inversely related to B, as C is inversely related to D, the proportion is of this form:

From: $A = \frac{1}{B}$, and $C = \frac{1}{D}$ mathematically:

$AB = 1 = CD$
$AB = CD$ mathematically we can then get this proportion (but it's an inverse one):

$\frac{A}{C} = \frac{D}{B}$ Using the values from the example:

$$\frac{\text{people A}}{\text{people B}} = \frac{\text{time B}}{\text{time A}}$$

$$\frac{1}{4} = \frac{0.25}{1}$$

$0.25 = 0.25$: since the ratios are equal, the values are correct

DEFINING THE MATHEMATICAL RELATIONSHIPS OF VARIABLES

The formal name of how variables and values are mathematically related is called variation, specifically, it is how a variable varies (ie. changes) when others vary (change). Most of the concepts of variation have already been mentioned in this book.

When a value is mathematically directly related to another value, this is sometimes noted as direct variation. For example:

> The formula for the circumference (C) of a circle is: circumference = (pi)(diameter) = C = pD, and this has a more generic mathematical expression form that is technically called a "linear equation" (that graphs as a line since the ratio of the variables is constant) of:

$y = cx$: Where (c) is an arbitrary constant which is sometimes noted as the constant of variation. This is easily seen since c = y / x always (ie a constant). It is also the multiplying factor or numerical coefficient to x. c is often found from experimentation and/or calculation. A common example of a constant is in the formula for the circumference (C) of a circle where C=pD. Here, p="pi" is a constant of about 3.14159, and D is the diameter of the circle. For any circle with it's own circumference and diameter, p=C/D always. When c, the constant is not indicated, it is understood as being 1. The constant of variation can also be thought of as the constant in the relationship of the variables that can change or variate.

Here, (y) is directly related to (x). An indication that this is so is to recognize that (x) is essentially placed in the numerator of the right hand expression whose denominator is 1, or understood as 1 when not indicated. If (x) increases, (y) increases. If (x) decreases, (y) decreases.

If (y) is mathematically inversely related to (x), the expression would look something like this:

$y = \frac{c}{x}$: or can be expressed as:

$y = c\left(\frac{1}{x}\right)$: to explicitly express the reciprocal or inverse relationship of y and x.

This is known as inverse variation. If (x) increases, then (y) decreases in an opposite or inverse manner. Likewise, if (x) decreases, then (y) increases. The indication that (y) is inversely related to (x) is that (x) is in the denominator of the right hand expression. (y) is mathematically related to the reciprocal of (x) which has the value of (1/x), and (x) is mathematically related to the reciprocal of (y) which is the value of (1/y):

$$x = c\left(\frac{1}{y}\right)$$

It is also easily possible for a variable to be directly related to one or more variables, and at the same time be inversely related to one or more variables. For example:

$y = \frac{cx}{z}$: again, here (c) represents a constant that does not change or variate like a variable can. Here (y) is directly related to (x) and inversely related to (z).

Knowing the concepts of variation can help you write equations and formulas. If given all the values of the variables in an expression, you can then solve for the constant of variation when needed, and write a formula showing the mathematical relationship among those variables.

Ex. The cost of a certain rectangular piece of material was $24 and this cost was directly related to its' size (LW = length x width), that is, the cost was directly related to the area of the material. The length of the material was 4ft. and the width was 2ft. Calculate the cost per square unit of area of this material. The basic equation or formula for this is:

$\text{total-cost} = c\,(LW)$: where c is the price per square foot.
$\$24 = c\,(4ft)(2ft)$
$\$24 = c\ 8ft^2$ solving for c:

$c = \frac{\$24}{8\text{ ft.}^2} = \frac{\$3}{1\text{ ft.}^2}$: $3 per square foot is the cost per square foot, and the basic formula becomes:

total-cost = (cost per square unit)(total number of square units)

$\text{total-cost} = (\$3/\text{ft.}^2)(LW)$ or = $(\$3/\text{ft.}^2)$ Area

If another section of that same kind of material was 5ft. long , and the width was 7ft., what would be the cost?

$$\text{total-cost} = \left(\frac{\$3}{1\text{ ft.}^2}\right)(5\text{ft.})(7\text{ft.})$$

$$\text{total-cost} = (\$3)\left(\frac{35\text{ft.}^2}{1\text{ ft.}^2}\right) = (\$3)(35)$$

$$\text{total-cost} = \$105$$

As a check, solving this problem using proportions:

$\frac{\$24}{8\text{ft.}^2} = \frac{x}{35\text{ft.}^2}$ solving for x:

$$x = \frac{(\$24)(35ft^2)}{8ft^2} = (\$24)(4.375)$$

$$x = \$105$$

In terms of the proportions, notice that the constant of variation, ($3 per square foot or= $3/1ft^2) above, is the constant of proportion or proportionality for this specific system, and it is the cost per square foot of a certain material.

If a variable is directly related in value to another, when one increases, the other will increase. When one decreases, the other will decrease.

If a variable is directly proportional to another, the variables are directly related, and when one increases by a factor or multiple value, the other will increase by that same factor or multiple value.

Ex. $a = b$, If (b) increases by a factor of (n), (a) will increase by (n), and so as to keep the equation in balance:
$na = nb$

Ex $a = b$, If (b) decreases by a factor of (n), (a) will increase by (n), and so as to keep the equation in balance:

$$\frac{a}{n} = \frac{b}{n}$$

If a variable is inversely proportional to another, when one increases by a factor or multiple value, the other will decrease by that same factor or multiple value and which could be stated that the other will decrease by the reciprocal of that factor value.

Here, (a) and (b) are inversely related. The numerator (1) in the fraction of (1/b) could also be any general value, but this expression of (1/b) explicitly shows the inverse relationship, and here it is also a reciprocal, mathematical relationship since the numerator is 1. For a reciprocal relationship, the two mathematically, inversely related values are factors of 1. (a)(b) = 1 , and a = (1/b) and b = (1/a)

Ex. $a = \frac{1}{b}$, If (b) decreases by a factor of (n), (a) will increase by that same factor of (n):

$$\frac{1}{\frac{(b)}{(n)}} = \frac{\frac{1}{1}\frac{(n)}{(b)}}{\cancel{\frac{b}{n}\frac{(n)}{(b)}}} = \frac{n}{b} = n\left(\frac{1}{(b)}\right) = n\,a$$

This book often uses the words "a proportional problem", and this is meant as how to solve for an unknown value if the relationships of the values and-or variables have a proportional, mathematical relationship. The process could then be called one of solving a proportional problem or "proportion equation":

Ex. $\frac{a}{b} = x$ and if both the num. and den. are multiplied by the same value: $\frac{a}{b} = \frac{a(n)}{b(n)} = \frac{a\,(1)}{b\,(1)} = \frac{a}{b} = x$

We see the multiplying both the numerator and denominator by the same value still produces the same ratio value as the result.

$\frac{a}{b} = \frac{c}{d} = x$ Since both fractions or ratios have the same value, here (s) it means that each corresponding set of values in the num. and den. were changed by the same factor value, say (n) or (1/n). Showing this intermediate step:

$\frac{a}{b} = \frac{an}{bn} = \frac{c}{d} = x$: the process created an equivalent fraction, and each faction is said as having the same portions and-or ratio value as the other, and this may be said as the numerator and denominator values are within proportion or have the same portions as that of another set of values. Equivalent portions are verified by having the same quotient or ratio, and here it is shown as (x).

In this example it could be said that the ratio of (c) to (d) has the same as the ratio or fractional value as that of (a) to (b), and here that value is shown as(x). For an explicit numerical example, rather than the algebraic example just given:

$\frac{5}{10} = \frac{2}{4} = 0.5$: Each numerator value is half of the denominator value. The numerators have the same portion, part or fraction value of the denominator. These fractions are equivalent, and have the same ratio and-or quotient value.

It could be said that one set (ie. the numerator and denominator of a fraction) is a magnified version of the other set, and-or one set is a demagnified version of the other set, and yet the parts of each set have the same multiple or fractional value with respect to each other. Consider this:

$\frac{10}{5} = \frac{50}{25}$: here the ratio of the numerator to the denominator parts of each fraction is 2, and that the parts of the fraction on the right are 5 times bigger since (num2/num1) = (50/10) = 5, and (den2/den1) = (25/5) = 5, hence a magnified set, instance or version of the portions.

$\frac{10\ (5)}{5\ (5)} = \frac{50}{25} = 2$, also consider the reverse, where the multiplier is the reciprocal of 5: (1/5) = 0.2 , hence a demagnified set, instance or version of the portions. $\frac{50\ (1/5)}{25\ (1/5)} = \frac{10}{5} = 2$

CHANGING UNITS

It is very possible to change units of a given measurement or value if the units being changed to are similar, such as being a length unit, such as converting a quantity of feet to a quantity of meters or vice-versa, or a volume unit, such as converting a quantity of gallons to liters or vice-versa.

Changing or converting units from one to another is easily accomplished by setting up an equivalent fractions or proportion type of problem. First, a basic relationship among the units given and the units you are solving for must be known. This relationship is commonly called a "unity", "units or "equivalency" ratio. This will be on one side of the equation. The other side will be the ratio of the value with its units being converted, and a placeholder variable for the converted value and its units. It is a usually easier to solve for the variable when it's in the numerator, and then be sure to keep corresponding units in both numerators, and both denominators on both sides of the equation.

Ex. Change 5000 feet to its equivalent value in miles.

The known relationship between miles and feet is that there is 1 mile unit per 5280 feet units, or 5280 feet per (1) mile.

From: 1 mile = 5280 feet After dividing one side by the other we have:

$\frac{1 \text{ mile}}{5280 \text{ feet}} = 1$ and $\frac{5280 \text{ feet}}{1 \text{ mile}} = 1$: 1 here means equivalence or unity since both 5280 feet and and 1 mile represent the same length or distance. If you were to subtract rather than divide, the result would be 0 since when you subtract equal values, their difference is 0.

$\frac{1\text{mi.}}{5280\text{ft.}}$ or $\frac{5280\text{ft.}}{1\text{mi.}}$: unity fractions for this problem

$\frac{1 \text{ mi.}}{5280\text{ft.}} = \frac{x \text{ mi.}}{5000\text{ft.}}$: setting up the proportion
Can be read as: "If 1 mile is to 5280 feet , then x miles is to 5000 feet".

After solving for x using the equation (here, multiply both sides by 5000ft) or (creating an) equivalent fraction method:

$$x = \frac{1\text{mi}(5000\text{ft})}{(5280\text{ft})}$$

$$x = 0.947 \text{ miles}$$

Hence, 5000 feet = 0.947 miles.

After a general observation of the above, you can convert feet to miles simply by dividing the number of feet by 5280. Division, rather than multiplication, is the essence of converting from smaller (sized) units to larger (sized) units since there is a lesser quantity of larger units.

From: x mi. = 5000 ft.

,we know that we can divide both sides of an equation by the same value and they will still be in balance. Letting that value be (use either equivalent side of) :

1 mi. = 5280 ft. : that is, you can divide one side by 1mi, and the other by 5280ft since these lengths are equivalent, even though they are mathematically represented differently with different quantities and units.

We can get (which can algebraically be found from the initial proportion shown) :

$\frac{5000 \text{ ft.}}{5280 \text{ ft.}} = \frac{x \text{ mi.}}{1 \text{ mi.}} = x$: x is the number of units which are known to be miles.
We see that x is basically the ratio of the left hand side.

On the other hand, multiplication is the basic essence of converting from a quantity having larger (sized) units to a quantity having smaller (sized) units since there are many more of the smaller units per each larger units of measurement. For example:

Given: 1 mi. = 5280 ft.

To convert 5 miles to its equivalent value of feet, you can set up a proportion type of problem, or simply multiply each side of the equation by 5 since 5 miles is a factor of 5 times larger than 1 mile; (5 = 5mi./1mi.) :

(5)1 mi. = 5(5280) ft.
5 mi. = 26400 ft. putting this in a general formula, for a "miles to feet" conversion formula:

x mi. = x (5280) ft. : which is the same as multiplying both sides by (x), and the equation will still be in balance

Here's how to convert between miles and inches if you do not know the direct "conversion factors" between miles and inches, but do know the conversion factor between feet and inches:

From: 1 mi. = 5280 ft. : eq. 1
And: 1 ft. = 12 in. : eq. 2 , multiplying each side of this equation by 5280:

5280 ft. = 63360 in. substituting this fact into eq. 1:

1 mi. = 63,360 in. multiplying both sides by x:

x (1 mi) = x 63,360 in

x mi = x 63,360 in : a general formula for converting miles to inches

Or, since as shown previously:

x mi. = x (5280)ft. : converting miles to feet

And likewise:

x (1) ft. = x (12) in. after mult. both sides by x, and substituting this into the above:

x mi. = x (5280) ft. = (5280)(x ft.) = (5280)(x 12 in.) = x (5280)(12) in. =

x mi. = x 63360 in. : a formula to convert miles to inches

Perhaps a similar and simpler derivation is from: 1 mi = 5280ft, then x miles would be equivalent to:

x mi. = x (5280)ft. = x 5280 (1 ft) = x 5280 (12 in) = x 63360 in.

Here, a proportion is used to solve for the number (N) of inches in a given amount (x) of miles.

$\frac{1 \text{ mi.}}{63360 \text{ in.}} = \frac{x \text{ mi.}}{N \text{ in.}}$ after solving for N inches:

Nin. = x 63360in. : an expression, or formula, for the relationship between a quantity of inches and (x) miles. Here, 63,360 is a constant in the relationship between inches and miles.

Ex. Here is a more advanced example. Given there are 231 cubic inches (231cu. in. = 231 in.^3 = 3.785$\underline{4}$ liters) per 1 American (U.S.) gallon of water, if it rains 1 inch deep over on an area of 1 square mile (1 sq. mi. = 1 mi.^2), how many total gallons did it rain? Extra note: 1 American (U.S.) gallon has 128 fluid ounces. The British gallon is 277.274 cubic inches = 4.546 liters and has 160 fluid ounces. The gallon unit is slowly becoming obsolete in favor of the metric system unit of liters, however the gallon unit is still needed for any past references and conversions.

From : 1 mi. = 5280 ft. squaring each side, we get:
(1 mi.)^2 = (5280 ft.)^2 : 1 square-mile in terms of square-feet, or vice-versa
1 mi.^2 = 27,878,400 ft.^2 : about 28 million square feet

From: 1 ft. = 12 in. squaring each side, we get:
(1 ft.)^2 = (12in.)^2
1 ft.^2 = 144 in.^2

Setting up a proportion problem:

$$\frac{1\ \text{ft.}^2}{144\ \text{in.}^2} = \frac{27{,}878{,}400\ \text{ft.}^2}{x\ \text{in.}^2}$$

$$x\ \text{in.}^2 = \frac{27{,}878{,}400\ \text{ft.}^2\ (144\ \text{in.}^2)}{1\ \text{ft.}^2}$$

x in.^2 = 27,878,400 (144 in.^2) = 4,014,489,600 in.^2 : a square mile in terms of square inches. Approximately 4 billion square inches.

Multiplying this by 1in. since the third dimension of the volume is 1 inch deep (of rain) in this problem:

(4,014,489,600 in.^2) (1 in. ^1) = 4,014,489,600 in.^(2+1) = 4,014,489,600 in.^3 : cu. in. of rain

$$\frac{1\ \text{gallon}}{231\ \text{in.}^3} = \frac{x\ \text{gallons}}{4{,}014{,}489{,}600\ \text{in.}^3}$$

$$x = \frac{4{,}014{,}489{,}600\ \text{in.}^3\ (1\ \text{gallon})}{231\ \text{in.}^3}$$

x = 17,378,743 gallons : about 17 million gallons of rain water when it rains 1 inch deep over a square mile

As an extra note, 1 gallon of water weighs about 8.3456 pounds (lbs.). Also, the equivalent gallons in 1 cubic foot (1 cu. ft. = 1 ft.^3) of water can found using the above proportion by expressing 1 cubic foot of water in terms of cubic inches of water: Since 12 inches equals 1 foot:

1 ft.^3 = (1 ft.)^3 = (1 ft.)(1 ft.)(1 ft.) = (12 in.)(12 in.)(12 in.) = (12)(1in)(12)(1in)(12)(1in) = (12^3)(1in)^3
1 ft^3 = (12^3)(1^3 in^3) = 12^3 (1 in^3)
1 ft^3 = 1728 in.^3

After solving the proportion for x gallons:

$$\frac{1 \text{ gallon}}{231 \text{ in.}^3} = \frac{x \text{ gallons}}{1728 \text{ in.}^3}$$

Therefore, 1 ft.^3 of water = 1728 in.^3 = 7.4805$\underline{2}$ gallons of water , and:

One ton (2000lbs) of water is equal to : 2000lb / 8.3456 lb / gallon = 239.6$\underline{5}$ gallons =~ 240 gallons
One cubic foot of water, or 7.4805 gallons of water weighs: (7.4805gal)(8.3456 lbs/gal) = 62.43lbs
One ton (2000lbs) of water is equal to : 2000lb / 62.43 lbs per cubic ft. = 32.03$\underline{6}$ =~ 32 cubic feet of water
Taking the cube root of a cube with 32.036 cubic units, here: ft.^3, is 3.17$\underline{6}$ ft per side: (l, w, or h).
This is just slightly more than a yard (3ft) per side, and also just slightly less than 1 meter (3.28 ft.) per side.

Ex. A basement is to be resurfaced with concrete. The dimensions of the basement are as follows: Length=30 ft., Width=12 ft., and the thickness or Height of the concrete is to be 1 inch deep. How many cubic yards of concrete will be needed?

First, we will convert all the measurements to their equivalent measurements with units of yards.

Since 3 ft. = 1 yd. we can write a proportion problem as:

$$\frac{1 \text{ yd.}}{3 \text{ ft.}} = \frac{x \text{ yd.}}{n \text{ ft.}} \qquad \text{solving for } x \text{ yd:}$$

$$\frac{(n \text{ ft.})(1 \text{ yd})}{3 \text{ ft}} = x \text{ yd.}$$

: Hence to find x yd. of a given length of feet, simply divide the number (n) of feet by 3. .

Here are the converted values: L = 30 ft. = 10 yd.
W = 12 ft. = 4 yd.

For the Height, we will first convert its value with units of inches to an equivalent value with units of feet, and then proceed as usual:

$$\frac{1 \text{ ft.}}{12 \text{ in.}} = \frac{x \text{ ft.}}{1 \text{ in.}}$$

$$x \text{ ft.} = \frac{(1 \text{ in.})(1 \text{ ft.})}{12 \text{ in.}} = (1/12) \text{ ft.} = 0.083333333 \text{ ft.}$$

: 1in =~ 0.0833ft

Dividing by 3, or multiplying by (1yd/3ft), to convert feet to yards, we have:

H = 0.083333333 ft. = 0.027777777 yd.

Since (L yd.)(W yd.)(H yd.) = x yd.^3 , we have:

(10 yd.)(4 yd.)(0.027777777 yd) = 1.111111111 yd.^3 : the minimum needed
Slightly more than 1.11 cubic yards.

Below is a small table that can be used for making typical conversions between the metric and American systems of units of measurement for length or distance:

Metric English-American

1cm = 0.393700787 in. : cm=centimeter, in.=inch. 1cm = (1/100)m = 0.01m , Note that 1 in = 2.54 cm, exact
1m = 3.280839895 ft. : m=meter, ft.=foot

1m = 1.093613298 yd. : m=meter, yd.=yard
1km = 0.621371192 mi. : km=kilometer, mi.=miles , 1km = 1000m

How about expressing these relationships the other way around? For example, here is 1 mile found in terms of kilometers without using the standard methods of conversion:

1km = 0.621371192 (1) mi. : units equivalence of distance

Dividing both sides by 0.621371192 will rid (1) miles of it multiplying constant:

$$\frac{1\text{km}}{0.621371192} = \frac{0.621371192\ (1)\ \text{mi.}}{0.621371192}$$ after dividing and switching sides:

1 mi. = 1.609344001 km : **When given a unit equivalence of two different units, the unit equivalence of the other unit is equal to the reciprocal of the given factor value of that other unit.**

Here is a similar example showing the number of centimeters per inch:

1cm = 0.393700787 (1) in. after dividing both sides by 0.393700787 and switching sides:
1 in. = 2.54 cm.

Conversions of weight: units:

A gram (g) or sometimes a kilogram, is the unit of mass (ie. substance or matter) in the metric system. A gram is physically defined as being equal to the mass of 1 cubic centimeter of water (which must have a temperature of only a few degrees above freezing, since as water is heated, it expands, and hence it's dimensions increase). The (corresponding) weight of a gram is also commonly used as the (adopted) unit of weight in the metric system, although the Newton unit is the actual unit of weight or force. Most modern scales will automatically convert a weight value to its equivalent gram value.

1g = 0.035273961 oz. : g=gram, oz.=ounce
1kg = 2.204622622 lb. : kg=kilogram, lb.=pound

Conversions of liquid volume:

A cubic centimeter (abbreviated as cu.c., or cc, or cm^3) is a unit of volume or three dimensional spacial area in the metric system. (10cm x 10cm x 10cm) or 1,000 cubic centimeters is defined as 1 liter = 1l.

1L = 0.264172052 gal. : l=liter, gal.=gallon

1 liter of water weighs 1 kg or 1000g since 1l = 1000 cu. c. , and each cu. c . weighs 1g.

Here is an example that is a conversion (called a reduction) within the metric system:

How many millimeters (mm) are in a centimeter (cm)?

Considering the basic facts: $1\text{ cm} = \frac{1}{100}\text{ m} = 0.01\text{m}$ and:

$$1\text{mm} = \frac{1}{1000}\text{ m} = 0.001\text{m}$$

Dividing the equivalent meter value for centimeters by the equivalent meter value for millimeters, we can find out how many times larger that a centimeter is than a millimeter:

$$\frac{1\text{ cm}}{1\text{ mm}} = \frac{0.01\text{m}}{0.001\text{m}} = 10$$

Therefore, a centimeter is 10 times larger than a millimeter. Considering the division this reciprocal way:

$$\frac{1\text{ mm}}{1\text{ cm}} = \frac{0.001\text{m}}{0.01\text{m}} = 0.1$$

We find that a millimeter is only a tenth of a centimeter. This can be mathematically verified from the above equation by multiplying each side by 1 cm:

$$1\text{ mm} = 0.1\ (1\text{ cm})$$
$$1\text{ mm} = 0.1\text{ cm} = \frac{1}{10}\text{ cm}$$

It can also be said that there are 10 millimeters in a (1) centimeter. This can be mathematically verified from the above equation by multiplying each side by 10:

$$10\text{ mm} = 1\text{ cm} \qquad \text{or} = \qquad 1\text{ cm} = 10\text{ mm}$$

This could have also been found from the original division shown above after multiplying each side by 1mm.

Before leaving this topic of changing units, consider these example equations below.

1ft. = 12in. Having some multiple of feet to convert to inches, its a matter of repeated addition or simply a multiplication. Multiplying each side by (x):

$$x\ (1\text{ft}) = x\ (12\text{in})$$

$x\text{ft} = x12\text{ in}$: to convert a number of feet to its corresponding number of inches

Given 1ft = 12in , and dividing both sides by 12:

$$1\text{in} = \frac{1\text{ft.}}{12} = 0.0833333\text{ ft}$$ when having some multiple of inches to convert to feet:

$$x\text{in} = \frac{x\ (1\text{ft})}{(12)} = \frac{x\text{ft}}{12} \quad \text{or} = \quad 0.0833333x\text{ ft}$$

You can also use equivalent fractions or "proportions" to solve conversion problems.

AN UNCOMMON METHOD OF CREATING AN EQUIVALENT FRACTION

There is a somewhat non-standard, perhaps novel, way worth mentioning of making an equivalent fraction. Given two equivalent fractions, you can add (or subtract) their numerators together, and add their denominators together to create a third fraction that is equivalent:

$$r = \frac{a1}{b1} = \frac{a2}{b2} = \frac{a1 + a2}{b1 + b2} \qquad : r = \text{ratio of the fraction(s)}$$

At first sight, this appears to go against everything learned so far, that is, you cannot add a (same) value to both the numerator and denominator to create an equivalent fraction. This is true, but here, the values added to the numerator and denominator are not the same (constant) value. Here is the verification that the sum of equivalent fractions is another equivalent fraction:

We know that to create an equivalent fraction, we multiply (or divide) the numerator and denominator by the same value, say (n) as shown below:

$$r = \frac{a1}{b1} = \frac{na1}{nb1} = \frac{a2}{b2}$$

Hence, we must verify that:

$$r = \frac{a1 + a2}{b1 + b2} = \frac{a1 + na1}{b1 + nb1} \qquad \text{factoring out common factors to each term on the right hand side :}$$

$$r = \frac{a1 (n + 1)}{b1 (n + 1)} \qquad \text{after canceling out the common factor of } (n + 1) :$$

$$r = \frac{a1}{b1} \qquad : \text{This checks since the ratio is still the same value}$$

Summarizing the results:

$$r = \frac{a1}{b1} = \frac{na1}{nb1} = \frac{a2}{b2} = \frac{a1 + a2}{b1 + b2} = \frac{a1 + na1}{b1 + nb1} = \frac{a1 (n + 1)}{b1 (n + 1)} = \frac{a1}{b1}$$

A small advantage of using this method to create an equivalent fraction is that addition is usually faster than multiplication.

Ex. $\frac{2}{4} = \frac{15}{30} = \frac{(2 + 15)}{(4 + 30)} = \frac{17}{34} \qquad : r = 0.5$

In short, to create a third equivalent fraction, you can add a fraction's numerator to the numerator of another equivalent fraction, and add the fraction's denominator to the denominator of that same equivalent fraction. The process, as shown above, appears to be that of "adding equivalent fractions" to create a third equivalent fraction, though it is really adding corresponding numerators and denominators of equivalent fractions to create a third equivalent fraction. As an extra note on this topic, since the ratios (r) of equivalent fractions are the same value, adding equivalent fractions will result in a value that is a multiple of (r) and which is therefore a different value than (r) which is needed so as to have an equivalent fraction.

AN OBSERVATION ON RECIPROCALS

When two values are reciprocals of each other, say (a) and (b), we know that their product equals 1.

$(a)(b) = 1$ and $a=1/b$ and $b = 1/a$

But what do we get when we divide these reciprocals by each other?

$$\frac{a}{b} = c$$

$$\frac{b}{a} = d$$

It may or may not be obvious or intuitive, but the quotients of dividing two reciprocals, here (c) and (d), are also reciprocals. For example:

Given: $a=0.5$ and $b=2$:

$(0.5)(2) = 1$ and $0.5 = 1/2$ and $2 = 1/0.5$: Verifying that 0.5 and 2 are indeed reciprocals since their product equals 1.

$$\frac{a}{b} = \frac{0.5}{2} = 0.25 = c$$

$$\frac{b}{a} = \frac{2}{0.5} = 4 = d$$

Observe that 0.25 and 4 are also reciprocals:

$(c)(d) = (0.25)(4) = 1$, and:

$1/c = 1/0.25 = 4 = d$, and:

$1/d = 1/4 = 0.25 = c$

So in a way, we are right back where we started with two reciprocals, and the process can be continued by dividing these new reciprocal values, and here they are 4 and 0.25.

Some other observations:

From: $ab = 1$, $a = 1/b$, $b = 1/a$: (a) and (b) are the reciprocals of each other

And: $\frac{a}{b} = c$: c = the quotient of the reciprocals (a) and (b), mathematically: It will be shown below that the square root of this quotient (here c) of two reciprocals is equal to the numerator, here a solving for c:

$a = bc = \frac{1}{b}$ solving for c:

$c = \frac{1}{b^2}$ after taking the square root of both sides of this equation:

$\sqrt{c} = \frac{1}{b} = a$, also, squaring both sides we have: $c^2 = a$

Ex. Given these two reciprocals: a=0.25 and b=4:

$\frac{a}{b} = c$: hence, a division of two reciprocals

$\frac{0.25}{4} = 0.0625$

$a = \sqrt{c} = \sqrt{0.0625} = 0.25$,checking: $a = bc = (4)(0.0625) = 0.25$

Likewise:

$\frac{b}{a} = d$

$\frac{4}{0.25} = 16$: 16 and 0.0625 are also reciprocals

$b = \sqrt{d} = \sqrt{16} = 4$

If you took two values that were not reciprocals and divided them, their quotients are still reciprocals, but the square root of the results generally would not be equal to these values.

Ex. $\frac{5}{10} = 0.5$: 5 and 10 are not reciprocals since their product does not equal 1. (5)(10)=50

$\frac{10}{5} = 2$ These quotients are still reciprocals of each other: (2)(0.5)=1

Since the these values, 5 an 10, were not reciprocals to start with, the square roots of their quotients are not equal to those values as shown here:

$\sqrt{0.5} = 0.707106781$ and $\sqrt{2} = 1.414213562$

The roots of the two quotients (0.5 and 2) are reciprocals. Checking:

$\sqrt{0.5}\sqrt{2} = \sqrt{0.5(2)} = \sqrt{1} = (0.707106781)(1.414213562) = 1$

Analyzing the results:

$ab = 1$: (a) and (b) are reciprocals

$\frac{a}{b} = c$ and $\frac{b}{a} = d$

$cd = 1$: (c) and (d), the two quotients of two reciprocals (a) and (b), are also reciprocals

$\sqrt{c} = a$ and $\sqrt{d} = b$: This is true only when (a) and (b) were reciprocals to begin with.
Here is a verification of this:

From: $ab = 1$

$$\frac{a}{b} = \frac{\frac{a}{1}}{\frac{1}{a}} = a^2 = c$$: a reciprocal divided by its reciprocal is equal to: numerator^2
taking the square root of both sides we have:

$$\sqrt{c} = a$$

An interesting pair of reciprocals is the square root of 10, and the reciprocal of this square root of 10. Both values have the same digits, but they are different by a factor of 10.

$$\frac{a}{b} = \frac{\sqrt{10}}{1/\sqrt{10}} = \frac{3.16227766}{1 / 3.16227766} = \frac{3.16227766}{0.316227766} = c = 10$$ checking:

$$\frac{a}{b} = \frac{\sqrt{10}}{1/\sqrt{10}} = \frac{10\text{^}0.5}{1/ 10\text{^}0.5} = (10\text{^}0.5)(10\text{^}0.5) = 10\text{^}(0.5+0.5) = 10\text{^}1.0 = 10 = c$$

Clearly, when two values differ by a factor of 10, as just shown, their digits will be identical.

$$a = \sqrt{c} = \sqrt{10} = 3.16227766$$

You can also use other values besides 10 for the radicand (N), and the two values ($\sqrt{N}$, and $1/\sqrt{N} = \sqrt{1/N}$) will differ by a factor of that specific radicand., but their digits will not be (visually) identical as when the radicand is 10. Also expressed is that the reciprocal of a root of a number is equal to the root of the reciprocal of that number:

$$\sqrt{1 / N} = \sqrt{1} \;/\; \sqrt{N} = 1 / \sqrt{N}$$: The root of the reciprocal of a number is equal to the reciprocal of the root of that number.

Note that::

$$\sqrt{1/10} = \sqrt{0.1} = \sqrt{1 / 10} = \sqrt{1} \;/\; \sqrt{10} = 1 / \sqrt{10} = 1 / 3.16227766 = 0.316227766$$ and

$$\frac{\sqrt{10}}{\sqrt{0.1}} = \frac{3.16227766}{0.316227766} = 10$$ checking by multiplying the divisor and quotient together:

$$10 \sqrt{0.1} = \sqrt{100}\,\sqrt{0.1} = \sqrt{(100)(0.1)} = \sqrt{10}$$

As an extra note or concept involving reciprocals, of which much has already been discussed:

If you have say 10 items, each (1) item can be said or indicated as: 1 in 10, 1 of 10, 1 out of 10 , and these can be numerically expressed as:

$\frac{1}{10}$ in standard fractional form as an expression or= 0.1 in standard decimal fractional form as a single numeric value

Hence given any number of items, say N, the numeric value of each item is simply the reciprocal of that number N = (1/N)
Ex. If given 5 items total, each item can be numerically expressed as: (item) / (total items) = 1 / 5 = "1 of 5" = 0.2

[This space for book edits.]

QUADRATIC EQUATIONS

In this book, we have already discussed and solved equations of the first degree or order. That is, the exponent of the variable being solved for has only been the first (1) power or degree. Below is a discussion on solving equations of the second order or degree, more formally known as quadratic equations. Here, the exponent of the variable being solved for is 2. The word quadratic comes from the word prefix of quad which means 4. Since these equations have a "squared variable" often associated with square shapes with 4 equal sides; (s) and area is (s^2), it makes some sense to call them quadratic. Another reason that they are called quadratic equations is in reference to their graph. When the graph of the quadratic equation is plotted on a perpendicular or rectangular-coordinate system of measurement and location on a plane, the curve will eventually occupy two or more quadrants (a 1/4, or a quarter section) of the rectangular-coordinate system. When plotted, the geometric shape of a quadratic equation or curve is called a **parabola**. "Parabolic" is a word that basically means "two-sided", and this curve is two-sided as being symmetrical (ie., symmetry, likeness, identical, mirrored) about the axis of the parabola curve. A common use for the parabola shape is with the shape of the large main (light collector) mirror of a reflector telescope where all the dim or faint incoming light is reflected to be gathered together and concentrated into a much smaller area or point of brighter or more intense light which can then be magnified and viewed by the eyepiece lens. This point is formally called the focus, or focus point of the curve or system, and which basically means the central or center of locus (of a path of related points) or location point of the parabola curve.

The general format of the basic linear (line) expression and equation is:

$ax^1 + b = ax + b$: (a) is a multiplying factor, or numerical coefficient to the variable (x).
(a) cannot equal 0, since the variable would essentially be eliminated
since anything times 0 is 0. (a) can be 1, and the expression would
simply be: $(1)x^1 + b = x + b$
(b) is some arbitrary constant added in and it could be 0, and the
expression would simply be: $ax + 0 = ax$
If (a)=1, and (b)=0, the expression would simply be: x

If the value of this expression was set equal to y, such as for graphing or plotting the relationship of, or between, y and x, and where y can be thought of as the output of the expression, and x as the input of the expression. The mathematical relationship between y and x is a linear (ie. proportional) type of relationship.

If the basic linear expression is multiplied by a constant (c), the result is another linear expression "in (variable) x":

$$c(ax^1 + b) = acx^1 + bc$$

That is, the expression still consists of a term which has (x) to the first power, and which is multiplied by a numerical coefficient, and has a (constant) value term added to the first or "variable term".

However, if it is multiplied by the variable (x) that is also within and defines that specific linear expression, the result is a quadratic expression:

$$x(ax^1 + b) = ax^2 + bx$$

As an extra note to consider: This is equivalent to repeatedly adding the expression or its resulting value a total of (x) times. For example:

$x(ax^1 + b) = (ax^1 + b) + (ax^1 + b) + \ldots + (ax^1 + b)$: here, the number of terms depends on the value of x
If x=3:

$$3(a3^1 + b) = (a3^1 + b) + (a3^1 + b) + (a3^1 + b) = a3^2 + 3b = 9a + 3b$$

We can add in an arbitrary constant (c) term, and set the expression equal to another variable such as (y) to hold the variable results of the expression. We can also set the expression specifically equal to 0 (ie., setting y=0) so as to have a more general format of a quadratic equation, and here with (x) representing any independent or "determining (of y)" variable that is used:

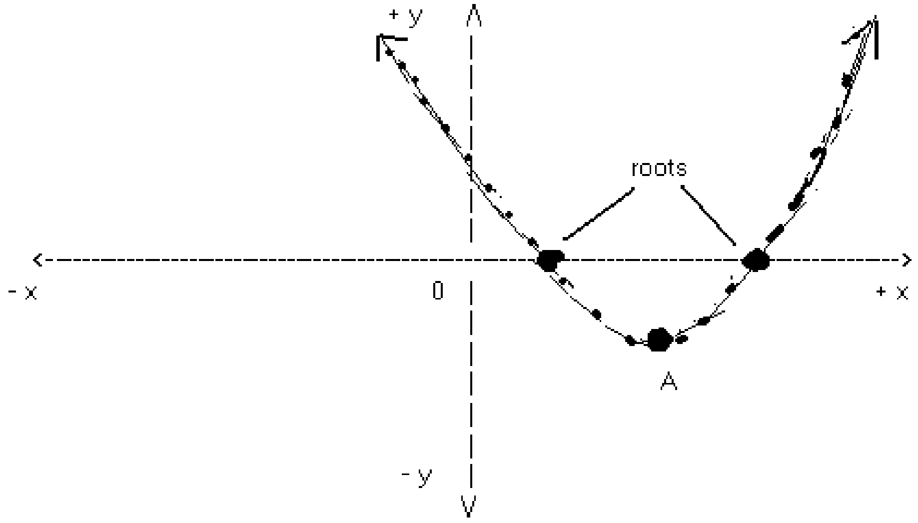
ax^2 + bx^1 + c = 0 : **BASIC QUADRATIC EQUATION** , (a /=/ 0, since the x^2 term must exist to be a quadratic equation)

Notice the descending powers of the variable in each term: (x^2, x^1, and x^0 = 1), this is the basic essence of formally defining equations of a higher degree. Variables a and b are numerical coefficients of the terms containing the variable x, and c is an arbitrary constant. Variables b and-or c can even have a 0 value, and hence those terms would not be present as expressed here:

ax^2 + c = 0 and ax^2 = 0 : these are sometimes called "partial quadratic equations"

By choosing values for variable x, and plotting (showing pairs of corresponding values of (x) and (y) as points or locations) a graph of the equation, it will show the overall relationship between the (x) or (independent or "input") variable and another corresponding variable (that is affected or determined by x), such as (y) that is set equal to the "output" or result of that equation. The graph or "curve" of the equation will visibly show the relationship of the variables over a large range of values.

If variable (y) is set equal to this basic or general form of the quadratic equation that was solved for and-or set equal to 0, it will essentially be setting (y) also equal to 0, and the corresponding value(s) of x are the coordinates or location of a point called the x-axis intersect (intersection or crossing) of the curve, and where all the corresponding values of y are equal to 0. Here is the general shape of the curve of a quadratic equation when plotted (placement of its points) as a graph with a natural-like smooth flowing curve between its points: [FIG 44]



Notice the point indicated as A on the graph. This is called the minimum (here, as in the minimum y value) point of the curve, or the minimum (least, smallest possible) value, output or result of the equation. If the curve opened downwards, instead of upwards as seen here in the graph, the point would be called a maximum point of the curve, or the maximum value, output or result of the result of the equation. There is a mathematical method, discussed briefly in this book, that can be used to find the exact location of this point. This method uses a special equation called a derivative (ie. an equation derived (ie. created) from or out of a given equation), for the slope (a measure of the steepness or incline) of the curve at any given point and-or value of x. At point A, the curve (as in the (y) values) is neither decreasing or increasing as the (x) variable increases, hence the "steepness of the curve" or slope at that point on the curve is said to be 0. Setting (y) of the derivative equation (which is basically an equation for the slope of the curve at a given point or value of x), or "slope [rate of change of the variables] equation" equal to 0, you can then easily solve for its corresponding value of (x), and then use this value of (x) in the actual quadratic equation to find its corresponding value of (y). For example, if the (x) variable was actually time (t), and the (y) variable was actually temperature (T), you can mathematically find or predict the exact point in time where the temperature was either at minimum or maximum value, and the corresponding value of that temperature.

The two axis of a rectangular measuring and location system will divide that plane into 4 areas called quadrants. (Quadrants (Q) are numbered counter-clockwise from the upper right quadrant which is considered as the first quadrant (Q1). The other quadrants are identified as Q2, Q3 and Q4.

Many other things can be observed from the curve of an equation. For example, in the above drawing, the co-ordinates of the minimum point, or any point, within the fourth quadrant will have the form of:

> Numerical signs of the co-ordinates of a point in the 4th quadrant are:
> p(x is positive in value, and y is negative in value)

Another observation is that the two roots (or "zeros") or x values where the curve crosses the x-axis and where y=0 will both be positive in sign since they are on the positive side of the x axis.

The word root (or "root of an equation") is often used to describe the solution of a quadratic equation expressed in the general format where y is set equal to 0. The description is used since the solution of any squared value, such as the variable (here x^2), is to take the square-root of it so as to have the "plain", "unsquared" and root value.

Another thing that can be observed is that the curve leftward of the minimum point slopes downward (as x increases). Here, the overall mathematical relationship between (y) and (x) is an inverse relationship. As (x) increases, the corresponding (y) co-ordinate of each point on the curve decreases. The curve to the right of the minimum point slopes upward. Here, the overall mathematical relationship between (y) and (x) is now a direct type of relationship. As (x) increases, the corresponding (y) co-ordinates of each point on the curve is also increasing. Due to this behavior of the slope of the curve not being constant, the mathematical relationship between variables (y) and (x) is not constant or linear in value, and is said to be a non-linear relationship.

The graph also indicates the value of (y) when the corresponding value of (x) equals zero. This point, p(0, y), on the curve is called the y-axis intercept.

When b=0 in a quadratic type of equation, the x^1 term is eliminated, and the resulting equation is reduced to a partial quadratic equation which can be easily solved:

$ax^2 + c = 0$ transposing c :

$ax^2 = -c$ dividing both sides by a:

$x^2 = \frac{-c}{a}$ taking the square root of both sides:

$x = \pm\sqrt{\frac{-c}{a}}$: note that since (c) and (a) are constants, the x-axis intercepts, p(x,0) where y=0, the value of x will be a constant

And for a real root (ie. not having an unknown or imaginary value), the value of the radicand must be positive in sign since the square root of negative numbers are not defined as being a real number and are considered as imaginary numbers or values that are to be imagined or conceived as being mathematically possible.

Ex. If (c) has a value of -16 and (a) has a value of +4:

$$x = \sqrt{\frac{-(-16)}{4}} = \sqrt{\frac{+16}{4}} = \sqrt{4} = +2 \text{ and } -2$$

If the given equation does not include the added in constant (the "constant term" (c)), the quadratic equation can easily be solved by factoring:

$ax^2 = bx$ placing this given equation into a form similar to the standard quadratic form:
$ax^2 - bx = 0$ factoring (x):

$x(ax - b) = 0$ since the product is 0, either or both factors must be, or can be considered as being, equal to 0:

$x = 0$: After dividing both sides by (ax-b). this is one root of the two possible roots.
root = p(x,y) = p(0,0)

After dividing both sides by x:

$ax - b = 0$: after solving for x:

$x = \frac{b}{a}$: this is another (or second) root of the two possible roots
root = p(x,y) = p((b/a) , 0)

If both the x^1 term and the constant term are present, the solution of (x) may not be so easy.

Ex. $x^2 + 2x = 15$ placing this equation into the std. quadratic equation form, so as to help solve it:

$x^2 + 2x - 15 = 0$

We see that a=1, b=2 and c = -15. Lets begin solving for (x) by transposing -15 and factoring (x) out of the left side:

$x(x+2) = 15$ dividing both sides by x:

$x + 2 = \frac{15}{x}$ transposing +2:

$x = -2 + \frac{15}{x}$ also note above that $x = \frac{15}{(x + 2)} = \frac{15}{2 + x}$

Now, how do we solve for a variable when that variable is part of the solution? In general, it cannot be done, that is, it can't provide an exact or algebraic solution as is. However, if used repeatedly, it can provide a solution which is as close to the actual or true solution as we need it to be. Methods of this type are called repeated or successive approximation (of the solution). First consider this simple analogy example. You are to guess a number someone is thinking. The assistance you will receive is an indication to go higher or lower of each next guess. You can do this by using an adjustment or change value (positive or negative in sign) to apply (combine) by adding it to that initial and any further guesses. Expressing this in a formula:

closer guess = guess + adjustment : of course, initially there is no adjustment, as if the adjustment is 0, and then the expression is essentially: guess = guess , and if it is incorrect (ie. the difference between it and the actual or true value is not close to 0), the adjustment process will need to be used.

This equation can also be expressed as:

new guess = guess + adjustment or:
closer guess = guess + adjustment

new guess will then be substituted into the guess position, and this "refining" or "zeroing in (getting closer, a low difference)" process can be continued.

After each step you are to take the value of the left side of the equation and substitute it into the right side of the equation and so as to automatically make adjustments and create a new closer value. When the new updated or modified guess or the numeric result of the equation is reasonably close to the true number that is being guessed or solved for, the process can stop. As you get close to the number, the adjustments should be "smaller and smaller" in absolute value. The concepts of "higher or lower" and "smaller and smaller" adjustments are automatically built into the mathematical method.

Continuing the example:

By replacing (x) in the denominator with its corresponding value (equation), we will have an equation where the computed value of (x) is nearer to the actual or true value of (x). Here, this method will create a "continued fraction":

$$x = -2 + \cfrac{15}{-2 + \cfrac{15}{x}}$$

: and so on. You will still have to guess at x at some point. It could be 0 if you want, or some value that you know is close to the true value of x. As you can imagine, if the initial guess or value chosen for x as a possible solution is close to the actual solution, the less computation needed to find the true result.

If you want to know some more about continued fractions, see Methods For Solving Square Roots in the appendix.

Let's call or assign the (x) in the denominator xn and the new, and more accurate solved for, or computed value of (x), as xn+1. In general, with the example given, if you already know or previously calculated a value for (x) such as from the continued fraction method just shown, then xn+1 can be found (without solving a lengthy continued fraction) by substituting the value of (x) for Xn and using the original equation again:

$x_{(n+1)} = -2 + \frac{15}{x_n}$: (where $x_n = x$) , or as noted above, $x_{n+1} = \frac{15}{(2 + x_n)}$: here, n and n+1 are not variables but are subscripts of the variable x that indicate a specific instance and-or value of that variable x. Hence, you cannot combine these variables: x_n and $x_{(n+1)}$ cannot be combined.

Note, to use this second formula noted, you must have calculated all previous values of (x) from this formula only. Likewise, to use the first formula noted, you must have calculated all previous values of (x) from that formula only.

Since an initial value of (x) might not be given or known, a guess close to -5.0 would be great for this example, but in general, if you don't like to guess, being in the "true" or exact realm of algebra, simply set (x) equal to any value up to infinity, of course using a value near infinity will usually take you longer to get sufficient accuracy in the result. A computer can do this type of mathematical repetition for you in usually less than a second of time. Note that a computer will usually signal an error and may stop processing the program if it (ie. the electronics) tries to divide by 0, hence, you may have to use an initial value of something other than 0 if you use a computer and-or a specific program being used by the computer. When doing the computation by hand, setting xn equal to infinity in the example shown will set the value of that term essentially equal to zero. This is due to the inverse relationship of the resulting quotient (ie. ratio value) and the denominator (ie. divisor). As the denominator increases the quotient decreases. A quotient does have a direct relationship to the value of a numerator.

$\frac{N}{\infty} \rightarrow 0$: --> means "approaches", or "the value will get nearer to this value". Here, as the denominator value approaches an infinitely high value, the quotient value will approach a value of 0.

For the example given, after repeatedly performing the indicated computation, the value of (x) will approach (and actually is) -5.0.

Checking:

$$\begin{aligned} x^2 + 2x &= 15 \\ (-5)^2 + 2(-5) &= 15 \\ +25 - 10 &= 15 \\ 15 &= 15 \quad \text{: checks} \end{aligned}$$

It should be of no surprise that there are two solutions (or "roots") to quadratic equations that are expressed using the basic quadratic equation form. These root values set the expression equal to 0. The two square roots of a positive value are the same in absolute value, and one root will be positive and the other root will be negative, however, with quadratic equations, the two roots' values are usually not the same in magnitude (absolute value), and might even have the same sign. Don't confuse the meaning of "roots" of equations with square-roots only because they are actually different concepts. If the quadratic equation was just $y=x^2$, then it is easy to understand where the term or word "root" comes from in relation to these types of equations since the solution of (x) is simply the root (here, the square root) of x^2 and-or its equivalent value of (y).

Here's how to get the other root of our example, and it uses a "continued radical" method:

$x^2 + 2x = 15$ solving for x^2 by transposing 2x:
$x^2 = 15 - 2x$ taking the square root of both sides:

$x = \sqrt{15 - 2x}$: and in general, we know that a variable cannot be part of it's own (strict algebraic) solution

As done in the continued fraction method just shown, replacing each (x), here in the radicand, with its equivalent value:

$x = \sqrt{15 - 2\sqrt{15 - 2\sqrt{15 - 2x\ldots}}}$ (and so on)

The initial value of (x) can be 0. This continued radical method will actually "zero-in" on a root more quickly than that of the continued fraction method. Here, (x) will approach (as is actually) +3.0.

Checking:

$$\begin{aligned} x^2 + 2x &= 15 \\ 3^2 + 2(3) &= 15 \\ 9 + 6 &= 15 \\ 15 &= 15 \quad \text{checks} \end{aligned}$$

This continued radical notation can also be placed into a more expressive notation for successive approximation:

$x_2 = \sqrt{15 - 2x_1}$ or : $x_{n+1} = \sqrt{15 - 2x_n}$ or: $x_{new} = \sqrt{15 - 2x_{old}}$

Here, x_2 is a closer approximation to the actual or true value of x. Repeat the process by setting x_1 equal to x_2 and evaluate the expression again until the desired accuracy (overall correctness) and precision **(**the smallest or "fineness, minute or fractional part of the value" considered, hence the least significant position [as in what decimal position] or weight**)** is achieved. When the difference between the input (here, x_1) and output (here, x_2) is 0 or as close as needed to it, the result has essentially been calculated or found:

When: $(x2 - x1) = 0$, the difference between the new and old values is 0, or is as small as needed, and the result has been found.

Factoring is another method to solve for the variable in a quadratic equation, however, its only sometimes feasible (especially when the coefficient of the x^2 term is not equal to 1) and therefore, it will not be discussed in great depth. It goes something like this: You can factor an (n) order equation (n=2 for a quadratic equation, a "second order equation") into a product of (n) linear equations (where the highest power of x=1).

First, here is the extended product of two binomials "in x":

$(x + a)(x + b) = x^2 + bx + ax + ab = x^2 + (a + b)x + ab$: clearly, this side is a quadratic expression

If you are given the quadratic expression or trinomial "in (powers of) x" (or whatever variable you happen to be working with) such as on the right hand side above, we now know that it can be factored to a product of two (linear, to the first power) binomials (sum of two terms) "in x" as shown on the left hand side of the equation. The first term of each binomial factor will be the square root of x^2, which is (x). Notice that when the factors (here, a and b) of the third term are summed, that this sum equals the coefficient of (x) in the second term. If the product (ab) is positive in sign, the second terms in the two (linear, first order) binomial factors are either both positive or both negative in sign (remember, a negative times a negative is a positive). When (ab) is positive and the sum of (a) and (b) is negative, that is, if the coefficient of (x) in the second term is negative, then both of the second terms in the binomial factors are negative in sign:

$x^2 - (a + b)x + ab = (x - a)(x - b)$

Ex. $x^2 -9x + 14 = (x -7)(x -2)$: $ab = (-7)(-2) = + 14$ and $(a+b) = (-7) + (-2) = -7-2 = -9$
Note, you will need to figure out which factors of +14 will actually sum to -9; algebraically, which factors of (ab) will sum to (a+b). Here is a pseudo algebraic form of this factorization method:

x^2 + (sum of factors of third term)x + (product of factors of the third term) = $(x+a)(x-b)$

, and where (sum) is the sum of the coefficients of (x^1), and (product) is the product of the coefficients of (x^1).

When (ab) is negative, and the sum of (a) and (b) is positive, the highest factor of (ab) is positive and the lower factor is negative. In general, the second term in only one of the two binomial factors will be negative in sign:

$x^2 +(a+b)x - ab$: here, expressing that when the product of (a) and (b) is negative, hence the term is negative. That is, think of (a) and (b) here as numeric values rather than variables which can generally have any (positive or negative) sign. This is the best we can do to mathematically to represent or express values that are signed constants, for this analysis.

$(x + a)(x - b)$: when (a) is positive and greater than (b) which is negative

Ex. $x^2 +5x -14 = (x +7)(x -2)$: $(+7)(-2) = -14$ and $(+7) + (-2) = 7-2 = +5$

$(x - a)(x + b)$: when (b) is positive and greater than (a) which is negative

When the sum of (a) and (b) is negative, the highest factor of (ab) is negative and the lower factor is positive. In general, when the third term is negative, the second term in only one of the two binomials factors will be negative in sign:

$x^2 -(a+b)x - ab$
$(x - a)(x + b)$: when (a) is negative and greater in absolute value than (b)

Ex. $x^2 -5x -14 = (x -7)(x +2)$: $(-7)(+2) = -14$ and $(-7) + (+2) = -7+2 = -5$

$(x + a)(x - b)$: when (b) is negative and greater in absolute value than (a), that therm is negative in sign

Ex. $x^2 -5x -14 = (x + 2)(x -7)$

Given: $(x + a) (x + b)$, the general factored form of a quadratic equation, it will now be pointed out that $-(a) = -a$, the negative or "negative counterpart" of (a), regardless if the actual value of (a) is either positive or negative. A variable can always be assumed to represent either a positive or negative numeric value unless told otherwise of the value(s) and its sign). $-(b) = -b$ are the actual roots of the corresponding quadratic equation. Note that (a) and (b) in these binomial factors are not to be confused with the variables used in the standard quadratic equation form of: $ax^2 + bx + c = 0$. With this in mind,now consider:

Setting $(x + a)(x + b) = 0$, we know that any value times 0 is equal to 0, so either factor or both can be set equal to 0, and we can solve for x:

$x + a = 0$ and, or $x + b = 0$
$x = -a$ $x = -b$: the two solutions, and roots of the quadratic equation of:
$(x+a)(x+b) = x^2 + (a+b)x + (ab)x = 0$

Letting: $r1 = - a$: r1 for "root one", and:
$r2 = - b$: r2 for "root two"

, and creating binomial factors where the constants are r1 and r2, and setting them equal to the standard quadratic equation, we get the generalized factored form of the generalized quadratic equation:

$(x + r1) (x + r2) = x^2 + bx + c = 0$ extending, or distributing on the left hand side:

$x^2 + xr2 + xr1 + r1r2 = x^2 + bx + c = 0$ factoring x out of the like terms:
$x^2 + (r1 + r2) x + r1r2 = x^2 + bx + c = 0$

By observation, we see that in the standard quadratic equation: $ax^2 + bx + c$:

$b = r1 + r2$: b = the sum or the roots and :

$c = r1 r2$: c = the product of the roots

Ex. Factor the following trinomial:

$x^2 + 5x + 6$: factors of 6 are: 6, 1, 3, 2. The factors of +3 and +2 sum to +5:
$(x+3)(x+2)$: you can check this with distribution
: $a=+3$, $b=+2$

Setting this equal to 0 (as when solving for the "roots" (where y=0) for the standard quadratic equation format) and solving for x:

$(x+3)(x+2) = 0$ dividing both sides of the equation by (x+2):

$x + 3 = \frac{0}{x+2} = 0$

$x = -3$: root , on the graph, this corresponds to point(-3 , 0)

Doing the same for the other binomial factor, we find:

$x = -2$: root , on the graph, this corresponds to point(-2 , 0).

In short, since the product shown above is 0, the method essentially assumes one or both factors are equal to 0.

Checking: $x^2 + 5x + 6 = (-3)^2 + 5(-3) + 6 = 9 - 15 + 6 = 0$ and:
$x^2 + 5x + 6 = (-2)^2 + 5(-2) + 6 = 4 - 10 + 6 = 0$

A quadratic equation or curve will only cross or intercept the y-axis once. Setting x=0, and solving for the corresponding value of y in either equation shown above, we find the y-axis intercept to be point(0 , 6).

There is a direct and preferred method to solve for the specific value(s) of the variable in a quadratic equation, and it is the same method so as to produce the two roots. This method uses the quadratic formula:

$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$: **QUADRATIC FORMULA** , given: $ax^2 + bx^1 + c = 0$,
a /=/ 0 , because the x^2 term must be present to be "quadratic" equation.
(b) and (c) are usually constants for a given "quadratic equation in (x)".

A derivation of this is as follows:

$ax^2 + bx + c = 0$: basic quadratic expression, transposing c:

$ax^2 + bx = -c$ dividing both sides by a:

$\frac{ax^2 + bx}{a} = \frac{-c}{a}$ the left side can be expressed as a sum of fractions:

$\frac{ax^2}{a} + \frac{bx}{a} = \frac{-c}{a}$ after canceling out the common factor of (a) in the first term:

$x^2 + \frac{bx}{a} = -\frac{c}{a}$

(*) The perfect square of a binomial is expressible in the general algebraic form of:

$(x+b)^2 = (x+b)(x+b) = x^2 + xb + xb + b^2 = x^2 + 2bx + b^2$, or=: $(1)x^2 + (2b)x^1 + (b^2)x^0$

The last expression, a trinomial, is equivalent to a perfect square of a binomial value, and specifically for this example, it is (x+b). Likewise, the square root of a trinomial that happens to be a perfect square of a binomial, is equal to that binomial:

Since: $x^2 + 2bx + b^2 = (x+b)^2$ taking the square root of both sides:

$\sqrt{x^2 + 2bx + b^2} = (x+b)$: the square root of a trinomial that is a perfect square

Now given only $x^2 + 2bx = 0$, what is a formula for the third term that can be added in (to both sides of course) so that $x^2 + 2bx + ?$ equals a perfect square of a binomial. Notice in the second term that the coefficient of (x) is represented as (2b). If we divide this value by 2 and square it, we will have the third formal term (of a perfect square of a binomial) which is represented as b^2. This process is known as "completing the square" and can be used as a way to check or determine if a trinomial is a perfect square of a binomial.

Given a general trinomial: $x^2 + (a + b)x + ab$, that is not a perfect square, but you can still create one out of it by using the above method. Take half of the coefficient of the x^1 variable and then square it:

$$\left(\frac{(a+b)}{2}\right)^2$$

You can then add this to the trinomial if you first transpose the (ab) term, a product and constant value, to the other side of the equation. If you do not transpose (ab), you must find the difference between (ab) and this value to be added in, and then add this difference to both sides so as to complete the trinomial that is a perfect square of a binomial. For example:

$(x + 2)(x + 4)$ these two different binomial factors will produce this trinomial:
$x^2 + 6x + 8$

By the above two different binomial factors, we know that this trinomial is therefore not a perfect square of a binomial. You can also find if it is a perfect square of a binomial by just considering the first two terms, completing the square and comparing this to the third term (here its 8):

$x^2 + 6x + ?$ completing the square:

$$\left(\frac{6}{2}\right)^2 = 3^2 = 9$$

Since the third term is not 9, it is also a confirmation that this trinomial is not a perfect square of a binomial. The third term or the "constant value term", the 8, is not correct for this to be a perfect square of a binomial, so an adjustment must be made. The difference between 9 and 8 is 1, therefore, if it is added to one side, it must be added to the other side of the equation so as to keep the equation in balance. Here is the resulting trinomial:

$$x^2 + 6x + (8 + 1) = 0 + 1$$
$$x^2 + 6x + 9 = 1$$

Taking the square roots of the first and last terms, we can find the terms of the binomial that this trinomial is a perfect square of.

$\sqrt{x^2} = x$ and $\sqrt{9} = 3$ therefore:

$x^2 + 6x + 9 = (x + 3)(x + 3) = (x + 3)^2 = 1$ taking the square root of both sides:

$\sqrt{x^2 + 6x + 9} = \sqrt{(x+3)^2} = (x + 3) = \sqrt{1} = 1$: this is one method to solve for (x) or a quadratic equation:

$x + 3 = 1$ transposing +3 :
$x + 3 - 3 = 1 - 3$ combining:
$x = -2$ If you put this in the original quadratic equation set equal to 0 to find the roots, you will see that this value of $x = (-2)$ solves it:

$0 = x^2 + 6x + 8$
$0 = (-2)^2 + 6(-2) + 8$
$0 = 4 - 12 + 8$
$0 = +12 - 12$: $0 = 0$: checks

Also: $(x+3) = 1$, $(-2) +3 = -2 + 3 = 1$: checks

For completeness, when the second term of a squared binomial is negative, the expansion becomes:

$(x -b)^2 = (x -b)(x -b) = x^2 -1xb -1xb +b^2 = x^2 - 2bx + b^2$

, so given any trinomial, if the second terms value (algebraically and formally expressed as: $+2bx$ or $-2bx$) is twice the square roots of the first and third terms, it is a perfect square of a binomial. The sign of the second term of this binomial will correspond to the sign of the second term of the trinomial.

In the above discussions, it is assumed that the coefficient of x^2 (usually indicated as (a) in ax^2) is 1. If it is not, then "divide through" each side by it, which is essentially dividing all terms on both sides of the equation by this coefficient (usually noted as (a)) if possible. At the above location in this book indicated as (*) in this derivation of the quadratic formula, the left side has an x^2 term and an x^1 term (which we know are the necessary terms of a formal quadratic trinomial or equation), hence we can solve for a value that when added in (to both sides of course) to that side, will make that side an expression equivalent to a perfect square of a binomial. The net result after some simplification is that we will have only one (solvable) unknown which is the variable we are solving for and its' equivalent value on the other side of the equation.

Even after dividing (b) by (a), in the trinomial, (b) which is the coefficient of the x^1 term is still twice (2) of what it needs to be for the binomial to be squared that represents the given trinomial. Dividing the co-efficient of this x^1 term by 2 so that we can find the value of (b) for the second term of the binomial squared that will be equal to the given trinomial. Algebraically expressing this process:

$\dfrac{\frac{b}{a}}{\frac{2}{1}} = \dfrac{b}{2a}$ squaring this, so as to help during some following rationalization of roots, we get:

$\left(\dfrac{b}{2a}\right)\left(\dfrac{b}{2a}\right) = \dfrac{b^2}{4a^2}$ adding this to both sides of the equation, so as to keep the balance on both sides:

$$\frac{x^2}{1} + \frac{bx^1}{a} + \frac{b^2}{4a^2} = \frac{b^2}{4a^2} - \frac{c}{a}$$

Now, the left side is equivalent to a perfect square of a certain binomial that represents or is equivalent to a given trinomial ("in x"). By taking the square roots of the first and third terms, (which are the (perfect) "squared" terms) we will have the terms of that binomial.

$\sqrt{x^2} = x$ and:

$\sqrt{\dfrac{b^2}{4a^2}} = \dfrac{\sqrt{b^2}}{\sqrt{4a^2}} = \dfrac{\sqrt{b^2}}{\sqrt{4}\ \sqrt{a^2}} = \dfrac{b}{2a}$: or= 0.5 (b/a). , hence:

$\left(\dfrac{x}{1} + \dfrac{b}{2a}\right)^2 = +\dfrac{b^2}{4a^2} - \dfrac{c}{a}$: the left side is a binomial squared that is equivalent to the trinomial ("in x") of $ax^2 + bx + c$ less the constant term c] . Algebraically, and-or mathematically, the right side is also equal to this trinomial.

Adding the fractions on the right side, (LCD = $4a^2$):

$$\left(\frac{x}{1}+\frac{b}{2a}\right)^2 = \frac{b^2 - 4ac}{4a^2}$$

Let's isolate (x) by first taking or expressing the square root of both sides

$$\frac{x}{1}+\frac{b}{2a} = \pm\sqrt{\frac{b^2 - 4ac}{4a^2}}$$ now solving for x by transposing non (x) or non-like terms:

$$x = -\frac{b}{2a} \pm \sqrt{\frac{b^2 - 4ac}{4a^2}}$$ the root of a fraction can be expressed as:

$$x = -\frac{b}{2a} \pm \frac{\sqrt{b^2 - 4ac}}{\sqrt{4a^2}}$$: taking the square root of the radicand factors in the denominator:

$$x = -\frac{b}{2a} \pm \frac{\sqrt{b^2 - 4ac}}{2a}$$ combining like fractions that have the same denominator, here (2a):

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$: **QUADRATIC FORMULA**
For finding (x) in a trinomial of the form: $ax^2 + bx + c$ $(a \neq 0)$

If (c) was equal to 0, the general form of the quadratic equation is reduced to a quadratic equation having the form of:

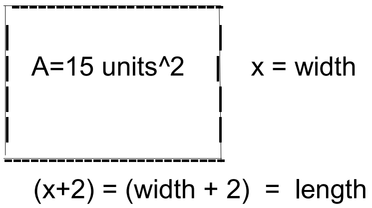
$$ax^2 + bx = 0$$

(x) can be solved for by "dividing through" (dividing each entire side of the equation) by (a), and then completing the square (of a binomial). (x) can also be solved for by using the quadratic formula, and the results are:

$x = -\frac{b}{a}$ and $x = 0$

Ex. A company manufactures a certain rectangular shaped object where its length must be 2 units longer than its width. If the total area of this rectangle is specified to be 15 square units, how long is the length and width?

Drawing a diagram of the situation: [FIG 45]



We know that: Area = (length)(width), and for our specific example, letting width = x, and length = (width + 2) = (x+2), we get:

$$\begin{aligned}(\text{length})(\text{width}) &= \text{Area}\\ (x+2)(x) &= 15\end{aligned}$$

Notice that this is the same equation that we had at the beginning of the discussion.

$(x+2)(x) = 15$ placing this into the std. quadratic eq. form, here by using distribution:
$x^2 + 2x = 15$
$x^2 + 2x - 15 = 0$ in relation to the standard quadratic equation form: $a=1$, $b=2$, $c = -15$

Substituting these values into the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

$$x = \frac{-(+2) \pm \sqrt{(+2)^2 - 4(1)(-15)}}{2(1)}$$

$$x = \frac{-2 \pm \sqrt{64}}{2} = \frac{-2 \pm 8}{2} \quad \text{hence:}$$

$$x = \frac{-2 + 8}{2} \quad \text{or} \quad x = \frac{-2 - 8}{2}$$

$$x = \frac{+6}{2} \quad \text{or} \quad x = \frac{-10}{2}$$

$$x = +3 \quad \text{or} \quad x = -5$$

As is the case for the solution of many problems with quadratic equations, the useful solution is usually the positive root only. For the last example, there is simply no physical length that can ever be negative in value, and for here, (-5) satisfies the quadratic equation mathematically, but it does not satisfy the given real or physical situation.

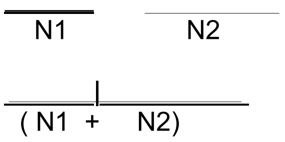
Checking:

$x^2 + 2x = 15$
$(3)^2 + 2(3) = 15$
$9 + 6 = 15$
$15 = 15$ checks

width = x = 3
length = (width + 2) = (x + 2) = 3 + 2 = 5

Area = (length)(width) = (5)(3) = 15 : checks

Ex. This example will discuss and derive the constant called the **Golden Ratio** = (GR). This value is about 0.618033988749894... and is used in many types of constructions (both man-made and natural) due to the supposed beauty it brings about. The Golden Ratio constant is an irrational value (like "pi" = 3.14159265... is) since it cannot be expressed as a ratio (ie. as a fraction) of two values since it does not in-fact have an exact value that could be easily representable mathematically since its digits never end, hence an infinite amount of digits. The derivation of the value of the GR is based on the magical-like concept when the ratio of N1 to N2, is equal to the ratio of N2 to the sum of N1 and N2. Graphically representing these values as line segment lengths:



: Let N3 = (N1 + N2)

And mathematically expressing a relationship:

$\frac{N1}{N2} = \frac{N2}{N3} = \frac{N2}{(N1 + N2)} = GR$: note here also, $(N2)^2 = (N1)(N3)$ and $N2 = \sqrt{(N1)(N3)}$

Now, we need some actual numeric values to find out just exactly what the value of this Golden Ratio constant is. Considering the value of N3 = (N1 + N2) as the whole (100% = 1) length, we will therefore assign it a value of 1, and then the problem can be analyzed using percentage or relative (to the whole or entirety) values.

$N1 + N2 = 1$ mathematically:
$N1 = 1 - N2$
$N2 = 1 - N1$

Placing these (algebraically) "derived" values back into the equivalent fractions or proportion equation, so as to use only the N2 variable and-or expressions that are "in terms" (ie., expressed with or as) of N2, it will effectively create a solvable equation which has only one unknown value.

$\frac{N1}{N2} = \frac{(1 - N2)}{N2} = \frac{N2}{1}$ solving for N2 :

$(1 - N2) = N2^2$
$N2^2 - (1 - N2) = 0$ distribute to clear grouping symbols:
$N2^2 + N2 - 1 = 0$: this has the basic form of: $1x^2 + 1x - 1 = 0$, and therefore: $x = \sqrt{1 - x}$
$x=0.618...$ Note alto that: $0.618^2 + 0.618 = 1$ and that $1.618^2 - 1.618 = 1$

We see that this is a quadratic equation with a = (+1), b = (+1), c = (-1). Using the quadratic formula:

$$N2 = \frac{-(+1) \pm \sqrt{(+1)^2 - 4(+1)(-1)}}{2(+1)}$$

$$N2 = \frac{-1 \pm \sqrt{1 + 4}}{2}$$

$$N2 = \frac{-1 \pm \sqrt{5}}{2}$$

: golden ratio mathematical formula, and the decimal equivalent of this is:
The square root of 5 is 2**.**236067978

N2 = 0**.**618033988749894... and N2 = -1**.**618033988749894... : these two values are negative reciprocals

Note that the second (root) value is actually the same value (has the same digits) as the first value plus 1, and is negative in sign, and it may not be apparent that they are also negative reciprocals of each other. The difference between these two signed values is the square root of 5 = 2.236067978**...** Due to the derivation, since the second value for N2 is negative in sign, and it will not be chosen as the ratio value we were seeking since there is no negative physical length, and hence, no ratio of real lengths that can actually be negative in value.

0**.**618033988749894... (about 61**.**8%) : **GOLDEN RATIO (GR, or "phi")**
The "reciprocal ratio" of this is:
$1/GR = 1.618033988749895... = 1 + GR$
$GR^2 = 0.381966011... = 1 - GR$

$1/GR = 1 + GR$ solving for GR by multiplying both sides by GR:

$GR^2 + GR = 1$ placing this into a quadratic equation form for the quadratic formula:

$GR^2 + GR - 1 = 0$: here, $a=1$, $b=1$, $c=(-1)$, after placing these into the quadratic formula and simplifying:

$$GR = \frac{-1 \pm \sqrt{5}}{2}$$

As an extra note: The sum of all the (integer powers of GR) = $(GR)^1 + (GR)^2 + (GR)^3 + \dots = 1/GR = 1.618\dots$

$N2 / N1 = 1.618$ and $N3 / N2 = 1.618$ or the reciprocal ratios: $N1 / N2 = 0.618$ and $N2 / N3 = 0.618$

If we let: $a=N1$, $b=N2$, and c=the total length of $(N1 + N2)$, we obtain the proportion or equivalent fractions of:

$$\frac{a}{b} = \frac{b}{c}$$ from this we mathematically obtain:

$$b^2 = ac$$ taking the square root of both sides:

$$b = \sqrt{ac}$$

: hence (b), (ie. N2), is the "**geometric mean**" (= square root of the products) of $(c) = (N1 + N2) = N3$, and $(a) = (N1)$.
Extra note ex.: the geometric mean of 10 and 20 is $\sqrt{(10)(20)} = \sqrt{200} = 14.142\dots$
$= \sqrt{10}\,\sqrt{20}$ or= $\sqrt{100}\,\sqrt{2} = 10\sqrt{2}$
$= 14.142$

The geometric mean of two vales tends to be closer in value to the least value, and this is due to the nature of squared values that increase rapidly in value.

In a simple way, you can think of the geometric mean of (10) and (20) as this example: If you had squares with areas of: 10 square units and 20 square units , their sides are about 3.162 and 4.47 units long respectively. The average of these two sides is about $3.81\underline{7}$ which corresponds to the side of a square having an area of about $14.5\underline{7}$

Another way to think of the geometric mean is this: Given an area with sides (a) and (c), and multiplying (a) and (c) together to find that area, we have: (a)(c), and to find the side length of an equivalent square shaped area which will have the same value for all its sides, we take the square root of this area value: $b = \sqrt{(a)(c)}$ b is therefor the side of a geometric equivalent area of another area having sides of (a) and (c).

A geometric mean could be considered like a geometric average, however, this average is of another form and calculated a different way because of the way the squared values grow or increase from one value to the next, and it is not an "arithmetic" or "linear" average that is located exactly between the two given values, For example, if we have the integer or "arithmetic" values of 2, 3 and 4, the average of 2 and 4 is 3. Now given the square of those values: 4, 9, and 16, the average is not 9. The linear average of 4 and 16 is actually: $(4 + 16)/2 = 20/2 = 5$. The geometric average is: $\sqrt{(4)(16)} = \sqrt{64} = 8$. This geometric series would be: 4, 8, 16, and we see that the common ratio= r=2. If we take the square root of 8, the corresponding series of these roots would be: 2, 2.828427... (not 3), and 4.

$$N2 = \sqrt{(N1)(N1 + N2)} = \sqrt{(N1)(N3)}$$ and also:

$$N2 = \sqrt{N1^2 + N1N2}$$

also:

$$c = \frac{b^2}{a} \qquad \text{and} \qquad a = \frac{b^2}{c}$$

$$N1 = \frac{N2^2}{N1 + N2} \qquad \text{and} \qquad N1 + N2 = \frac{N2^2}{N1} = N3$$

From the formal definition of GR, we can also obtain this fact:

$$\frac{N1}{N2} = \frac{N2}{(N1 + N2)}$$ simplifying to rid fractions:

$$N1(N1 + N2) = N2^2$$

$$N1^2 + N1N2 = N2^2 = N1(N1 + N2) = N1\,N3$$ The left side can be expressed as:

$$N2 = \sqrt{N1\,N3}$$

$N1N2 = N2^2 - N1^2$: this has the basic format of:
(product of values) = (difference in the squared values)
Due to the derivation of all this, it is only applicable to values that have
a golden ratio factor between them, such as $N2 / N1$ and $N3 / N2$.

The golden ratio (GR = 0.618033988749894. and is sometimes noted as "phi") is typically found or used in geometry and constructions. If you take a pentagon (5 equal sided plane figure) and draw a diagonal within, the ratio of this diagonal to a side is that of the golden ratio. A certain and simple series of integer numbers or terms that get larger is called the Fibonacci numbers and they are closely related to the golden ratio, and it is discussed further ahead in this book.

Also consider for example, by using 1.619 for (phi):

$(\mathrm{phi}) - (1/\mathrm{phi}) = 1$, and $\mathrm{phi}^2 + (1/\mathrm{phi})^2 = 3$, which is a rational value from the irrational golden ratio (phi).
$(\mathrm{phi})^3 - (1/\mathrm{phi})^3 = 4$, A pattern here is to increase the exponent by 1, alternate the sign, and the result is the sum of the previous two results. The result is a Fibonacci-like series: 1 , 3 , 4 , 7 ,11, 18 , 29 , 47 . . . : the ratio of successive terms approaches (phi).

If you were to multiply a quadratic equation by (x), the result is a cubic equation:

$x\,(ax^2 + bx + c)$, a simple example of this is: $x\,(x^1) = x^2$ and $x\,(x^2) = x^3$
$ax^3 + bx^2 + cx^1$ adding in an arbitrary constant, here (d):
$ax^3 + bx^2 + cx + d$: general or formal cubic expression or (algebraic) polynomial, here, "in x"

When there is no known formula for direct solution of an equation, the methods of numerical computation can be employed, as shown previously. Successive approximation is typically used. The appendix contains a computer program to solve an equation, particularly the square root of a value, using successive approximation. There are also many other algebraic and-or basic calculus methods to solve for the roots of equations, and these methods are often found in the mathematical topic that is called such as : Theory Of Equations, or Equation Theory.

Here is another successive approximation example.

Ex. $x^3 + x^2 = 12$ solving for (x):
$x^3 = 12 - x^2$ isolating (x) by taking the cube root of both sides:
$x = \sqrt[3]{12 - x^2}$

Expressing this in successive approximation form:

$x2 = \sqrt[3]{12 - x1^2}$:where x2 is a better approximation than x.

Continue till the difference between x2 and x1 is as small as desired. For this example, the true value of (x) is 2. Another recursion formula that can be derived from the original example is:

$x2 = \sqrt[2]{12 - x1^3}$: Note that the value of the second term cannot exceed 12 (ie. > 12) because it would cause the creation of a radicand that is negative in value and we can't solve for the square root of a negative value.

For equations other than linear (where the variable is only to the first power), it is possible, as shown previously, that there is more than one solution to an equation. Though not discussed in this book, there are some formally defined ways to determine the number of roots of an equation. By graphing an equation that is placed in "root form" (ie. algebraically set equal to 0) you can determine the number of roots of an equation, and you can also find the approximate values of those roots. You can then use each of these approximate values in a successive approximation equation. Using the last example, the "root form" of the equation for plotting (and for finding the roots or solutions) is:

$x^3 + x^2 - 12 = 0$: the result of the expression is set to 0, hence y=0, and we are then solving for a specific value(s) of x such that its corresponding value of y is equal to 0.

By also setting (y) equal to this expression, we create an equation and numerical relationship between two (or more) variables. This relationship can now be graphed as:

$y = x^3 + x^2 - 12$

The examples above were mainly quadratic or second degree equations since they are encountered more often in mathematics than equations of any higher degree. Another use for being familiar with different types of equations and their graphs is in design. The graphs or curves of many equations, or some combinations of equations, have a beauty in their own right. A part of the equation's curve can be used as the model for some form of construction, and can always be described, or duplicated to any size if given the (same) source equation and "boundary points" (ie. the two "end" or "extreme points" bounding or defining what specific part) of the curve is in question. By using the concepts of calculus, the (bounded) curve's length, and other useful facts (such as the area beneath a curve, or area between two curves) of that portion of the curve can be calculated.

Given two equations, each with their own graphing or curve shape, they can be expressed as being mathematically summed together and the result is a point per point, or instance per instance, amplitude (ie., the y values) summation of each, and it will produce a third or resulting curve or waveform. As a very simple example to this consider two waves colliding, combining or summing such that the peak (say +1 in value) of one wave is combined with the trough (say -1 in value) of another wave, and the result is: (+1) + (-1) = 0, no signal and-or energy. This is the case when the waves have the same frequency and amplitude, and are 180° (ie., opposite) out of timing or phase at the intercept or combining location. This concept is sometimes called destructive interference, as opposed to when the signals would combine to produce a larger signal (ie., amplitude, strength) and which is called constructive interference. For example: (+1) + (+1) = +2. In electronics, the electric signals (waveform, frequency, amplitude or voltage strength) might be combined in or across a resistor or transistor. The third or resulting wave is sometimes said as being composed of two or more other waves. As a simple and practical verification to all this, consider how two colors of light can be combined to produce a third color.

[This space for edits.]

ALGEBRAIC EQUATIONS WITHOUT A SPECIFIC SOLUTION

For equations that do not have a specific solution because of having unknown values that are part of the solution, simply express the relationship of the variables,

Ex. $x + y = 20$ solving for x and y:

$x = 20 - y$ and $y = 20 - x$: variables expressed "in terms" of the other variables, this is a linear or line equation, and it can even be (point per point) plotted and graphed (ie., connecting the points) as a curve. Technically, a line is considered as a unique instance of all the possible curves.

The corresponding solution depends upon the specific value of the other variable, hence if there are an infinite number of values for the value of this variable, their is an infinite number of corresponding results.

Here, we see that the values for either variable, x or y, depends on the other variable. We could say that each variable is a function of the other variable. If you pick a value for y, there is a certain or corresponding value for x such that their sum is equal to 20. If you pick another value for y, then there is a different value for x such that their sum is still equal to 20. In other words there is an infinite number of solutions rather than just a single specific solution. In short, when a variable is expressed in terms of another variable(s), there is no specific numerical solution, and only a certain expressed relationship of the variables. A formal equation of a line is one such example:

$y = cx$^1 $+ b$: the relationship of (y) to, or in terms of: (x), after solving for (x):

$x = \frac{y - b}{c}$: the relationship of (x) to, or in terms of: (y)

Ex. $y = 3x + 2$

$3x - y = -2$

$x = \frac{y - 2}{3}$

A relationship between variable(s) is typically called a "dependence" or "function". For example, it could be said for the above equations that "y is a function of x" or that "the value of y depends upon the value of x". If the equation is rearranged as shown above, we find that "x is a function of y", and a function expressed this way is sometimes called an "inverse function", such as to solve for the corresponding value of the independent variable when initially given a value of the dependent variable.

SOME ADVANCED EXAMPLES OF USING ALGEBRA

These examples use the mathematical operations previously covered in this book, and they also show some new concepts related to that particular type of example, and are good mathematical tools to have available. They will be helpful to your understanding of further topics in this book and elsewhere. A main point of these examples is to give more insight into algebra and how mathematical formulas can be made and utilized.

WHEN TWO OR MORE THINGS ARE WORKING TOGETHER

When two or people work together on a project or job, it is called cooperation, and that job can then get done or completed in a shorter amount of time and less effort and energy required from just one person. An easy to realize descriptive example is this: If it takes 1 person working for a year (365 days) to complete a project or job, then 365 people can complete the project in 1 day. In both cases, it takes 365 "man-days" (ie., a unit of measurement) or= 365 "people-days" to complete the project.

365 people-days = (number of people)(number of days) : basic formula to complete this specific job

365 people-days = 1 person x 365 days or:
365 people-days = 365 persons x 1 days If there are only 10 people on the team cooperating:

365 people-days = (10 persons) x (X days) After dividing both sides by 10 people: X days=36.5days
365 people-days = 10 persons x 36.5 days : 10 people can complete the project in 36.5 days

In terms of the typical 8 working hours per day for a person, you can multiply the number of days needed to complete the project by 8 so as to find the number of "man-hours" or "people-hours" needed to complete the project:

1 people-days = 1 people (day x 8hours/day) = 1 people (8 hours) = 8 people-hours
Also: people-hours / 8 = people-days
365 people-days = 365 people (day x 8 hours/day) = 2920 people-hours

Ex. A tank of water takes 10 minutes to be filled by pipe 1 (P1). The flow rate of water through and out of the pipe is 5 gallons (a volume unit) a minute (5gal / 1min). If pipe 2 (P2) is added to the system and its flow rate is 2 gallons per minute, how long will it take both to fill the tank?

Clearly since another pipe, P2, was added to the system, the tank will fill "faster", "quicker" or in less time than 10 minutes as it would with just P1.

Total flow per minute = Flow of P1 per minute + Flow of P2 per minute : gal/min
Total flow per minute = 5 gal/min + 2 gal/min
Total flow per minute = 7 gal/min : flow or flow rate

The total amount of water the tank holds can be found from what we know about with just information or data given for P1:

From : distance = (rate) (time) : rate = rate of change, here it's the change in distance per unit time, and it's usually called the speed or velocity of motion or moving. For a constant distance value, note that rate and time are inversely related.

volume = Total water = (rate) (time) = (amt. of flow per unit time)(time of flow) : here, rate is the change in volume per unit time
rate = R = flow rate

$$\text{Total water} = \frac{5\text{gal}}{\underset{1}{\cancel{1\text{min}}}} \times \frac{\overset{10}{\cancel{10\text{ min}}}}{1} = 50\text{ gal} = \text{Total Volume} = V_t = R\ T$$

Setting up a proportion or equivalent fractions equation:

$$\frac{50gal}{xmin} = \frac{7gal}{1min}$$ solving for x:

$$x = \frac{50gal\,(1min)}{7gal} = 7.14\underline{3} \text{ minutes}$$: mathematically: Total Volume = (Flow Rate)(Time) = R T , and here:

From this example, we will now solve it another way.

For each pipe filling the tank alone. We have 50gal to be filled by P1 that has a flow rate of 5gal/min.

From Total = (rate) (time)

$$time = \frac{Total}{rate}$$

$$time = \frac{\frac{50gal}{1}}{\frac{5gal}{1min}} = \frac{\frac{\overset{10}{\cancel{50gal}}}{1}\;\frac{(1min)}{\cancel{(5gal)}}}{\frac{\cancel{5gal}}{\cancel{1min}}\;\frac{\cancel{(1min)}}{\cancel{(5gal)}}} = 10\ (1\ min) = 10\ min$$

Doing the same for P2, we find that it will take 25 min.

Setting up a proportion from the data for P1:

100% is to 10min, as x% is to 1min. : note that full or whole = 100% = 1, and that relative values will be used here:

For P1:

$$\frac{1}{10min} = \frac{x}{1min}$$

$$x = \frac{1min}{10\ min} = \frac{1}{10} = 0.1$$: P1 will fill 1/10 = 0.1 = 10% of the tank per one minute

Now doing the same for P2, we find that it fills 1/25 = 0.04 = 4% of the tank per minute.

Full = 100% = 1 = total amt. due to P1 + total amt. due to P2
1 = (flow rate P1)(time) + (flow rate P2)(time)
1 = (R1)(T1) + (R2)(T2) When full, T = T1 = T2, the same value, therefore:
1 = (R1)(T) + (R2)(T) : an equation with only one unknown value to solve
1 = 0.1 T + 0.04 T Or perhaps expressed as:
1 = 1/10 T + 1/25 T = T (1/10 + 1/25)
1 = 0.14T solving for T: Notice the sum of rates, or= "total rate".

$$T = \frac{1}{0.14} = 7.143\ \ min$$

Checking:

Total gallons = total amt. due to P1 + total amt. due to P2
Total gallons = (5gal/min)(7.143min) + (2gal/min)(7.143min)

Total gallons = 35.715 gal + 14.286 gal
Total gallons = 50 gal : checks

Another note to make clear here is that time (T) and rate (R) are inversely related. At completion = 100% = 1.0 we have this:

$1 = (R)(T)$:R=total rate, T=total time, mathematically then:

$T = \frac{1}{R}$ and $R = \frac{1}{T}$: this is very similar to the relationship between cycles or frequency and time in the study of mechanical motion-or electronics: $T = 1/F$ and $F = 1/T$

At completion of a system with several things or parts of it working together, and with each having their own rate of doing or performing it, the time of completion of doing something is the same for all the parts of the system working together. The total rate is simply the sum of all the rates of the parts of that system as shown in the example above:

$Rt = R1 + R2 + R3 + \ldots$ and we have:

$1 = (T)(R1 + R2 + R3 + \ldots) = (T\,R1) + (T\,R2) + T\,(R3) + \ldots = (T)(Rt)$ and:

$$T = \frac{1}{R1 + R2 + R3 \ldots} = \frac{1}{Rt}$$

If each pipe took a certain amount of time to fill the tank, with having several pipes working together for the system, the total time would be inversely related, or less than just one pipe in the system.

From $Tt = \frac{1}{R1 + R2 + R3 + \ldots}$ this can be expressed as:

$$Tt = \frac{1}{\frac{1}{T1} + \frac{1}{T2} + \frac{1}{T3} + \ldots}$$

If only two pipes, machines or perhaps people are working in the system then we have:

$$Tt = \frac{1}{\frac{1}{T1} + \frac{1}{T2}} = \frac{1}{\frac{T1 + T2}{T1\,T2}} \quad \text{therefore:}$$

$Tt = \frac{T1\,T2}{T1 + T2}$: product divided by the sum

Checking using the last example:

$Tt = \frac{(10m)(25m)}{10m + 25m} = \frac{250m}{35m} = 7.14\underline{3}m$: checks with the previous results

LINEAR EXAMPLE

A linear mathematical relationship is when the rate of change between one variable with respect to another is constant. A graph of their relationship will also look like a line.

Ex. Two objects, say A and B are traveling, or are to travel, along the same path. A is 1 mile ahead of B, and is traveling at a rate of 25 milers/hour. B is traveling at 50 miles/hour. How long (in time) will it take B to catch up to and reach A, where at this point, the distance (ie., the difference) between them will be 0 miles.

First, it must be noted that B will never catch up to A if B is going slower than A. B's speed must be at least be slightly faster than A's speed if it is to ever reach A's position. Of course, if B is only slightly faster, it may take a considerable time and distance (since distance traveled is directly related to time of travel) to catch up to A.

Solution: Write the distance equations relating to each object. The general distance equation (or formula) is:

distance = speed x time **:** this is an example of an equation having the linear equation format

This formula comes from the fact that distance is directly related to the speed of travel. We also see that distance, a length measure of the change in location or position due to movement, is directly related to the time needed to move, travel or "go" that amount of distance. If either or both speed or time of the movement increases by some factor, the corresponding distance associated with that change will likewise increase by that same factor value. If either or both speed or time decreases, the corresponding distance associated with that change will decrease. Consider:

If you traveled at a speed of 7 miles/hour for 2 hours, and then traveled a speed of 5 miles/hour for 3 hours, the total distance you traveled is:

total_distance = sum of distances
total_distance = D1 + D2 : or= Dt
total_distance = (speed1)(time1) + (speed2)(time2)
total_distance = (7mi/h)(2h) + (5mi/h)(3h)
total_distance = 14mi 15mi
total_distance = 29mi :"29 miles"

total time = sum of times = time1 + time2 = 2h + 3h = 5h :"29 miles in 5 hours"

average speed = total_distance / total time = 29mi / 5h = 5.8 mi / hour :"an average speed of 5.8 miles per 1 hour"

Mathematically rearranging the basic distance equation, we have speed and time::

$$\text{speed} = \frac{\text{distance}}{\text{time}}$$: the units for speed are of the units for distance divided by the units for time. Mathematically:

$$\text{time} = \frac{\text{distance}}{\text{speed}}$$: we see that time and speed are inversely related. The faster you complete the distance, the shorter (less) the time taken.

For both equations, we will use miles for the distance units, hours as the units of time, and therefore use (miles/hour) for the speed units. These units were chosen since these were the units stated in the problem. Actually, any units could have been used as long all their quantities are properly converted to be in reference to that new unit.

Let's use variable D to represent distance, S for speed, and T for time. Hence:

D = S x T Writing the distance equations for each object:

$DA = SA\ TA$ + distance A already traveled or "lead" distance at the start, where $T=0$: distance for object A
$DB = SB\ TB$ + distance B already traveled or "lead" distance at the start, where $T=0$: distance for object B

The added term to the distance value is included as a possible adjustment, and it is a constant added to the equation.

At the start of the system in question, where $T=0$, we know that:

$DA = 25m/h\ Th + 1m$: when $T=0h$, $DA = 1m$ as mentioned in the statement of this example
$DB = 50m/h\ Th + 0m$

At a point in time, which is what we are solving for, the difference between the distances of the two objects is 0m. That is: $DA - DB = 0$ (or: $DB - DA = 0$). Likewise, it could be said or easily verified algebraically, that at a certain point in time, the distances of the objects are equal: $DA = DB$, and the distance or difference between them is 0m.

$DA - DB = 0$ substituting values:
$(25m/h\ Th + 1m) - (50m/h\ Th) = 0m$ clearing some grouping symbols:
$25m/h\ Th + 1m - 50m/h\ Th = 0m$ combining like terms and transposing the +1m:
$-25m/h\ Th = -1m$ isolating Th:

$$Th = \frac{-1m}{-25m/h} = 0.04h$$

Let's convert this fraction of an hour value to a more practical value of minutes:

$$\frac{60min}{1h} = \frac{xmin}{0.04h}$$

$x = 2.4min$

Let's check using substitution:

$DA = 25m/h\ (0.04h) + 1m = 2m$
$DB = 50m/h\ (0.04h) = 2m$: checks, and:

$DA - DB = 2m - 2m = 0m$:checks, at the point of intersection or meeting, their difference in distance, and-or distance between them, is 0m.

This 2m value also tells us the total distance that B will travel in order to catch up to A. A will only travel only 1m (check: 25m/h x 0.04h = 1m) further since it already had a lead or initial distance of 1 mile from the start of this system where Th is considered as 0h for both objects. A's "meet-up" to B distance, or A's distance to go, in this system (where T starts at 0) - A's lead distance = 2m - 1m = 1m.

Note that in the stated problem that object A's distance lead could mean several things. For example, it could mean that the objects started from the same initial physical point or place as B, or it could also mean that A's starting position is in fact 1m further away or distant along the route from that of B's starting position.
If it was stated that A also had a time lead before the start of the current system or situation of both the objects, its' equation would look something like this:

$DA = Sm/h\ (Th + \text{time lead}) + \text{distance lead}$: extra, this could be thought as: DA = lead distance, when $T=0$, and then substitute this in:
$DA = (Sm/h)\ (Th + \text{time lead}) + \text{lead distance}$

Likewise, the system such as that just mentioned can just as well be analyzed where one object lags behind in time (ie. a "time lag"). For example if Th represents the time object A has traveled, that is, Th is the system time for both object A and object B, and object B lags behind in (the systems) time by 1 hour (ie. it effectively sat idle and not changing in distance after the start (where T=0) of the system, or perhaps was late to arrive at the start of the system). The equations for this situation are:

DA = speed x time = speed x Th : regular equation, no lags
DB = speed x time = speed x (Th - 1) : if there was a lag. A time lag effectively causes a distance lag

Note, that as long as speed (or velocity)) remains constant, then these distance equations will all have the same format as that of the basic linear (line) equation or formula of:

y = mx + b : for linear or line studies, the formal variable (a) that is the coefficient of (x) is often replaced and identified as: (m) as shown. Note that (a) and-or (m) is a constant value, and it and its value is associated with the specific linear mathematical relationship between (y) and (x).

Some forms of this equation will also note (b) as (c), and this is simply a constant (often used as an adjustment needed) added in. Using letter (c) helps indicate it as a constant.

In this equation, (y) is the dependent variable whose value is mathematically related to and depends upon the value of the independent variable (x). In perhaps simpler words, (y) is said to be a result, output, or "a function of" the given expression and here it's (mx + b). Since this expression is equal to (y), the expression is said to be the (processing, working, source of) function (in a noun sense). Since (m) and (b) remain constant for linear equations, (y) is realistically, a function of (x), and would then be often mathematically expressed or indicated with the function (f) syntax (grammar) of: y = f(x), and this notation is read or spoken as: "y is (or equals) a function of x". In this example, y = f(x) = mx + b. The group or set of independent values (here, all the possible values of x) of a function is often called the "domain" of the function, and the corresponding group of dependent values (here all the y values) to those domain values is often called the "range" of the function. If this line equation is graphed or plotted using the common rectangular (planar or two-dimensional) coordinate system, variable (m) (ie,.the speed for this example) is the slope (or "steepness") of the line, or more technically, the rate (a measure, or ratio, of change) of the corresponding change of (y) with respect to (x). Variable (m), or whatever happens to be the coefficient of (x), is always a constant value for linear or line equations. Slopes are also discussed ahead in the TRIGONOMETRY section. (b) is a constant that is the initial or "lead" value of (y) when (x) = 0. In relation to the example, D corresponds to (y), S corresponds to (m), T corresponds to (x), and the (distance) lead corresponds to (b):

y = mx + b : the basic form of a linear equation
D = ST + distance lead : the example's specific and-or linear equation

Linear equations, when plotted on a graph where one axis, usually the x or horizontal axis, of reference or dimension represents increasing values of the independent variable, and the other axis, usually the y or vertical axis, of reference or dimension, represents the values of dependent variable, always produce a straight line. Lines indicate that the rate (expressed as a ratio) of change (ie., the slope = m value) of the dependent variable (such as y) with respect to the independent variable (such as x) is a constant value. This type of mathematical relationship is then called a linear or a (mathematically) constant relationship. If b=0, this can be clearly seen:

From: y = mx : here, b=0. If m=1, the equation reduces to: y = 1x = x , clearly a direct relationship. From the equation we algebraically get:

$m = \frac{y}{x}$: **m = slope** of the line, it's a constant value for a certain equation and line and is not a variable, and it is the numerical coefficient of x. This value of (m) is the rate of change of the corresponding values of (y) in relation, or with respect to changes in (x). Basically, it is a measure of how the value of (y) changes when (x) changes by 1.

For example, if $m=3$, when (x) changes by 1, the change of, or in (y) with respect to (x) is (the factor of) 3.

From the equation: $y = 3x$, we have: $3 = m = \frac{y}{x}$: when variables are said to have a linear mathematical relationship, the rate of corresponding changes in their values is constant.

The above quotient, ratio, or "magnification factor" indicates that the corresponding value of y will always be three times greater than the value of x. This value also indicates that for each (1) unit change in or of the value of (x), then the corresponding value of (y) will change in value by 3 times that change. If (x) changes by 1, (y) will change by: (3)(change in x) = (3)(1) = 3. If the value of (x) changes by 2, the corresponding value of (y) will change by: 3(2) = 6. More specifically for any change in (x), the corresponding change in (y) will be 3 times that change. This is the mathematical relationship between (y) and (x), and it is a linear or constant mathematical relationship as indicated by the constant factor value (m), and here for this example or equation, it is 3.

change in y = (3) change in x since $m=3$, mathematically then:

$m = \frac{\text{change in y}}{\text{change in x}}$: regardless of what b, the arbitrary constant, is. Let's give some more verification:

Consider one instance of the line eq.: $y1 = mx1 + b$: eq. 1
Consider another instance of the same line eq.: $y2 = mx2 + b$: eq. 2

This second equation can be expressed (using substitution) in relation (or in "terms of") to the first equation as:

First, below, y2 will be expressed in terms of y1, and x2 will be expressed in terms of x1. Change is essentially, and calculated as, the difference between y2 and y1. It could also be said as how y1 was changed, or the change applied to y1, so as to have the new value of y2:

From: $(y2 - y1) = (\text{change in y1})$: or= (change in y values) = (change in y) , solving for y2:
$y2 = y1 + (\text{change in y1})$: likewise, $(x2 - x1) = (\text{change in x1})$ or= (change in x)

$$\begin{aligned} y2 &= m\,x2 + b \quad \text{, and using substitution for the values:} \\ y1 + (\text{change in y1}) &= m\,(x1 + \text{change in x1}) + b \\ y1 + m\,(\text{change in x1}) &= m\,x1 + m\,(\text{change in x1}) + b \end{aligned}$$

$$mx1 + b + m\,(\text{change in x1}) = m\,x1 + m\,(\text{change in x1}) + b$$

Transposing +(m)(change in x1), we find this must be true (especially, since we used: m(change in x1) for (change in y1)) because we arrive at the original equation (eq 1) that we know is true:

$y1 = m\,x1 + b$: b is also known as the "y-axis intercept or crossing" where $x=0$, that is, the coordinates of this point are $(x,y) = (0,b)$
When $b=0$, we can still see that $y1/x1 = m$

Also from the above equation, and substituting the values of: (mx1+b) for y1, and (change in y1) for m(change in x1) :

$$\begin{aligned} y1 + m\,(\text{change in x1}) &= m\,x1 + m\,(\text{change in x1}) + b \\ mx1 + b + \text{change in y1} &= m\,x1 + m\,(\text{change in x1}) + b \end{aligned}$$ after Transposing. mx1, and b:

$(\text{change in y1}) = m\,(\text{change in x1})$

Hence:

$$m = \frac{\text{change in } y1}{\text{change in } x1} = \frac{y2 - y1}{x2 - x1}$$

: showing that (m) can be calculated from (any) two points on a line, or two pairs of corresponding values of variables (x) and (y). This mathematically verifies that variable (m) is also equal to the rate of change in the values of the variables, here (y) and (x). If the change in (x) is 1: m = (change in y1) / 1 = (change in y1). In other words, when (x) changes by 1, (y) will change by (m), and this is a simple way to think of what (m) does.

Since this will also be the case for any two points on the line, the formula for (m) can be generalized and noted as simply:

$$m = \frac{\text{change in } y}{\text{change in } x}$$

Also to consider:

$$y1 = m\,x1 \text{ , and: } \quad y2 = m\,x2 \quad = \quad y1 + \text{change in } y1 \quad = \quad m\,(x1 + \text{change in } x1)$$

$$m = \frac{y1 + \text{change in } y1}{x1 + \text{change in } x1} = \frac{y2}{x2} = \frac{y1}{x1}$$

The coordinates ("x,y pairs") of two or more points on a line are said to be proportional to each other,and whichis basically an equivalent fraction concept. Actually, for this to be true, (b) must equal 0. For example considering two points on a line:

$$\text{From: } \quad \frac{y1}{y2} = \frac{x1}{x2}$$

$$r = \frac{y1}{x1} = \frac{y2}{x2}$$

let's verify this, also note that here, r = m (the slope of the line):

$$\frac{y1}{x1} = \frac{y2}{x2} = \frac{y1 + (\text{change in } y1)}{x1 + (\text{change in } x1)} = \frac{y1 + m(\text{change in } x1)}{x1 + (\text{change in } x1)}$$

Observing the first and last fractions:

$$\frac{y1}{x1} = \frac{y1 + m(\text{change in } x1)}{x1 + \text{change in } x1}$$

We note that this is very odd since the right hand (equivalent) fraction is created by adding to the numerator and denominator, and not the typical way where both the numerator and denominator are multiplied (or divided) by the same value. Adding is allowed if it is done right, as mentioned previously, as a unique way for creating an equivalent fraction, and the value to be added cannot be the same in the numerator and denominator, nor just any values. The right hand side has the form of:

$$r = \frac{y1 + a}{x1 + b}$$

: where (a) and (b) are any proper pair of values to make an an equivalent fraction. Setting n(y1) = (a), and n(x1) = (b):

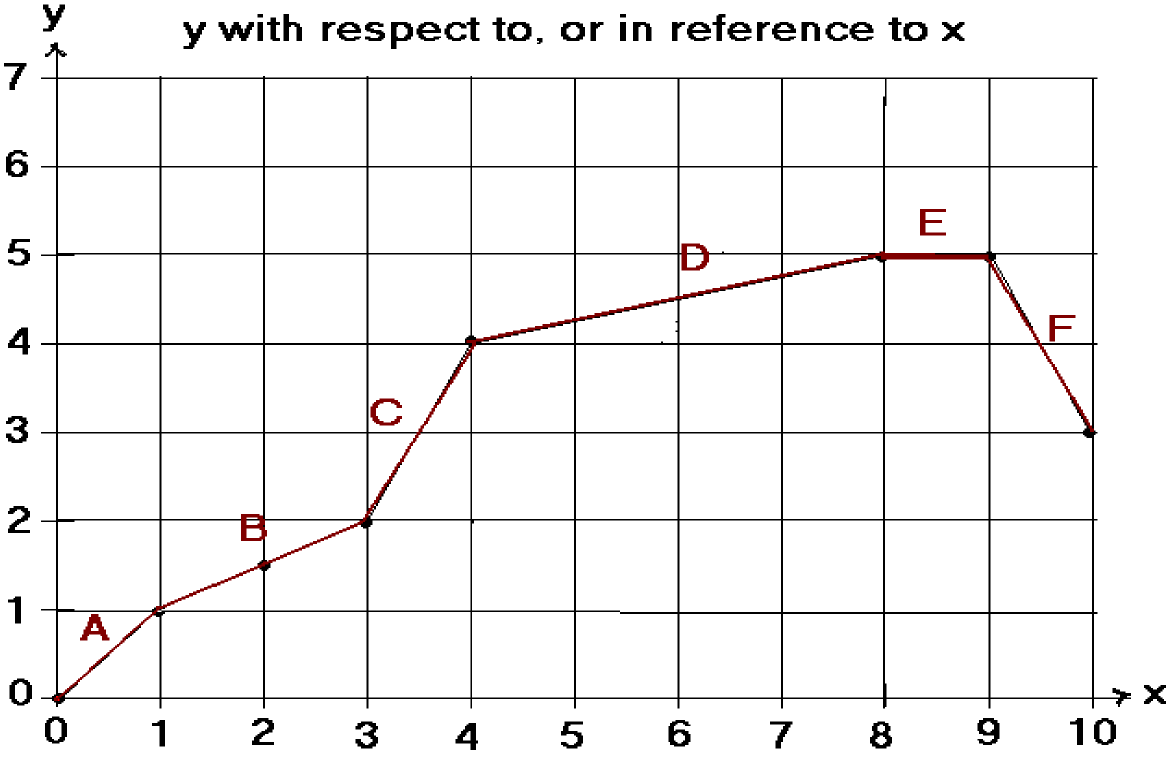
$$r = \frac{y1 + n(y1)}{x1 + n(x1)} \qquad \text{extra: } = \frac{y1\,(1 + n)}{x1\,(1 + n)} = \frac{y1}{x1}$$

: shows they are equivalent fractions. Here, the value that was essentially added to the numerator and denominator had the same multiple (here n) of itself.

Letting n(y1) = change in y1, and n(x1) = change in x1 :

$$r = \frac{y1 + \text{change in } y1}{x1 + \text{change in } x1} = \frac{y2}{x2}$$

Here is graph for a basic example of seeing, calculating and understanding slope values on a graph: [FIG 46]



This graph would be typical of a object that occasionally changed its speed while moving. The slope of the indicated line segments (indicated as A through F) is as follows:

The main changes in the slope (and its mathematical value) of the line are indicated where the curve or line segment on the graph changes to be more or less vertical which indicates an increased or decreased slope value. The slope value visually and mathematically expresses the relationship between the changes in (y) and (x). The slope value is calculated by using the (ratio of) corresponding changes in the (y) and (x) values. When there is no corresponding change in the relationship of the (y) values when the (x) or independent variable changes, the line segment or curve will be horizontal. The slope of the line is 0 or "flat" meaning the object is not moving and not increasing its distance.

When there is no noticeable change in the current slope or "vertical tilt" of the curve or line segment, then the slope is a constant value, and the mathematical relationship is then said to be "linear" (a linear mathematical relationship) which means a constant mathematical relationship. Between any two points on any line segment, such as seen in the above graph, the slope is constant. At any point where the slope changes, the (rate of changes) or "speed" has changed. If the speed is greater, the slope on the graph is greater, and the distance traveled will be greater per unit change in x or time.

A: From x=0 to x=1, the slope is: (change in y) / (change in x) = (y2 - y1) / (x2 - x1) = (1-0) / ((1-0) = 1/1 = 1
This value can be thought of as: As (x) changes by 1, (y) changes by 1.

B: The next part of the curve, or relationship between (y) and (x), is not as steep or vertical.
From x=1 to x=3, the slope is: (change in y) / (change in x) = (y2 - y1) / (x2 - x1) = (2-1) / ((3-1) = 1/2 = 0.5
This value can be thought of as: As (x) changes by 1, (y) changes by 0.5

C: The next part of the curve, or relationship between (y) and (x), is steeper and more vertical.
From x=3 to x=4, the slope is: (change in y) / (change in x) = (y2 - y1) / (x2 - x1) = (4-2) / ((4-3) = 2/1 = 2
This value can be thought of as: As (x) changes by 1, (y) changes by 2.

D: The next part of the curve, or relationship between (y) and (x), is not that steep, and is somewhat horizontal.
From x=4 to x=8, the slope is: (change in y) / (change in x) = (y2 - y1) / (x2 - x1) = (5-4) / ((8-4) = 1/4 = 0.25
This value can be thought of as: As (x) changes by 1, (y) changes by 0.25 , or "not that much"

E: The next part of the curve, or relationship between (y) and (x), is that the curve or line segment is horizontal.
From x=8 to x=9, the slope is: (change in y) / (change in x) = (y2 - y1) / (x2 - x1) = (5-5) / ((9-8) = 0/1 = 0
This value can be thought of as: As (x) changes, (y) is not changing and is a constant value of 0.

F: The next part of the curve, or relationship between (y) and (x), is that the curve or line segment tilts in a vertically downward direction as (x) increases. From x=9 to x=10, the slope is: (change in y) / (change in x) = (y2 - y1) / (x2 - x1) = (3-5) / ((10-9) = -2/1 = -2. This value can be thought of as: As (x) changes by 1, (y) changes by -2, hence (y) decreases by (-2) for each change in (x).

GRAPHING AN EQUATION

Below is an example of graphing an equation that is for a line.

Given an algebraic equation, it can be represented geometrically, and most commonly as a graph on a (flat) plane. If the equation is plotted and produces a line, the equation is a linear equation. For example:

$$x + y = 10$$

This is a two variable linear equation. There isn't a single specific solution to it since an infinite number of solutions is possible. Each corresponding pair of variables is unique to one solution only when the variables are considered ordered, that is, as an "ordered pair" (ie., coordinates of a point) they will only occur in that unique (corresponding) order or way only once. This pair of variables is therefore often called an "ordered pair". For example, the following pairs of variables will solve the equation shown above:

x	y
11	-1
10	0
9	1
8.5	1.5
5	5
1	9
0	10
-10	20

Mathematically: $y = 10 - x$ and $x = 10 - y$

$y = -x + 10$ $x = -y + 10$

Notice that the variables (y) and (x) are inversely related. That is, as one variable increases, the other will decrease, and vice-versa, to satisfy (make it true) the equation. Clearly with the data we have, as variable x decreases, variable y increases. It could also be said that as variable x increases, variable y decreases.

For plotting purposes, it is best to arrange the equation in terms of just one variable since the graph of the equation plotted on a rectangular coordinates, location and-or measuring system will show or represent the relationship of two variables, and in particular, one variable "against" or "versus" (ie., with reference or respect to) the other. Usually (y), is expressed in terms of (x), and the actual variable names, symbols or identifiers you can use depends on the information expressed in the given problem and-or equation.

From: $y + x = 10$ we algebraically have:

$$y = -x + 10$$

The connection between algebra and geometry is that every set or pair of variables that satisfies this equation will produce a point which is a geometric concept. Likewise, any point on the geometric graph of the equation will satisfy (be a solution to) the algebraic equation.

In theory, any two points can be used to define a line on a graph. In practice, the two points used are separated by a reasonable distance (not so close together, and the farther, the better results displaying, plotting or verifying all other points on the line), and a third point, also on the line, will be used as a check to ensure that the two "end" or "defining" points (of that line segment,or line) are not two completely random points on a plane, but are also defined by the equation and plotted (placed, indicated) at the right location on the graph.

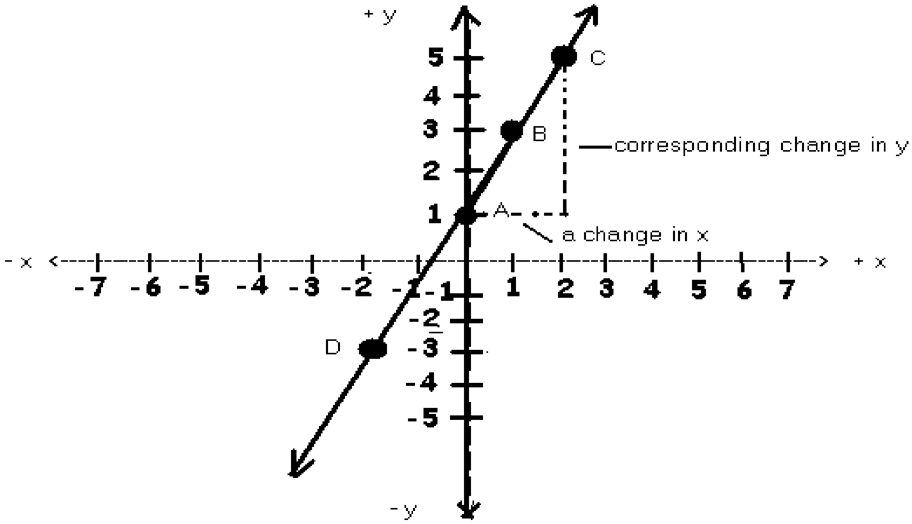
Any two points can be used to define and draw a line for plotting on a graph. In practice, the two points used are separated by a reasonable distance, and a third point will be used as a check to ensure that the other two "end" or "defining" points (of that line and-or line segment) are correct.

Ex. Graph the line: $y = 2x + 1$

Substitute three values for (x) and solve for the corresponding values of (y). Each corresponding value of (x) and (y) will be the coordinates ((coordinating, coordinated, or corresponding) "address" or location) of a point on a line within the rectangular co-ordinate system that is usually used for identifying points and places (locations) on a plane. A rectangular co-ordinate system, as described previously, is simply two number lines that cross perpendicularly at both their reference or "0" positions. Each point in this system is located at the horizontal and vertical intersection of its defining co-ordinates.

Point	x	y
A	0	1
B	1	3
C	2	5
D	- 2	- 3

Once you have the co-ordinates of some sample points of and on the line, plot (display, draw or indicate) them, and then use a straight surface, such as a ruler's edge, as a helpful guide to draw and connect these points on the line. [FIG 47]



The point where the line crosses the y-axis is called the (y) or vertical (axis) intercept. Here, the corresponding (x) co-ordinate of that point is always 0. To find this specific (y) co-ordinate, first set (x) to a value of 0, and then solve for (y):

$y = 2x + 1$
$y = 2(0) + 1$
$y = 1$: this value is always equal to the (b) variable in the basic expression of a linear equation: $y = mx + b$

Algebraically, and graphically, the coordinates of this point are: P(0,b) : "y (axis) intercept point" of a linear equation, or "dependent axis intercept". This could be thought of as a "lead value" for (y) when (x) has no value yet and-or is equal to 0.

The point where the line crosses the (x) axis is called the (x) or horizontal intercept, or "root" of the equation. Here, the (y) co-ordinate of that point is always 0. To find the corresponding (x) co-ordinate, set y=0 and then solve for x:

$y = 2x + 1$ Let's rid non x termed variables to one side, or place x termed variables on one side to isolate x.
$0 = 2x + 1$ T. (+1), transpose +1 by adding the negative of that term to each side of the equation :
$-1 = 2x$ isolating x by dividing by its multiplying factor or coefficient, and then switching sides:

$$x = \frac{-1}{2} = -0.5$$

In general, the algebraic formula for this x coordinate can be created using the basic (slope-intercept form, of a) linear or line equation:

$y = mx + b$ setting y=0 and solving for x, we find:

$x = \frac{-b}{m}$ or $= -\frac{b}{m}$: x coordinate of the x-axis intercept of a line

Algebraically, the coordinates of this point is: P(-b/m , 0) : "x intercept point"

Checking the slope (m) between points A and C, as indicated on the graph:

$\text{slope} = m = \frac{\text{change in Y}}{\text{change in X}} = \frac{YC - YA}{XC - XA} = \frac{3 - 1}{1 - 0} = \frac{2}{1} = 2$: checks

What does this value of 2 mean? In short, and as discussed previously, the answer is that when (x) changes by 1, (y) changes by 2. For each and every one unit change in (x), (y) will change by 2 units. It's basically an equivalent fraction concept where the ratio (here m, the slope value) of the corresponding changes in the values of the variable is a constant value of 2. The rate of change in a linear equation is a constant value. If the rate of change between the two variables was not a constant value, then there would be a variable involved in the calculation for that (non-constant, or varying) rate of change of one variable with respect to, or in reference to, another variable. In a linear, first order or degree equation, the rate of change of Y with respect to X is a constant value of (m) which is the coefficient of the (X) or independent variable. In the **Extras And Late Entries** in this book, there is **a graph to help under linear equations and slopes**.

$m = 2 = \frac{\text{change in Y}}{\text{change in X}} = \frac{n\,(\text{change in Y})}{n\,(\text{change in X})}$: if the change in X was increased by a factor of (n), the corresponding change in Y will be increased by that same factor.

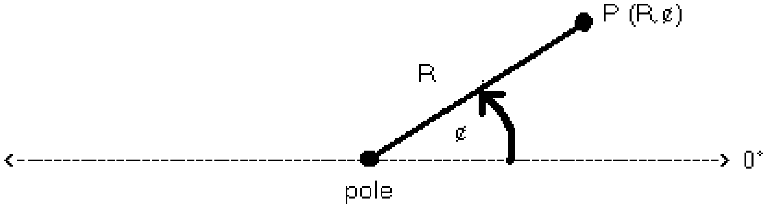
From this, we can find out how much Y will change when X changes by some value.

(change in Y) = m (change in X)

The higher (m), the slope, is in absolute value, the more vertical the line. The lower (m) is in absolute value, the more horizontal the line. When slopes are negative in value, this indicates that the line or line segment will slope downward (ie., y coordinates are decreasing) as the x coordinates increase in value. A negative slope indicates an inverse relationship between the (x) and (y) values at that location on the graph or curve of an equation.

The rectangular co-ordinate system is simply an extension of the geometric concept of a plane. In simple terms, a plane is an infinitely flat surface in all directions. Hence a plane can be thought of as having only a horizontal and vertical dimension, and lacking any third or "depth" dimension used to define space or volumes. All points on a plane can therefore be identified by their corresponding two location or dimension values from any point chosen as a reference (of measurements) or "origin" location, position or point, usually p(0,0), on that plane. Each location, or coordinate, is actually the measured or scaled (dimensional, and perpendicular) distance in units from the origin. Each coordinate is therefore also equal to the perpendicular distance from the other coordinate's axis (reference (of measurement) line). The point is located at the intersection of these (imaginary) perpendicular "distance or coordinate lines". The coordinates of a point is essentially the location or address of that point with respect or in reference to the origin of that (addressing and measuring system) system.

The graph (geometric representation) of an inequality is a segment or portion of a plane. As a simple example, the inequality ($y>5$), "y if greater than 5", represents the plane portion or segment that is composed of all the points (x, y) where the corresponding (y) coordinate of any point within that plane segment is greater than 5. This could be expressed as: $p(x, y>5)$. Note, the number of points within a segment or portion of a plane is just as infinite as the plane itself. There is another standard, though perhaps less used, co-ordinate or location addressing system for points and it is called the polar co-ordinate system. Here, a point's (P) location is defined as its straight-line distance, known as the radius vector (R), from the origin (or "pole") to that point, and to distinguish it from all other possible points at this same distance (like the points on the circumference of a circle, all being the same distance since they all have the same (radius) distance from the center of a circle), its location includes the radius vector's angle from a reference line (called the polar (system) axis). The figure below shows polar co-ordinate system within a two dimensional rectangular system. It is very possible to have three-dimensional co-ordinate system for either or both methods. [FIG 48]



Briefly, you can convert between polar and rectangular coordinates of a point when you consider the radius-vector line as the hypotenuse side or line (segment) of a right triangle and whose two other sides or lines are equal to the rectangular coordinates of that point. These two other sides can be used to determine the angle of the radius-vector line, and vice-versa. A minimal amount of the knowledge of trigonometry, as discussed ahead in the TRIGONOMETRY section of this book, will be of assistance for these calculations. Polar coordinates will not be discussed further in this book, but further ahead, this book does include a basic discussion about vectors.

Given two lines, there are several methods to solve for the point of intersection of those lines. The lines cannot be parallel lines since parallel lines are defined as never intersecting. Here is a simple algebraic method.

$y1 = m1x1 + b1$: a line equation general format
$y2 = m2x2 + b2$: another line equation general format.

Note, if $m1=m2$, and the value of (b) is different for each unique line, the lines are parallel. Parallel lines have the same slope both graphically, and numerically, which is the same rate of change of the dependent variable (y) with respect or in reference to the independent variable (x).

At the **point of intersection of two lines**, the difference between both the (y), and-or both the (x) co-ordinates of both points located at the point of intersection is 0 since they will have the same value for both points. This concept can also be used for many types of equations and curves.

$y1 - y2 = 0$ substituting their equivalent expressions:
$m1x1 + b1 - (+ m2x2 + b2) = 0$ distributing:
$m1x1 + b1 - m2x2 - b2 = 0$ at the intersection, $x1 = x2$, so let's express this value as just (x):
$m1x + b1 - m2x - b2 = 0$ factoring (x) out of the left side:
$x (m1 - m2) + b1 - b2 = 0$ transposing b terms:
$x (m1 - m2) = b2 - b1$ isolating x:

$$x = \frac{b_2 - b_1}{m_1 - m_2}$$: **X CO-ORDINATE OF POINT OF INTERSECTION OF TWO LINES**

The corresponding (y) value of the point of intersection can be found by direct substitution of this value of (x) into one of the original linear equations.

Ex . Eq 1: $y_1 = 2x_1 + 1$ Eq 2: $y_2 = 3x_2 + 2$

$m_1 = +2$ $m_2 = +3$

$b_1 = +1$ $b_2 = +2$

At the point of intersection: $x = \frac{b_2 - b_1}{m_1 - m_2} = \frac{2 - 1}{2 - 3} = \frac{1}{-1} = -1$

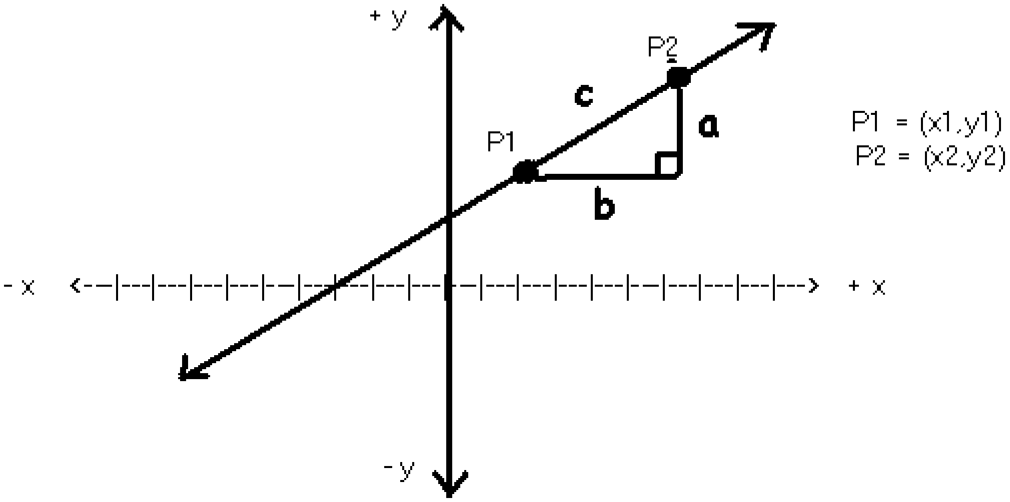
By substituting this value of (x) into either of the original equations, we will have the corresponding (y) value of the point of intersection (Pi) of those two equations or lines:

$$\begin{aligned} y_1 &= 2(-1) + 1 &= \quad y_2 &= 3(-1) + 2 \\ y_1 &= -2 + 1 &= \quad y_2 &= -3 + 2 \\ y_1 &= -1 &= \quad y_2 &= -1 \end{aligned}$$

Pi = (-1, -1) : point of intersection for the given and specific system of two equations or lines

Writing An Equation Of A Line:

For plotting points on a line, or for predicting data (information, values or points) that is line-like (having a linear-like relationship), you must know or create (write, express) the linear equation for the mathematical relationship that corresponds to these points. The minimum number of points needed to plot or draw any specific line is two, and it is also the minimum number of points needed to create the corresponding linear equation. If it is stated or understood that a line crosses at the origin (0,0), then this point can also be used as one of those two points necessary to define a line. Observe the drawing below: [FIG 49]



First, lets find the slope (m) of the line with the given co-ordinates of two points on it:

$$\text{slope} = m = \frac{\text{vertical change}}{\text{horizontal change}} = \frac{(y2 - y1)}{(x2 - x1)} = \frac{\text{side (a) of a right triangle}}{\text{side (b) of a right triangle}} = \frac{\text{"rise"}}{\text{"run"}}$$

Now, find the Y-axis intercept value. This is the corresponding y value where x=0. It is often assigned the variable identifier of: (b) since it is the next letter following the letter (a) in the alphabet, and of which is the formally expressed coefficient of the variable in a general linear equation of: $y = ax^1 + bx^0 = ax + b$

$y = mx + b$
$y = m(0) + b$
$y = b$

Now that (m), the slope of the line, has been solved for, take the coordinates of a known point on the line and substitute them into the basic form of a linear equation and solve for the actual value of (b) for the specific line:

$y = mx + b$ solving for b:
$b = y - mx$

Finally, write the equation of the line, substituting the found values for (m) and (b):

$y = mx + b$

Ex. $y = 2x + 3$: where m=2, and b=3

Given a set of points or data that appear (perhaps after plotting some points) to be linear or line-like, you can do the above process to find the equation of the corresponding line. Perhaps this equation can be used for predictions or estimates of data values, etc., however, given real-world data points, it is possible that several lines (although probably close together) could be created. There are advance methods of writing line equations that takes this into account and to create a single, "average" or "best fitting" line and equation to represent the given data. The appendix contains a simple or practical approach to finding a "reasonable equation" of a line given a set of points.

The following is a method of writing an equation of a line, however, it is one of the few discussions in this book that has a forward reference, particularly of the Pythagorean Theorem that is found in the TRIGONOMETRY section.

Notice in the drawing that if you let (c) represent the length of the line segment between the two points, that this is the (hypotenuse, longest side) side of a right triangle. The other two sides (a and b) of this triangle are the distances (here, calculated by difference) between the corresponding coordinate values of the points that define that line segment. By using the Pythagorean Theorem, we can write a general formula for the distance between any two points on a line, or anywhere within a coordinate system where both axis (reference of measurement lines) use the same units of measurement and scaled (indicated, successive increments of the units) distances.

$c^2 = a^2 + b^2$: **Pythagorean Theorem** for right triangles where (c) is the longest side

$c^2 = (\text{vertical change})^2 + (\text{horizontal change})^2$ taking the square-root of both sides :

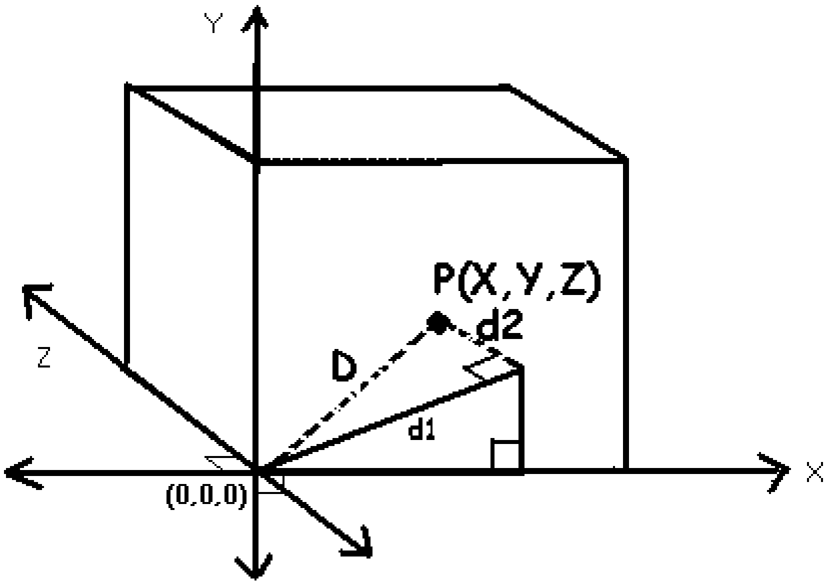
$c = \sqrt{(\text{vertical change})^2 + (\text{horizontal change})^2}$ letting c = distance = d , this is calculated as:

$d = \sqrt{(y2 - y1)^2 + (x2 - x1)^2}$: **DISTANCE FORMULA BETWEEN TWO POINTS (2-D)**
(on a plane or two-dimensional "flat" surface).

For this formula, it makes no difference which point (with its coordinates) is chosen as "point 1" and which point is chosen as "point 2" since the square of the difference of the points corresponding coordinates, whether this difference (or length if you will) is positive or negative in sign (both differences would have the same absolute value), is always a positive value. In particular, a negative times a negative is still a positive value, and here, a positive value as required for any length to be physically real.

When a plane (2 dimensions) is moved perpendicularly, along another axis that is perpendicular to its' own two (reference or start of measurement) axis, a three-dimensional (3-D) space, or volume is defined. For example, if you take a part (ie. bounded and defined region such as a square) of a common two-dimensional (2-D), X and Y plane and move it perpendicularly above or below itself along a different axis (typically called the Z axis) or dimension, a three-dimensional space is defined. A common geometric example of three-dimensional space is a cube, and a cubic unit is naturally and commonly used as the reference unit of measurement for any volume or space. If you take a square (a region of a plane) which has 1 unit for its two (perpendicular) side dimensions and move it 1 unit perpendicularly to both of those side dimensions, a cube is created and the cubic unit (of measurement for space or volumes) is defined. Another common example of a three dimensional space is when a circle, or disk is moved a height, and this creates a cylinder or solid rod shape, "space" or volume.

The formula for the distance (D) between any two points within a three-dimensional space is very similar to that used for a two-dimensional system. The formula for the two-dimensional system is also used in the analysis for creating the formula to use for a three-dimensional (measuring and location) system. As shown in the drawing below of a three-dimensional system, (d1) is the distance between the two points when considering only the (X) and (Y), two-dimensional, coordinates of the point. This value of (d1) is also a side of a right-triangle within the three-dimension system, and the other side of this right-triangle is (d2) and which is perpendicular (ie. at a right-angle) to (d1) and extends into the (Z) plane or third-dimension, and its length is the difference between the (Z) coordinates of the two points in question that we are to find the distance or length between them: [FIG 50]



Dotted or broken lines in drawings typically indicate a construction that cannot be seen normally in a 2-D diagram or graph that tries to represent a 3-D diagram or graph. In the above drawing, the broken or "dotted" lines are for parts or constructions that extend into the Z plane. This is as if the broken or dotted lines extend behind, through or into this page that you are viewing.

change in Z = d2 = (Z2 - Z1) : in particular, considering the third dimension for d2

d1^2 = (X2 - X1)^2 + (Y2 - Y1)^2 : considering just the first and second dimension for d1

Substituting this value for $d1^2$ into the Pythagorean Theorem to solve for D:

$$D^2 = (d1)^2 + (d2)^2$$

$$D^2 = (X2 - X1)^2 + (Y2 - Y1)^2 + (Z2 - Z1)^2$$ taking the square root of both sides:

$$D = \sqrt{(X2 - X1)^2 + (Y2 - Y1)^2 + (Z2 - Z1)^2}$$:**DISTANCE BETWEEN TWO POINTS (3-D)**
(in a three-dimensional system)

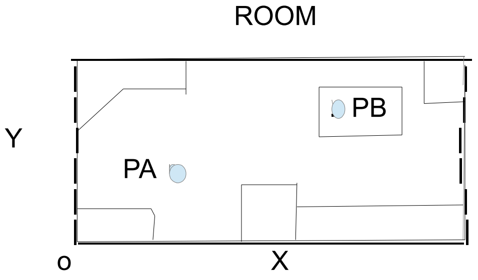
OR simply:

$$D = \sqrt{(\text{change in } X)^2 + (\text{change in } Y)^2 + (\text{change in } Z)^2}$$

If one of the "end points (at the farthest or extreme ends of the line segment, hence it could also be an initial, defining or starting point)" of this line segment was located at the origin (0,0,0), then P1(X1,Y1,Z1) = P1(0,0,0), and the equation reduces to simply:

$$D = \sqrt{X2^2 + Y2^2 + Z2^2}$$

Ex. Below is a simple "blueprint" (a drawing, often with a blue colored background, and which is a demagnified and proportional (often spoken as: "drawn to scale") image or drawing of the construction it represents. Here, the image is of a room as viewed from above it. In the room, you are to find the distance (D) between point A and point B. These points are located at different heights above the floor of the room. The length of the room can be considered as the X dimension, the width as the Y dimension, and the (vertical) height or depth as the Z dimension. The lower left corner on the floor of the room is arbitrarily chosen as the origin (o) or point of reference for this three-dimensional analysis and co-ordinate system. [FIG 51]



Let PA = P(X1 , Y1 , Z1)
Let PB = P(X2 , Y2 , Z2)

SCALE: 1/8 inch (on blueprint) = 1 foot (real)

$$D = \sqrt{(X2 - X1)^2 + (Y2 - Y1)^2 + (Z2 - Z1)^2}$$

Ex. Given a cube which is a 3-dimensional, volume shape with square sides (s) all of equal length, what is the length of the diagonal within it? We will be using the full side lengths where a side starts at 0 length, hence, for example: Letting: X = (x2 - X1) = (x2 - 0) = X2 = s . If each dimension (length, width, and height) side has a length of 1: side X = side Y = side Z = s

$$D = \sqrt{s^2 + s^2 + s^2} = \sqrt{1^2 + 1^2 + 1^2} = \sqrt{1 + 1 + 1} = \sqrt{3} = \mathbf{1.73205808}$$:**Cube Diagonal Constant**

$$\mathbf{D} = \sqrt{3s^2} = \sqrt{3}\sqrt{s^2} = \mathbf{1.7320808\ s}$$ **: Diagonal formula of a cube with side (s)**

If the point of reference (ie., p(0,0,0) is considered as: p(X1, Y1, Z1) , the equation reduces to : $D = \sqrt{X2 + Y2 + Z2}$

Given the side of a cube, the diagonal length of that cube will be greater by the factor of 1.73205808

Ex. If s = 5 cm, D = 1.7320808 (5 cm) **=** 8.660254038 cm

If the side length (s) increases by a factor of (n), the diagonal length of that cube will also increase by that same factor of n. For a square, the diagonal constant is 1.414213562 which is the square root of 2. The sum of the square root of 2 and the square root of 3 is 3.14626437... and it is very close to the value of (pi) = 3.141592654... , and with a difference of just 0.004671716...

$$D = \sqrt{(ns)^2 + (ns)^2 + (ns)^2} = \sqrt{3(ns)^2} = \sqrt{3}\ \sqrt{n^2}\ \sqrt{s^2} = \sqrt{3}\ n\ s = 1.73205808\ ns$$

A square also has a diagonal constant. $D = \sqrt{s^2 + s^2} = \sqrt{2 s^2} = \sqrt{2}\ s =$ **1.414213562 s :Diagonal in a square**

Besides the two endpoints of a line segment, or anything analyzed like a line, the point exactly between them is called the **midpoint of a line** (segment) and is often of importance for various constructions. Since midpoint means the "half-way" (of full length), half-length (length/2 = distance/2), "middle", "midway", or center point, simply divide the given length or distance by 2 so as to find this half-way length. half-way length + half-way length = 2 (half-way length) = full length

If the three dimensional equation for points is set equal to a constant such as r=radius, all the points that satisfy or complete this equation will be part of a **sphere** (= a disk or circle and-or its circumference rotated 360° [= the standardized angle of 1 full rotation] about its center point), and with the center point being at p(0,0,0). If the result of the equation is less than (r) then the point is withing the sphere. If the result of the equation is greater than (r), then the point is outside the sphere.

Continuing the main discussion:

Ex. If the length of some material is 20 inches long, the half-way point is at:

$\frac{20 \text{ inches}}{2} = 10$ inches : half-way point of 20 inches

This length of 10 inches can be thought of as starting at the 0 point of a number line since from the concept of length, all lengths start from nothing and are in reference to this nothing or "0" point of length. For this example, 10 means 10 from or with respect to 0, and not from any other reference value: [FIG 52]

```
|-------------------|-------------------|--------------->
0                  10                  20             n units
```

A length can also be thought of as a difference or change between any two points on this number-line or one-dimensional measurement system. For example, here we are to find the midway point of the length (L) of the line segment bounded by the point identified as 100 and 120: [FIG 53]

```
|------------------------------------------------|------------|-------------->
0                                              100          120            n units
                                                 |--    L   --|
```

The difference or change between these two points which defines the "length" or distance between those two points is:

(max. value - min. value) = change = difference = length
120 - 100 = 20

Half of this length is:

$$\frac{\text{length}}{2} = \frac{20}{2} = 10$$

This value of 10 is half of the length of the line segment between the numbers, points or locations of 110 and 120, and is only in reference to the start (ie., 110) of that line segment only. Though 10 is the center point of half the distance value between the two defining points on the line, what is that center point's corresponding value, location or point on the line of which the defining, delimiting or bounding locations or points of that line segment were given and which are in reference to 0? We must now adjust this center point or midway value of 10 to be in reference to this entire system or line, hence in reference to 0. Notice that this line segment (from point 100 to point 120), and all points on and associated with it, are effectively shifted or increased from the "0" position (of reference for the entire system) by a value equivalent to the minimum point or location of the two points bounding that line segment in question. This minimum point is effectively the "0" or reference point of just the line segment or length in question, and not the entire number-line system. Since this "new 0" or reference point of length is shifted (ie. added to) by a value equal to the lengths starting or min. value within the entire system:

First,here are some abbreviations for the points or locations on the reference (of measurement) line:
min. = minimum = smallest, least , mid. = midway = center , max. = maximum = largest

For the example given: the min. and max. points or locations are in reference to the 0 reference point of the entire system. min = 100, and max = 120. These points also define a line segment, and they are its boundary or defining points.

$$\text{mid.} = \frac{\text{length}}{2} + \text{min.}$$

: length = length of the line segment, here its 10, using substitution: This mid. point or location is the value that corresponds to the line segments center point's location on and in reference to the entire line.

Since the length of the line segment is the difference between its boundary points or locations: (max. value - min value):

$$\text{mid.} = \frac{\text{max.} - \text{min}}{2} + \text{min.}$$

: for this example, min=100, and max=120

This formula algebraically leads to a "simple average" formula:

$$\text{mid.} = \frac{\text{max.} - \text{min}}{2} + \text{min.}$$

combining fractions:

$$\text{mid.} = \frac{\text{max.} - \text{min}}{2} + \frac{2\ \text{min}}{2} = \frac{\text{max.} - \text{min.} + 2\ \text{min}}{2}$$

Combining like terms in the numerator:

$$\text{mid.} = \frac{\text{min} + \text{max.}}{2}$$

: "middle or center" value between two other values.
: This is similar to an average of two values formula

Or, as indicated above, and will be shown further below:

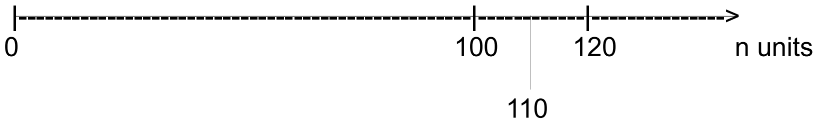
$$\text{mid.} = \text{min.} + \frac{\text{change from min.}}{2}$$

, or = min. + 0.50 (change from min.)
: = "min. value plus half the total change"

For the last example:

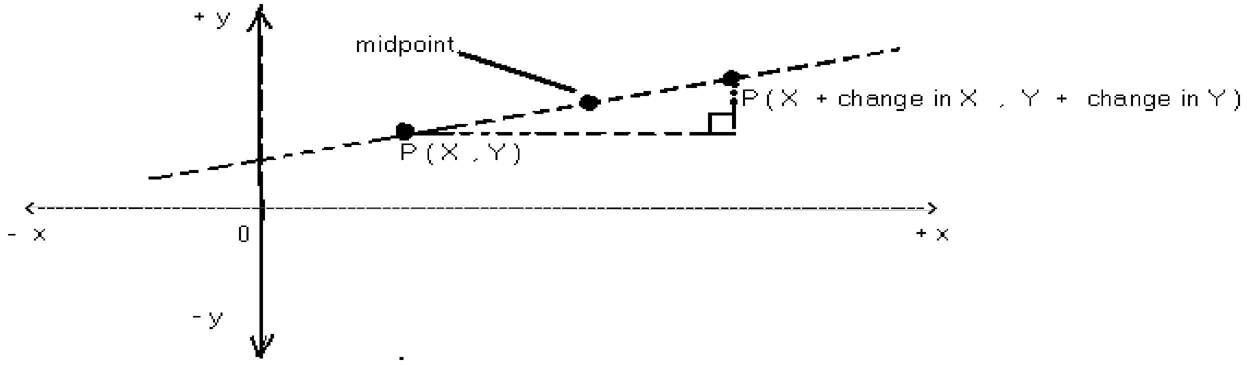
$$\frac{100 + 120}{2} = \frac{220}{2} = 110$$

: the center point of 10 of the line segment corresponds to the point or location of 110 on the main reference line or system



: [FIG 54]

The co-ordinates of the midway point between two points in a two-dimensional co-ordinate system is analyzed as follows: [FIG 55]



Here, X and Y are effectively the min. values for each dimension and are "offsets" or distances from the origin (0) in the system.

From: $\text{mid.} = \dfrac{\text{min.} + \text{max.}}{2}$ and observing the diagram:

$$\text{midx.} = \frac{\text{min. X} + \text{max. X}}{2}$$: X coordinate of midpoint

$$\text{midy.} = \frac{\text{min. Y} + \text{max. Y}}{2}$$: Y coordinate of midpoint

$$\text{Pmid.}\left(\frac{\text{min. X} + \text{max. X}}{2} , \frac{\text{min. Y} + \text{max. Y}}{2} \right)$$ **: COORDINATES OF MIDPOINT BETWEEN TWO POINTS ON A PLANE**

Or by using a substitution for max X:

$$\text{midx.} = \frac{X + (X + \text{change in X})}{2} = \frac{2X + \text{change in X}}{2}$$: X = min. X
(Change in X) = (X2 - X1)

$$\text{midx.} = X + \frac{\text{change in X}}{2}$$: X coordinate of midpoint

$$\text{midy.} = Y + \frac{\text{change in Y}}{2}$$: Y=min. Y, midy = Y coordinate of midpoint, hence :

$$\text{Pmid.}\left(X + \frac{\text{change in X}}{2} , Y + \frac{\text{change in Y}}{2} \right)$$: COORDINATES OF MIDPOINT BETWEEN TWO POINTS ON A PLANE

Hence: Pmid = (X + half the change in X , Y + half the change in Y)

As was previously noted about a variable being a place holder for any value, being either positive or negative in sign, and therefore, the actual value of (b) in a linear equation can either be negative or positive. Given a basic linear equation of:

$y = mx + b$

, the mathematical relationship between the (y) and (x) variables is a direct relationship when (m), the slope, is positive in sign. If (x) increases, (y) increases and vice-versa. However, if you know of a linear like relationship where as one variable increases and then the other variable decreases, or vice-versa, the mathematical relationship between those two variables is said to be an **inverse relationship**. This would happen in a linear equation when (m), the slope, is negative in sign.

We know that the inverse or counterpart of a value is expressed by taking the negative, or "counterpart" of that value:

The inverse of $+y$ is $-(+y) = -y$
The inverse of $+x$ is $-(+x) = -x$

If (y) was equal to (x) as in the most basic of linear relationships:

$y = x$: a linear equation, where m=1, b=0

and if the relationship between (y) and (x) is an inverse relationship, that is, if the inverse of (y) is (x), or vice-versa:

$-(y) = x$
$-y = x$ by multiplying or dividing each side by (-1), this can be expressed as:

$y = -x$: y equals the inverse or negative of x. Note that x, a variable, can still be either positive or negative in value, and this expression essentially means the inverse of any value that variable may have. Here, as the value of x increase, the value of y decreases, and this is an inverse relationship.

If the value of (y) is related to (x) (either directly or indirectly) by some constant factor (called m) other than 1 as seen above in: $y=(-1)x = -x$, this must be noted in the equation. That is, if the ratio of (y) to (x) is always the same constant:

$\frac{y}{-x} = m$ therefore: $y = m(-x)$: the variable name assigned for this constant is (m), and mathematically, we then have:

$y = -mx$: this indicates that y is always the same multiple of x. Adding in the arbitrary constant of (b):

$y = -mx + b$: an "inverse form" of the basic linear equation of: $y = mx + b$

This form now implies the same linear equation but which now has the negative of a given slope. Linear equations where the (x) term is negative, such as when the coefficient (the slope, m) of (x) is negative, the corresponding (y) values for each (x) value get smaller as the (x) values increase. The effect on the line is that it will slope vertically (upward, in the (+y) direction) downward, rather than vertically upward, as (x) increases, as should be expected for an inverse relationship where as one value increases, the other value decreases.

Even though the line of a linear equation and the line of the inverse of that linear equation will cross, don't assume they cross perpendicularly. Lines that cross perpendicularly will and must have negative reciprocal slope values:

$m1 = -\frac{1}{m2}$ or = $m2 = -\frac{1}{m1}$: **SLOPES OF PERPENDICULAR LINES**
This is verified in the TRIGONOMETRY section.

Note also that (m1)(m2) = -1 always. For any two perpendicular lines (other than the axis or reference of measurement lines), one line will have a positive slope and the other line will have a negative slope, hence their product will always be a negative value (such as -1). As indicated in the equations above, these slopes are also inversely related. If one line has a very low absolute value for its slope, the other line will have a high absolute value for its slope.

Note, if the (b) term is present in the equation of a line, the fundamental relationship between (x) and (y) is still linear, but the numerical relationship, as in the form of a constant ratio, between each corresponding pair of (y) and (x) is no longer a constant, and only the slope remains constant, defining what is known as a linear relationship. Consider this example where the ratios of corresponding values is not constant:

Ex. $y = 2x + 3$: m = slope of the line = 2

$$y(1) = y = 2(1) + 3$$
$$y = 2 + 3$$
$$y = 5$$

: y(1) is a simple notation which means solve for the value of (y) when x=1, a more general or formal expression for this notation is: y(x) = "y at x" which means to evaluate the value of y when x is this value". When no value of x is specified, y(x) means: "y is a function of x".

$$\frac{y}{x} = \frac{5}{1} = 5$$

$$y(3) = y = 2(3) + 3$$
$$y = 6 + 3$$
$$y = 9$$

$$\frac{y}{x} = \frac{9}{3} = 3$$

Though the ratio of (y) to (x) is no longer a constant due to the (b) term, the slope (m) of any line, as in the above example, is constant, and here it is a value of 2. Besides being obvious in the equation that the slope is 2, using the two points found using these two instances of the equation, we can calculate the slope:

$$m = \frac{\text{change in y}}{\text{change in x}} = \frac{9-5}{3-1} = \frac{4}{2} = \frac{2}{1} = 2$$: when x changes by +1, y will change by +2

The higher (x) is, the value of (y/x) will approach that of (m) since the value of (b) will have less and less effect on the value of (y) as compared to the larger effect a high value of (x) would. For example, using the last examples equation, and letting x = 1000:

$$y = 2(1000) + 3 = 2003 \quad \text{and} \quad \frac{y}{x} = \frac{2003}{1000} = 2.003$$: nearly 2

We see that although there can be a constant numeric relationship, such as the rate of changes between the values of variables such as (y) and (x) as for a linear equation, the relationship between (y) and the entire expression or function value that (x) is in, may not be always be constant as shown above for a linear equation. Clearly given an equation of:
$y = mx + b$, y is obviously not equal to x, but y is equal to the whole expression or function that x happens to be in. It is said that y is a function of x, rather than y is equal to x. y = f(x) is the mathematical notation or expression for "y is a function of x", and even this can be stated as meaning: "y is equal to the entire expression or function containing the variable x". The word "function" is used and meant to imply or stress the concept of the dependent relationship of y and-or its value due to x and-or its value.

Given a certain construction, when lengths of corresponding pairs of line segments are said to be proportional (equivalent in ratio), the ratios of their lengths is constant. When the ratios of corresponding sides (or side lines if you will) of two triangles (discussed in the TRIGONOMETRY section) are equivalent, the sides are often spoken of as being proportional since a proportion is two (or more) equivalent ratios. This is the case when the triangles are said to be similar (as in similar looking or similar shaped constructions) triangles, and which are essentially magnified versions of each other.

An extra note, before this example is finished, is about using subscripts to indicate a particular instance of the same equation, and therefore, a particular instance of the variable(s). In this manner, the subscripts effectively identify (with mathematical notation) the corresponding results and values used in that equation. For example, given:

$y = 4x + 32$: $f(x) = 4x + 32$, hence $y = f(x) = y(x)$ = "y is a function of x"
Again this is just notation, f(x) and y(x) does not mean multiplication.
Given (4x + 32) is a stated function in or of x, and if we set y equal to this, it gives
that function a specific name or identification. The function can now be called or
indicate as y, and instead of using f(x), we can use y(x) to be more specific as to
what specific function is a function of x. There could be other functions of x such as:
g(x), h(x), etc., which generally would have different expressions containing the
independent variable x.

$y1$ would correspond to the value $x1$ used in the equation.
$y1$ is a specific instance of y and $x1$ is a corresponding and specific instance of x.
$x1$ and $y1$ would be the coordinates of a point: $p(x1 , y1)$ or $p1(x1 , y1)$

$y2$ would correspond to the value $x2$ used in the equation, and so on.
$x2$ and $y2$ would be the coordinates of a point: $p(x2 , y2)$ or $p2(x2 , y2)$

$y = f(x) = y(x) = 4x + 32$: main function or relationship

$y1 = f(x1) = y(x1) = 4(x1) + 32$: instances of the function
$y2 = f(x2) = y(x2) = 4(x2) + 32$

LINE AND CIRCLE EXAMPLE

In this example, the circumference of a circle will be intercepted and passed through by a line. There will be two points of interception associated with this. Write a line (linear) equation of this intercepting line if the radius (r) of the circle is 3, and the (x) coordinate of the point of interception is 2. This line passes through the center of the circle which happens to be located at the center or origin (0,0) of a rectangular co-ordinate system.

The basic equations (including subscripts for this example) of a circle and line are:

$y_1 = mx_1 + b$: basic line equation
$r^2 = x_2^2 + y_2^2$: basic circle equation , and this also resembles the Pythagorean Theorem

(Note above, the subscript identified as 1 refers to the line, and the subscript identified as 2 refers to the circle).

Solving for and expressing the equations in terms of y:

$y_2^2 = r^2 - x_2^2$
$y_1 = mx_1 + b$

When $x_2 = 2$, and evaluating the equation or function for y_2 at this value; this can be noted with functional notation as f(2), or $y_2(2)$, which means to evaluate the expression or function when (x)=2: :

$y_2^2 = r^2 - x_2^2$
$y_2^2 = 3^2 - 2^2$
$y_2^2 = 9 - 4$
$y_2^2 = 5$ taking the square root of both sides:
$y_2 = 2.236067977$

At the point of interception, the two points (one on the line, and one on the circle) have the same location, and therefore have the same value: $x_1 = x_2$, and $y_1 = y_2$, hence:

$x_1 = x_2 = 2$
$y_1 = y_2 = 2.236067977$ substituting these values into the linear equation:

$y_1 = mx_1 + b$
$2.236067977 = m(2) + 0$: letting (b), the vertical or (y) intercept, equal 0 since this line passes through the y-axis at (0.0). The line also passes through the center of the circle which is located at the center or origin of the rectangular co-ordinate system. If the center of the circle is not at the origin, all points associated with the circle are effectively offset or "adjusted" by some (same) value from the origin, and therefore, the basic equation of the circle must be "adjusted" if the circle is to be in reference to this specific, "new" or local rectangular system located within the larger rectangular system. If the center of the circle is now at p(a,b), rather than (a=0, b=0) as in the larger or standard rectangular coordinate system, the (x) coordinate of the center and all other points associated with the circle's system must be incremented by (a) to so as to be in reference to the larger rectangular coordinate system. Likewise, the circles (y) coordinates must all be incremented by (b) so as to be in reference or with respect to the larger rectangular coordinate system. The equation of the circle therefore becomes this so as to be in reference to the main system:

$r^2 = (x + a)^2 + (y + b)^2$: **GENERAL CIRCLE EQUATION**

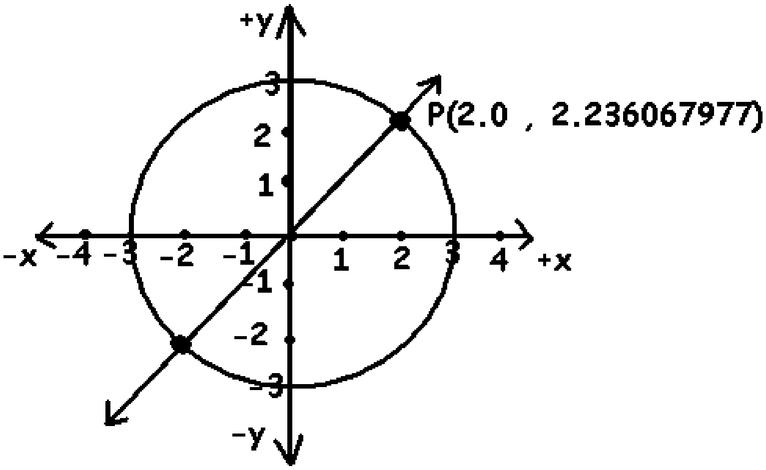
(When the center is not at the origin at (0,0), and the coordinates of the circle's and other (x,y) points are in reference to another location other than (0,0) of the larger rectangular system. Still, (a) and (b), and point(a,b), the center point or origin of the specific, local, "sub, or" micro" rectangular system. are in reference to the larger macro rectangular system. The value of (r) does not need to be modified since it is a fixed length value, and not a (variable) location.)

After solving for m:

$m = \frac{2.236067977}{2} = 1.118033989$ putting this value of m into the line function or equation:

y1 = 1.118033989 x1 : equation of the line in question , and where b = the y-axis intercept = 0 for this line. The y-axis intercept, where x=0, is: p(b,0);

[FIG 56]



Given the equation of the circle and the equation of the intercepting line, the point of intersection of the two curves can still be found. We know that at the point of intersection, that the difference of the (x) and-or (y) values of both equations is 0 since the equations at that point will have the same value.

In theory or consideration, a line is a special case or instance of a curve, and you can think of this as a portion, or (line-like) segment of the circumference of a circle that has a very large or infinitely large radius or diameter.

y2 - y1 = 0 : at the point of interception of two curves, therefore, mathematically:
y2 = y1

And the known equations are:

y2^2 = 9 - x2^2 : circle

y1 = 1.118033989 x1 : line

There are several ways to solve for (x) when subtracting the equations, for example, you can square both sides of the linear equation and subtract it from the other equation, and with the difference in y values defined as being 0. Here is a method that uses algebraic substitution:

from $y2^2 = 9 - x2^2$ solving for y:

$$y2 = \sqrt{9 - x2^2}$$

Removing the subscripts since (x) and (y) are the same value at the intersection point, and substituting this into the linear equation:

$y2 = y1$: at the point of intersection of the two curves or equations

$\sqrt{9 - x^2} = 1.118033989\,x$ squaring both sides of the equation :

$9 - x^2 = 1.25\,x^2$ transposing ($-1x^2$) to solve for (x) :

$9 = 2.25\,x^2$ isolating the (x) variable, and then taking the square roots of both sides:

$x = \sqrt{\dfrac{9}{2.25}} = \sqrt{4} = 2.0$ solving for (y) using algebraic substitution:

$y = 1.118033989\,x$
$y = 1.118033989\,(2.0)$
$y = 2.236067977$: checks

By observing the above procedure carefully, a formula for the (x) coordinate of the point of interception can be derived:

$x = \pm\sqrt{\dfrac{r^2}{m^2 + 1}}$: X COORDINATE OF CIRCLE AND LINE INTERCEPTION (center at origin (0,0), and b=0 for the line)

This can also be expressed as:

$$x = \frac{\sqrt{r^2}}{\sqrt{m^2 + 1}} = \pm\frac{r}{\sqrt{m^2 + 1}}$$

(y) can be found by substituting the value for (x) into one of the original equations, or from:

$m = \pm\sqrt{\dfrac{r^2}{x^2} - 1}$: this was derived from the above expression for x

and since $m = \text{TAN}\ ¢ = \dfrac{y}{x}$: TAN ¢ = tangent of the angle. More exactly, it is the ("tangent") ratio of two specific side lengths of a triangle. tan = opposite side/adjacent side. For this example and line, The angle is between the line and the x-axis.

When (change in y) = y, and (change in x) = x,(ie,. one point being at the origin, p(0,0)) we can algebraically get:

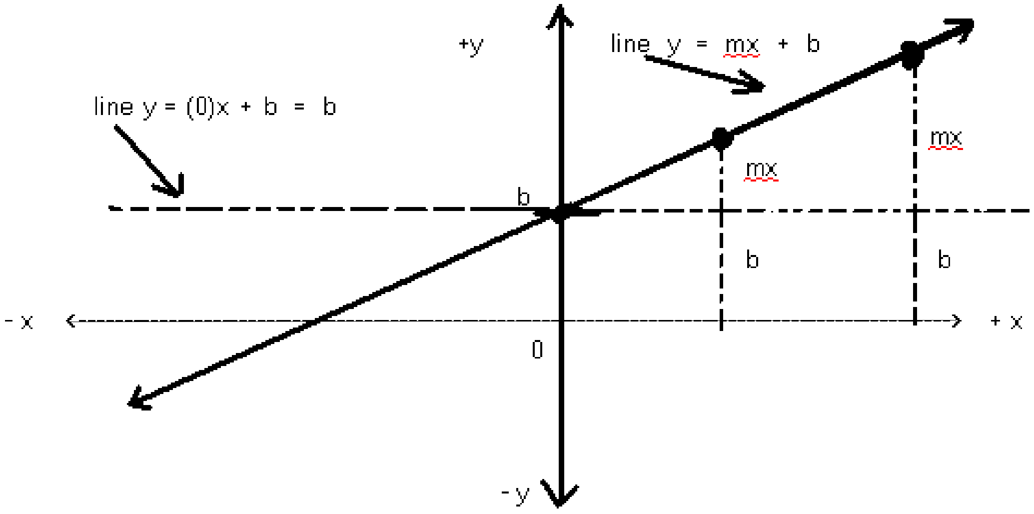
$y = mx$: the basic linear equation (when b=0). Since (m) is a initially an algebraic variable, it can have any value, including (1). If m = 1, the result is the simplest linear equation of: $y = x$.

Given: y = mx, mathematically, we have: (y / x) is always a constant value of (m) = the slope of that line. Given: y =mx, (y) is a (constant=m) multiple of (x).

When the line does not cross at the origin point of the system, the vertical intercept (b) is not at y=0 but some other value of y we will note as (b). When x=0, the corresponding y value or coordinate on the line is this value of (b). This point is therefore p(x,y) = p(0,b). It could be said that (y) already has an offset, initial or "lead value", and this value is y=b. The basic equation of y = mx is still used, but now with an adjustment term added or combined in to it. For all values of (x), each corresponding value of (y) is increased, changed, or adjusted to automatically account for and contain this constant value of (b). Reflecting this as a linear equation:

y = mx + b : the basic linear equation.

In the graph of a general line equation below, note that when (b) is positive in value, causes a "lead" in the (y) values which corresponding to the (x) values, and is seen as an "upward vertical shift or offset" (from the origin and-or x-axis) and-or a "leftward horizontal shift or offset" (from the origin and-or or y-axis) for the entire line. [FIG 57]



The general linear equation is also verified ahead in the discussions of similar triangles.

LINEAR TEMPERATURE EXAMPLE

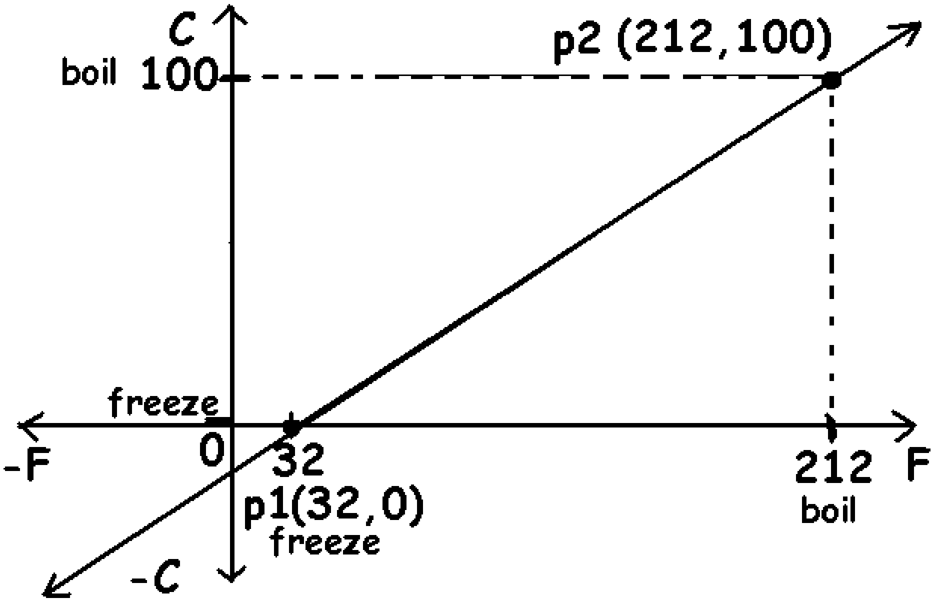
Here, we will derive the mathematical relationship between the Fahrenheit and Celsius temperature scales. Temperature is basically defined as the amount of energy something has. The more energy, the hotter (higher in temperature) it becomes. This is a direct relationship. The temperature measured is linear for both the Fahrenheit and Celsius temperature scales. If the objects (including the air) temperature doubled, the measured temperature indicated on a thermometer (a temperature metering or measuring device) will double in value. For both systems, the temperature with respect to the energy of an object, can be plotted as straight lines. If the energy of an object doubles (2), its temperature likewise increase by that same factor value and double. The Celsius temperature scale is named after **Anders Celsius**, from Sweden, who originally conceived of it in 1742. "Centigrade" (ie., 100 gradients) is an older word for the Celsius scale.

What is generally or commonly known about the Fahrenheit and-or Celsius scales is the temperature of the freezing point and boiling point of water:

	Freezing	Boiling
Fahrenheit:	32°	212°
Celsius:	0°	100°

: the Celsius scale appears to be more "metric-like". Some have even proposed that time and clocks should also be based on a "metric-like" system with 10 hours before noon, and 10 hours after noon. Each hour would have 100 minutes, and each minute would have 100 seconds.

Observe the drawing below: [FIG 58]



For finding the slope of this line shown, we will use these two known points on the line that have the format of: p(x , y) = p(Fahrenheit , Celsius). The values of the two shown points are: p1(32,0) and p2(212,100):

$$\text{slope} = \frac{\text{vertical change between points}}{\text{horizontal change between points}} = \frac{\text{change in Celsius}}{\text{change in Fahrenheit}} = \frac{(100 - 0)}{(212 - 32)} = \frac{100}{180} = \frac{0.5555\ldots}{1} = 0.5555\ldots$$

Hence for each increment (1), or degree change in Fahrenheit temperature, the corresponding Celsius temperature will change by 0.5555... degrees which is a little over a half (1/2 = 0.5) a degree Celsius.

By taking the reciprocal of this value, we can find that for each degree change in Celsius, Fahrenheit will change by (1/0.5555..) ~= 1.8 degrees, or derived as:

$$\frac{\text{change in Fahrenheit}}{\text{change in Celsius}} = \frac{212 - 32}{100 - 0} = \frac{180}{100} = 1.8$$: almost 2 degrees (Fahrenheit temperature units)

If we use P(32,0) consistently as the second point in the above formula we would still have the same rate or slope value:

$$1.8 = \frac{F - 32}{C - 0} = \frac{F - 32}{C}$$: using p(F,C) as general variable notation for the first point. Solving for F:

$F = 1.8C + 32$: relationship between corresponding Fahrenheit and Celsius temperatures
This is a linear equation with m=1.8, and b=32.
We can see clearly that when C=0, F=+32
Solving for C:

$$C = \frac{F - 32}{1.8}$$ which can be expressed as the sum of two fractions:

$$C = \frac{1F}{1.8} - \frac{32}{1.8}$$ by canceling fractions, this can be expressed as:

$C = 0.55\underline{6}F - 17.7\underline{8}$: relationship between corresponding Celsius and Fahrenheit temperatures
This is a linear equation with $m=0.55\underline{6}$, and $b = -17.7\underline{8}$
We can see clearly that when F=0, $C=-17.7\underline{8}$
This slope for the Celsius equation is the reciprocal of the slope for Fahrenheit equation: $1/m2 = 1/0.55555 = 1.8 = m1$

Extra: -40°F = -40°C : same numeric value for these different temperature units, and this is only a special instance

Although the Celsius and Fahrenheit temperatures scales are each linear, that is, if the energy doubles, the temperature or thermal energy measurement will double on each scales, however the Celsius and Fahrenheit values are not proportional to each other due to that each linear or line-like scale has a different rate of change, hence a different slope. For example, trying to make a conversion using proportions will not work, for example, consider this for when trying to convert 30° Celsius temperature to its corresponding Fahrenheit temperature:

$$\frac{212°F}{100°C} = \frac{X°}{30°C}$$, after solving for X°: $$X° = \frac{30°C\ (212°F)}{100°C} = 63.6°F$$:**the is wrong**
The correct result is X° = 86°F

It should be noted that the outside **air temperature** is, in most cases, standardized as the temperature of the air only, and the thermometer and-or temperature sensor is placed the shade such as in a shaded, and air-vented box with no sunlight energy directly or indirectly (by reflections of light) upon the thermometer, and which would otherwise significantly (and incorrectly) increase the measured, true air temperature to be displayed as say 130°F instead of correctly as 85°F. To prevent an incorrect measurement by possible sunlight and-or reflections of sunlight and its thermal energy heating of the box and air in it, the box should be in the shade and-or double or triple insulated (via air gaps or spaces) and ventilated to prevent any heat build up and a corresponding increase in the temperature reading or measurement.

When wind contacts the surface of your bare unprotected skin, the wind essentially gets heated up by the warm skin (typically about 98.6 degrees Fahrenheit) and removes some thermal energy from it. This will cause you to feel cooler in those areas initially, and if it continues, it will effectively be like having an air-conditioner to cool you down in that uncovered or uninsulated area, and your entire body temperature can drop dangerously low because the healthy thermal energy in your body tissues and blood will be wasted to the outside world. This initial effect on the surface of your skin (or any other object such as the ground, water, buildings) is called **windchill** (ie., cooling due to the wind), and it is similar to the concept of evaporative cooling where water humidity (water vapor ="water-gas", cool steam) or moisture can effectively absorb and remove heat from an object, and then that moisture rises or is blown away by a wind and the object then has a reduced temperature. This is essentially what happens when a person sweats so as to help the body cool down. If the air temperature is at or below the freezing temperature of water, the wind can hasten frostbite (frozen, damaged body tissue) in those areas since it is removing what little amount of heat was still in those areas so as to keep them warm and unfrozen. The temperature that the bare unprotected skin will feel when wind is blowing upon it is called the windchill temperature. The windchill temperature is a calculated value using a formula that depends mainly on both the air temperature and the wind speed. Obviously, for a constant air temperature value, the "windchill temperature" depends mainly upon the wind speed. The windchill temperature will be lower than the actual air temperature. When the air temperature is of a lower value, and for a constant wind speed, the difference between the actual air temperament and the windchill temperature increases. In wintertime with cool air temperatures, the wind has a significant impact on how cold you will feel, especially if not wearing several layers of typical clothing (like insulation), and usually shirts, so as to retain much body heat so as to feel warm. For a basic idea of the (subjected, human perceived) mathematical relationships, given a constant wind speed, for every 10 degrees colder in actual temperature, the windchill temperature feels about 12.6 degrees colder. The windchill temperature formula usually reflects only the data for temperatures 50° or lower where the effects are most noticeable. The windchill formula is not overly complex, but its derivation is beyond the space and scope of this book. Due to the average person only having a temperature reading or estimate, and maybe a windspeed estimate and no other data, here is a very simplified formula to obtain a rough value for the windchill or "feels like" temperature:

A windchill estimate temperature = F° - windspeed mph : A simplified and practical windchill estimate formula

The author of this book has found that the wind is one of the worst parts of winter, and so therefore, you need to first check the outside temperature and windspeed, and then dress accordingly such as with several layers of shirts and possibly pants before venturing outside. The lower the air temperature, the more the wind will have a cooling effect. Denim pants are not ideal for cool climates because they do not seem to keep the heat in and keep you warm. "Sweat pants" are much better than denim (ie. tightly woven cotton material) "blue-jeans" in the winter if you will be outside doing things, and without much of the worry of constantly trying staying warm. Wear a winter hat and gloves, and keep them immediately available and close by (ie., in a pocket or bag) for when you will need them. Wearing two coats is sometimes necessary, depending on the temperature and-or windspeed. If in a difficult situation with no warm shelter, brisk or fast walking can help raise your body temperature. Shelters can be made from sticks, rocks, mud, leaves, snow, etc.

The concept of **heat-index** is essentially the opposite of the windchill concept. The heat-index is the temperature of how hot the air temperature feels like depending on both the actual current air temperature and the humidity level. Surely, whether hot or cold, the sunlight will always make the air temperature feel warmer, perhaps an additional 10°F warmer , and so this measurement, like the windchill temperature, also uses the measured air temperature in the shade. **Humidity** is moisture in the air which can carry much heat with it and make the air temperature feel hotter. It is essentially a "steam (heat) bath". **Danger:** If a persons core body temperature is 104°F = 40°C or greater, they are in severe health danger, and will most likely have symptoms of various mental confusion, especially if they are dehydrated and in need of plain drinking water. Overworking and in the sunlight and-or stress can quickly cause dehydration in the body. A person having these conditions needs to be cooled down fairly quickly. Place that person in the shade and remove any restrictive and warm clothing. Let them drink some water and sit in front of a fan and-or cool off in water with constant supervision by the persons(s) aiding them. A person can also be cooled off by immersion of their feet or hands into a container (such as a dishpan) of water that feels cool to them. The higher the humidity, the higher the heat-index temperature because evaporation to cool the body has slowed down. The transfer of heat energy from the body to the air is less or slower in higher humidity or moisture climate conditions. Occasionally, cool moist air can actually make a person feel cooler, and the heat-index temperature will be slightly lower than the actual air temperature.

Heat Index estimate temperature = °F + (%humidity in decimal form)(10) °F :Generally when the humidity is >= 50% and Temp. >= 50 °F :

:**A simplified and practical, heat-index estimate formula. This is the "feels like temperature" when the humidity is considered. Ex. If the humidity is 70% , add (0.70)(10) = 7 °F .**

If the wind-chill effect or skin cooling due to of the wind essentially absorbing heat from your body is to be considered in the above heat index formula, the wind will reduce the "feels-like" temperature of the heat index temperature. A simple value to use is to subtract 1°F for each mile / hour of wind speed. With sunlight upon a dark colored, non-reflective surface, it will heat or warm up, but it will generally release that heat back into the air like a heat sink does. You will feel about 10°F warmer in the direct sunlight than in the shade without direct sunlight.

The average or normal, internal body temperature is: 98.6°F = 37°C =~ 310.15°K :**Normal Human Body Temperature**

When the human body can not create enough thermal energy to maintain its core or internal temperature (normally 98.6°F) due to the external cool air and-or cool water, or possibly an internal health problem, it will begin to reduce in temperature. This can lead to a dangerous health condition called **hypothermia** when the temperature of the body is just 95°F = 35°C and obviously less. In this condition, a persons normal mental and physical activity will slow down. The person may have uncontrollable shivering at first so as to create some heat, and then could become unconscious (ie., "pass out", faint), and will die if they are not heated up externally. It is also common for people in the cold weather to forget things, particularly when they are physically exhausted such as climbing a mountain. Swimmers in apparently warm comfortable water that is about 82°F =~ 27.78°C can eventually, over time, loose enough body heat by the contact (ie., thermal conduction) with that water, and can get hypothermia. In fact, being in water that is 95°F = 35°C for a very long time, perhaps a few days, will eventually cause a person to get hypothermia if they cannot maintain a higher internal temperature than this. Try to keep yourself and others warm so as to prevent hypothermia, and to warm a person and seek help from others if someone has the conditions associated with hypothermia. Going into cool water for just a quick swim can also be a health risk for some people with existing medical problems because their body will try to get warm by increasing their heart rate and blood pressure, and they are then at an increased risk for a heart attack, stroke or other medical problems. If a person is to go swimming, it is best to mention to them about hypothermia, and to gradually acclimate their body response to cool water, and that is to initially place their feet into the water for a few minutes, and then their legs for a few minutes before attempting to "go swimming". A person can drown if they cool down too much and get sluggish (slow, low-energy) at swimming. People also need to be reminded to not panic if they fall into cool water, but rather go to and-or or swim to safety, even if its just by grabbing onto something that can keep them a float until they are rescued. To help prevent such dangerous issues, people on boats need to be reminded of having a flotation device(s) such as a "life vest", "life ring" or a container filled with air, and-or wearing a hollow container(s) capable of supporting and-or floating their body in the water. It would also be helpful for people on boats to have a signaling device(s) such as a flashlight (a.k.a. (electric) torch), strobe-light, flare, signaling flag, signaling mirror, communication radio, etc., so as rescuers can locate them more easily if they fall into the water and-or the boat may sink.

TEMPERATURE AND ALTITUDE

As the elevation increases, the air is less compressed (ie., squashed by force) because the effective column of weight of air above that location is less. Since the air is less compressed, the air has less pressure and density (mass/volume), and therefore fewer atoms to have heat energy (ie., thermal capacity) and the (average) temperature will be less.

When the air temperature is measured with a thermometer, it is taken in the shade because the Sun's light will cause the thermometer to get heated, and this will cause an incorrect air temperature measurement.

The global average temperatures is 57°F at sea level, and the value for a specific location on Earth depends on that locations specific weather conditions (ie., altitude, rain, snow, season, current temperature, sunlight energy, etc) and the Sun angle (location [latitude or "lateral side" of the Earth's location from the equator line] on Earth, time of day, day of year). The example temperatures shown below correspond to heights above sea level at 57°F, and the formula shown below is generally a average global estimate for altitudes up to 30000 ft. At 60000 ft., the temperature begins to increase slightly above the calculated value, and at about +5 °F per 10000 ft higher in altitude, and to up to about 100000 ft. in altitude at where it begins to decrease again.

Altitude: 0ft = 0m = Sea Level
Temperature: 57°F ~= 13.889° = 14°C

Altitude: 7200ft
Temperature: 32°F = 0°C = water freezes

Altitude: 16300ft
Temperature: 0°F =~ -18°C

Altitude: 60000 ft =~ 11.4 miles ~= 18.3 km
Temperature: -68°F =~ -56°C

Altitude: 30000ft   : about the height of Mt. Everest
Temperature: -47F ~= -44°C

The temperature will decline at a fairly constant or steady rate (change in temp/change in altitude) from sea level to about 30000ft high. Lets derive a basic formula for the typical and average change in temperature per change in altitude:

$$\frac{\text{(change in temperature)}}{\text{(change in altitude)}} = \frac{(32°\text{F} - 57°\text{F})}{(7200\text{ft} - 0\text{ft})} = \frac{-25°\text{F}}{7200\text{ft}} = \frac{-0.0034722°\text{F}}{1\text{ft}} \sim= -0.0035°\text{F per foot higher in altitude}$$

Since a meter is 3.28 times longer or higher than a foot, the above rate corresponds to: -0.01148°F / meter

For every 1000ft higher the predicted, average change in temperature would be; according to the above equation:

(change in temperature) = (change in altitude)(-0.0035°F / 1ft)

change in temperature = (1000ft)(-0.0035°F /1ft) = -3.5°F

A general formula for the global average temperature at an altitude above sea level and up to 30000 ft is:

temperature at altitude = 57 °F - (altitude)(change in temperature / change in altitude)

temperature at altitude = 57 °F - (altitude in feet)(-0.0035°F / 1ft)   : *

*** : In place of the value of 57°, you can substitute your local air temperature.**

For conversions, and as shown in the book, a change of 1°F corresponds to a change of 0.55555°C, therefore, using proportions or equivalent fractions, a change of -0.0035°F corresponds to a change of -0.0019444°C =~ -0.002°C, and the above formula can be expressed as:

temperature at altitude = 57° - (altitude in feet)(-0.002°C / 1ft)

The change in temperature per 1000ft ~= 305m =~ 0.305km is about -3.5°F ~=   -1.9444°C =~   - 2 °C

The change in temperature per 1km = 1000m =~ 3280ft is about -11.48°F ~=   -6.38 °C .

For some other conversions (approximate):   1m = 3.28ft   , 1 ft = 0.3048 m ,   1km = 3280ft = 0.6214 miles ,
1mile = 5280ft = 1.60934 km = 1609.34m

A change or increase of 1 °C corresponds to a change or increase of 1.8 °F. From this, we can solve for 1°F by dividing each side by 1.8, and we have: A change or increase of 1°F corresponds to a change or increase of 0.555...°C.   =~   0.56 °C = (roughly) 0.5 °C

0 °C = 32 °F

Due to the non proportional scale relationship, and even though each scale is linear in temperature, here we **cannot** then simply solve for 1°F by dividing each side by 32. A change of 1°C does not equal a change of 1°F,and vice versa, and as noted above, the change is another (constant) value other than 1.

0 °F = 17.7<u>8</u> °C

Extra: More about humidity and cloud cover of the Earth's entire surface and during a year of time.

Surely there are places on Earth's surface where there is not much rain, and yet other places with much rain, sometimes seasonal throughout the year. In the cooler regions of Earth, such as at the higher latitudes, the climate is cooler in temperature, and having less humidity on average - even if the ground is covered in snow, and this is due to that the humidity in the atmosphere there has became snow and is no longer in the air.

* About 70% of the Earths surface is ocean water which composes about 95% of all the water on Earth. About 30% of the surface of Earth it land. It is also of note that only a fraction of that land is usable for farming and reasonable living conditions, hence only about 10% of the surface of Earth s moderate in climate and enough for humans to grow food and exist without too much problems. Since the oceans cover most of Earth's surface, most of the water vapor or moisture in the air is due to the ocean surface water evaporating into the air, molecule by molecule, and without any salt attached to it. It is this water vapor that can later condense into clouds and rain which brings fresh drinking water for all forms of life.

If there are signs of drought (lack of moisture, rain and-or water) coming, then it is a good idea to begin to save vast quantities of it for high-priority use later, and this can be various cisterns, ponds, lakes, ditches (even in and-or along a stream) and various water containers. Drinkable water is often called "potable water", and which had any possible debris filtered out of it, and-or sanitized (sterilized of harmful germs, etc) by various methods (a few drops of bleach, vitamin C, UV light, etc, and you will have to research these). The low tech. version of water sanitation would be to filter and then boil the water for several minutes, and-or let it sit in the bright sunlight for several house.

* The amount of cloud area or "cloud cover" over the Earth is about 67% on average and this is due to humidity (warm water vapor molecules) rising upward in the more dense, cooler air and then condensing enough to form clouds.

* The amount of cloud cover over the oceans is about 90% on average.
Due to this there is a great amount of desalinated water vapor in the air there, but warmer air and water temperatures, and sunlight (ie., without clouds), greatly helps the process of evaporation.

* The amount of cloud cover over land is about 70% on average.

* The average humidity over the oceans is about 80% near the surface.

* The average humidity over the surface of the entire Earth is about 50%, and with nearly all of it being less than three miles high.

* The humidity level is lower at higher altitudes since there is less air and cooler, and therefore, less water vapor which is actually denser than the air gasses and tends to be at lower elevations.

* Higher latitudes are cooler in temperature due to the tilt of the horizontal surface of the Earth in those locations, and the reduced solar thermal radiation due to having a longer path through the atmosphere (ie., air gas).

* The warmer or higher in temperature ocean water is, the more thermal energy it will have, and the easier it can then evaporate upward into the as water vapor molecules, and the more humid the air area above the ocean level will be. Warmer air can hold more moisture or water vapor. As the air gets cooler, the water vapor (water molecules having less mass than both oxygen and nitrogen) starts to condense and fall out of the air due to gravity.

* When it is said that the air is saturated , it means it cannot hold any more moisture.

* The average amount of water vapor or moisture in the air near Earth's surface is 0.25% of the mass of the air. Water vapor molecules in the air also affects the local air pressure. The STP **d**ensity of air is about 1.24g / L depending upon the temperature, pressure, and moisture (humidity). density = **p** = m/V, and m = pV , (1.224g air / 1L) (1L) = 1.24g of mass of air in 1L of air. (mass of air in 1L) / (mass of water vapor in 1L) =~ 1.24g / 0.02g = 0.62g / 0.01 g = 62. Therefore, in theory, 62 L of air will contain about 1 g of water vapor or moisture. Note that on a cool day, it can still be foggy or misty with visible, condensed humidity, and therefore, this air can be denser than that without that amount of humidity.

* The ratio of actual amount of water vapor in the air to the maximum amount it can possibly be at a given

temperature is called the **relative humidity**. When the relative humidity is at 100%, the air is said to be saturated with water vapor or humidity, and it cannot hold any more and be higher, and the temperature when this happens is called the dew point (temperature) and this actually happens at a cooler temperature where the water moisture or vapor in the air has lost much of its kinetic energy and is condensing together into (larger, visible) dew or rain drops.

SQUARED VALUES EXAMPLE

Find an algebraic expression for the value of the next squared integer from any given squared integer, and the expression for their difference.

If we can let (x) algebraically represent any integer, then (x + 1) represents the next integer in terms of that (previous) integer (x). If we can find an algebraic formula for the difference between their squares, we can add this difference to any squared integer value so as to find the value of the next squared integer.

$(x + 1)^2 - x^2 = D$: D = difference , Extending the first term (into a trinomial):

$(x + 1)(x + 1) - x^2 = D$ distributing:
$x^2 + x + x + 1 - x^2 = D$ combining like terms:
$x^2 + 2x + 1 - x^2 = D$ combining like terms and switching sides:

$D = 2x + 1$: difference between consecutive square integers
where x is the first integer to be squared. Then:

$(x + 1)^2 = x^2 + D$: from the first equation above, and with substitution for D:
$(x + 1)^2 = x^2 + 2x + 1$: the formula we seeked; the value of the next squared integer

Notice that this difference is not a constant since it depends upon the value of (x) used. Since this difference directly related to the specific value of (x), and the higher (x) is, the greater the difference (D) between consecutive squares.

For the sake of algebraic notation, we can also let Xn be any integer and Xn+1 be the next consecutive integer in the "chain of values or terms" for this specific system, then:

$(Xn+1)^2 - (Xn)^2 = D$ therefore, algebraically:

$(Xn+1)^2 = (Xn)^2 + D$ or:

$(Xn+1)^2 = (Xn)^2 + 2Xn + 1$: formula for the value of the next consecutive squared integer

Ex. Find the value of the next squared integer after 4.

$(4+1)^2 = 4^2 + 2(4) + 1$: here, x=4, and (x+1)=5 , 5 is the next integer after 4
$5^2 = 4^2 + 2(4) + 1$
$5^2 = 16 + 8 + 1$
$25 = 25$: checks

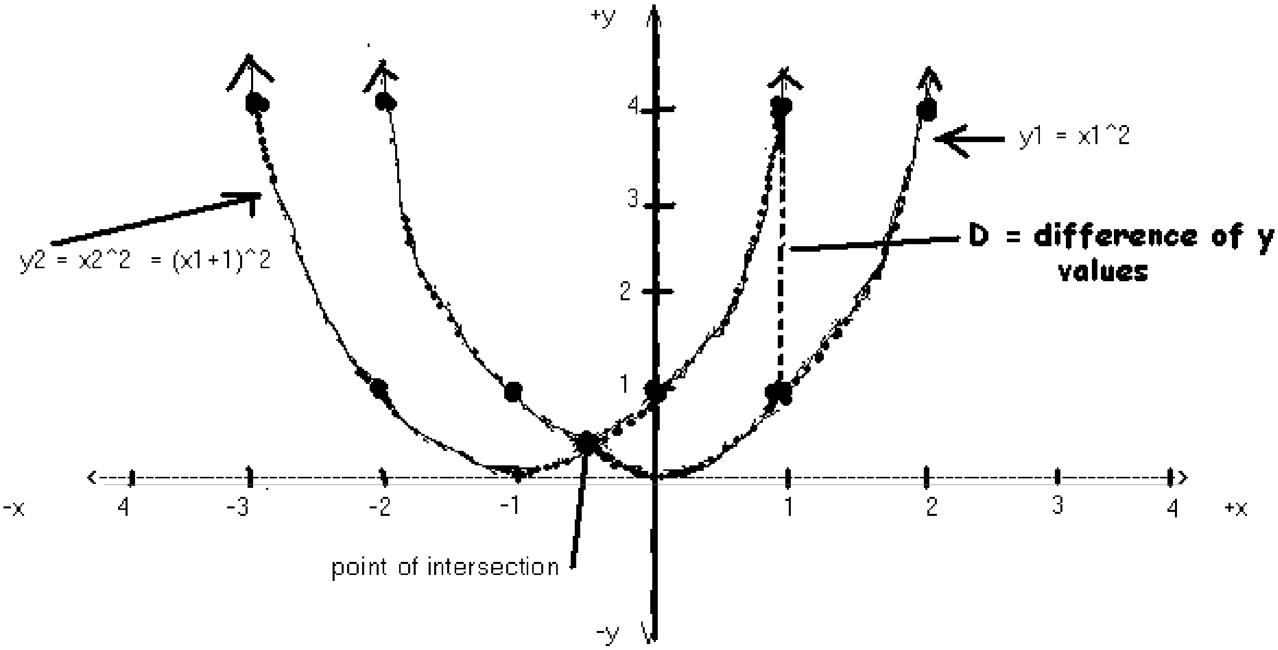
The curves of $y = x^2$, and $y = (x + 1)^2 = x^2 + 2x + 1$ are identical in shape except that the $y = (x+1)^2$ curve is effectively shifted or offset leftward ("has a left shift") by 1 along the x-axis. Consider this example data:

x = 0 1 2 3 4 . . . (and so on)

y = x^2 0 1 4 9 16 . . .

y = (x + 1)^2 1 4 9 16 25 . . . : notice the same values as the previous set of values

Here is a graph of the two curves: [FIG 59]



As an extra note; clearly, the curves cross or intersect at some point. The difference between their x values (and y values) is 0 since the x values are identical at this point. You can find this (x) value by setting the y values equal, that is, set the two equations as equal:

y = y1 = y2 : at the point of intersection, the values are equal. Using substitution:
x1^2 = (x1 + 1)^2 extending the right side:
x1^2 = x1^2 + 2x1 + 1 transposing the left side:
0 = 2x1 + 1 : essentially setting the difference D = (y2 - y1) = 0.
After solving for x1 (or the general x variable at the point of intersection):

x = x1 = x2 = $\frac{-1}{2}$ = - 0.5 : the x coordinate of the point of intersection

Even though -0.5 is not an integer number, it goes to show that it is possible that the expressions of x^2 and (x+1)^2 can and do have the same values at one point. The y value of this intersection point can be found by the substitution of this value of x into the any or both of the original equations:

y = y1 = x1^2 = x^2 = -0.5^2 = 0.25 = y2 = (x1 + 1)^2 = (-0.5 + 1)^2 = (0.5)^2 = 0.5^2 = 0.25

The point of intersection is therefore: p(x, y) = p(-0.5, 0.25)

Now, let's discuss the value of the difference (D) a bit more.

The difference between $(x + 1)^2$ and x^2 is:

$(x+1)^2 - x^2 = 2x + 1$ substituting a value for x:

Ex. let x = 2: $(2+1)^2 - 2^2 = 2(2) + 1 = 4 + 1 = 5$

The difference between $(x + 2)^2$ and $(x + 1)^2$ is:

$$(x + 2)^2 - (x + 1)^2 = 2x + 3$$

Ex. let x=2: $(2 + 2)^2 - (2 + 1)^2 = 2(2) + 3 = 7$

The difference between $(x + 3)^2$ and $(x + 2)^2$ is:

$$(x + 3)^2 - (x + 2)^2 = 2x + 5$$

Ex. let x=2 $(2 + 3)^2 - (2 + 2)^2 = 2(2) + 5 = 9$

Now note that the change in the differences between two consecutive squared values:

$(2x + 3) - (2x + 1) = 2x + 3 -2x -1 = 2$
$(2x + 5) - (2x + 3) = 2x + 5 -2x -3 = 2$

We see that when (x) changes by 1, that the difference (from the previous difference) changes or increases by 2, that is, 2 is a constant in the relationship between any two consecutive differences. You could say that it is the difference or change between any two consecutive differences, or simply as: "the difference in the differences". Also, even though the difference of (2x + 1) between two squared successive integers is a fixed or constant expression that doesn't change, the actual numeric value of this difference or expression is not a constant since it depends upon the value of (x) used, as was already previously noted. The higher (x) is, the greater the differences will be, but it will only be a value of 2 greater than the previous difference.

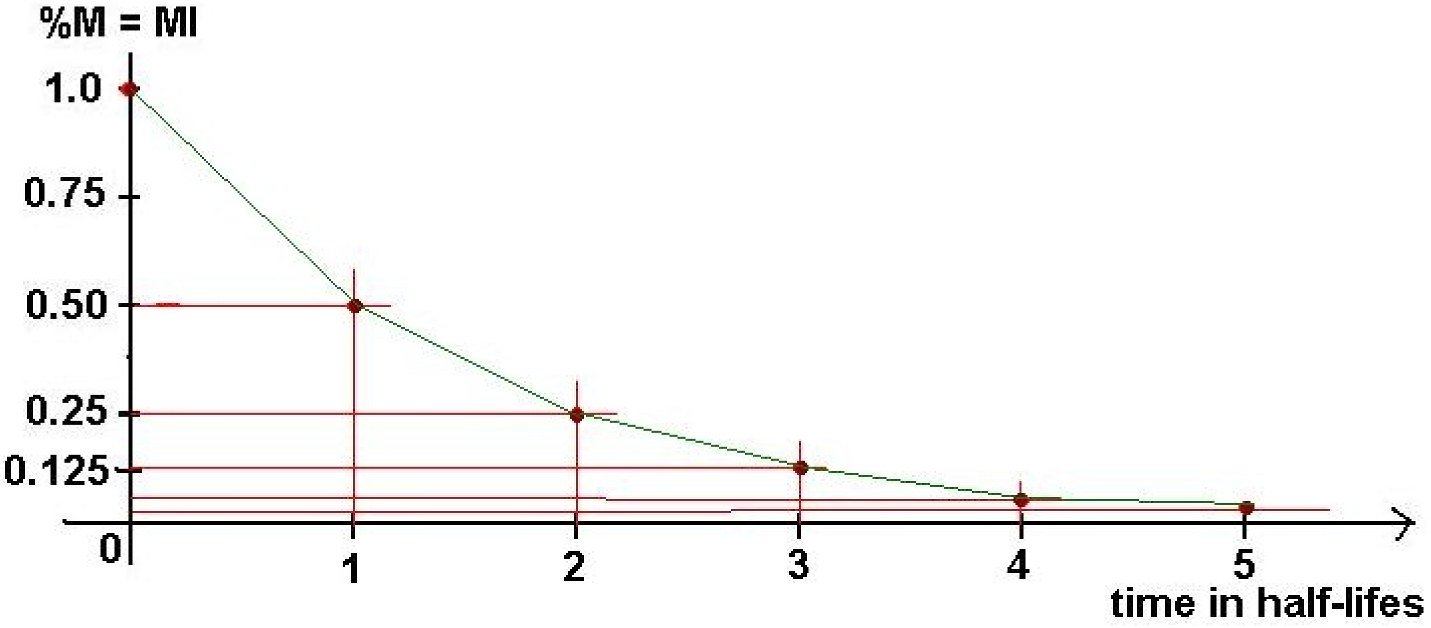
In more advanced mathematics, the expression for the value of the difference (D) as (x) increases or changes by 1 is defined as the rate of change of-or in (y) with respect to a change in (x). It (here D) is an expression of how (y) will change when (x) changes by (1). As with lines, this rate is commonly known as the slope of the curve at that point. This concept of the "instantaneous slope" (rate of change [of the dependent variable with respect to the independent variable] at a specific point only) or "derivative" is directly related to the concept of slope. The expression for D above is often formally called the (first) derivative. The change in this difference (D) as (x) increases or changes by 1 is formally defined as the slope of the slope, that is, it is the rate of change of the slope value. This value is therefore a derivative of a derivative, and it is therefore often called the second derivative. For the last example, the second derivative was a constant value of 2. In perhaps more simple wording: The slope of an equation is the rate of change of one variable (say y) with respect to the other (say x). Given different equations to start with, this slope, or derivative, value may not always be a constant or specific numerical value, and hence it changes or varies since it could be an equation of which includes a variable (such as x). The rate of change of this slope or (first) derivative with respect to the other variable (ie here, the independent variable = x) is called the second derivative. It is even possible to have further derivatives of derivatives, but once a derivative is a constant numerical value, instead of an equation, there will be no further derivatives possible since the rate of change of a constant is nonexistent or 0 since a constant value does not change in value. For the example above, it could be said that the rate of change of D with respect to (x) is 2.

$\frac{\text{change of y}}{\text{change in x}} = D = 2x + 1$: a rate of changes, and this value is how the dependent variable (y) will change with respect or in reference to the independent variable (x) for the given equation. This equation is the first derivative.

$\frac{\text{change of D}}{\text{change in x}} = 2$: this is due to and signifies that the difference, D=2x+1, is not a constant and changes by 2 for each increment of (x). That is, the difference is also changing in value, and for this example, is by a constant, steady value and rate of 2. This is a "derivative of the derivative", hence the second derivative.

HALF-LIFE EXAMPLE

Half-life is the period (time to complete a repeating cycle or event) it takes a decaying radioactive ("giving off", releasing, radiating energy) mass to effectively equal one-half (1/2) of it's original or "starting" radioactive "mass" and-or measured value. Mass is essentially the quantity or amount of the substance (ie. it is number of atoms which occupies a specific volume [a three-dimensional measure of space]). Remember, mass is not the same as the weight (a force) of something, but a mass under the influence of-and being constantly accelerated by gravity (a force) will produce a weight (force). The same mass or amount of matter on one planet will weigh differently on another planet where gravity is stronger or weaker than that of Earths gravity. A good example of the use of the concepts of half-life is in the dating old objects such as by using a process called "carbon-14 dating" which is also called "radiocarbon dating". This process is credited to **Willard Libby** in 1949. For example, a reference mass of 1 gram of a certain type of living tree contains a certain mass of carbon-14 while it is living and absorbed. Carbon-14 is produced high in the thin atmosphere after **cosmic rays** (usually highh speed protons and nuclei (nucleus, and-or particles) of atoms, from stars) have struck the air gas atoms and caused some free neutrons which might collide into a nitrogen-14 atom and creating a (unstable, slightly radioactive) carbon-14 atom of which then combines with oxygen to form (slightly radioactive) carbon dioxide which plants absorb or "breath" for food. After a tree or animal dies, the carbon-14 in it will start to decay (decrease in amount and radioactivity) back to nitrogen-14. To determine how long ago a similar tree died (which is roughly how old the artifact is, give or take 20 years for a large animal, or 200 years for a typical tree), the carbon-14 mass remaining in a size equivalent to the reference size (one gram for this example) is determined from the artifact (a tree or piece of wood in this example), and that value is then used in an algebraic formula to determine how old it is. Carbon-14 dating is practical for objects as old as about 50,000 years. [FIG 59A]



Let: Mo = Original or starting radioactive mass of the decaying substance. %M is shown in decimal value in the figure.
MI = The remaining radioactive mass of the decaying substance left after a period of time (such as the half- life time). "Mass left". The higher MI is, the higher the emitted radiation and decay.
P = Half-life time, or time the period (length of time) of the half-life of a certain radioactive, decaying material
N = (Number of the) Period in question.

T = Time elapsed.

Clearly, the total time elapse (T) is equal to the time of each period (P) times the number (N) of periods gone by. That is:

T = 1 period of time + 1 period of time + 1 period of time . . .
Since all terms are the same, and there are N terms, this repeated addition can be expressed with multiplication:

T = N x period of time = NP , and:

$T = NP$: 0P ------------ 1P ------------ 2P ------------- 3P ------------ 4P ---- . . . (and so on)

$$Ml = Mo \qquad \frac{Mo}{2} \qquad \frac{(Mo)}{\frac{(2)}{\frac{2}{1}}} = \frac{Mo}{2^2} \qquad \frac{Mo}{2^3} \qquad \frac{Mo}{2^4} = Mo\ 2^{(-4)}$$

: an inverse or reciprocal exponential decay

Hence, to find the value of Ml after the next period of time, the value of Ml is divided by 2, and we find that the denominator to Mo is equal to an indicated power with a base of 2 which has an exponent that corresponds to, and is equal to the period in question, that is, the denominator after the end of each period in question (N) and-or start of the next period of time is: (2^N).

from: $T = NP$, $N = \frac{T}{P}$

hence: $2^N = 2^{(T/P)} = 2^{(\text{total Time elapsed / time of Period})}$: for this example, time of period = half-life time

By using this expression for N, we can account for the mass left at all times, even when the time is in-between periods (ie. portions or fractions of a period gone by). Expressing all this data into an algebraic formula for the mass left after any period or amount of elapsed time in question:

$$Ml = \frac{Mo}{2^N} = \frac{Mo}{2^{(T/P)}} \quad \text{or} = \quad Mo\ 2^{-(T/P)}$$

: **MASS LEFT FORMULA**, , and here, of the Carbon-14
(for half-life, or 50% decay rates per period)
T=total time elapsed, P=period time of the half-life
Mass lost and-or decayed = Md = (Mo - Ml)

Solving for T which is the time elapsed or age of the artifact:

$Ml = \frac{Mo}{2^{(T/P)}}$ clearing fractions and ridding non-variable (T) terms to one side:

$2^{(T/P)} = \frac{Mo}{Ml}$ taking the log of each side to isolate (solve) for the exponent:

$\log 2^{(T/P)} = \log \frac{(Mo)}{(Ml)}$ using the log exponential rule:

$\frac{T}{P} \log 2 = \log (Mo/Ml)$ dividing each side by log 2, and multiplying each side by P:

$T = P \frac{\log (Mo/Ml)}{\log 2}$: TIME ELAPESED OR "AGE" FORMULA
(Use a consistent (ex. e, or 10) log base for both the dividend and divisor)

Also, solving for P by multiplying each side by $\underline{\ \ \log 2\ \ }$ and canceling:

log (Mo/Ml)

$$P = T \frac{\log 2}{\log (Mo/Ml)}$$: PERIOD OF HALF-LIFE FORMULA

Ex. You started with 1 gram of some substance that decays naturally, and after 70 days the amount of the substance remaining was 0.825 grams. How long (total) will it take till 0.750 grams (ie. three-quarters of a gram = 3/4 grams) remains?

First calculate the half-life period. "Natural-Logarithms" (have base of (e) = a constant value of about 2.71828)) will optionally be used, however you can use any base, perhaps 10, as long as you use it consistently.

$$P = T \frac{\ln 2}{\ln \left(\frac{Mo}{Ml} \right)} = \frac{70 \text{ days } (0.69314718)}{\ln \left(\frac{1 \text{ gram}}{0.835 \text{grams}} \right)} = \frac{48.52030264 \text{ days}}{0.180323554} = 269.07 \text{ days}$$: period of "half-life"

You could have initially converted 70 days to its' equivalent number of years so as to have the period expressed with time units that is also years. You can also convert 269.07 days to its equivalent number of years. Since P is less than 1 year, it is perhaps better to express it, and other calculations using it, in terms of days rather than awkward fractions of a year.

Now using this period value to find the time till 0.750 grams remains:

$$T = P \frac{\ln (Mo/Ml)}{\ln 2} = \frac{(269.07 \text{ days}) \ln (1.0g/0.750g)}{0.69314718} = \frac{(269.07 \text{ days}) \ln (1.333333333)}{0.69314718}$$

$$T = \frac{269.07 \text{ days } (0.287682072)}{0.69314718}$$

$$T = 111.67 \text{ days}$$

Given 1 gram of this particular substance, it will take 111.67 days till 0.750 grams of it remains. Likewise, it will take this long for (1g - 0.750g) = 0.250 grams of it to disappear or change to another state or substance.

Frequently, the period of half-life of a substance, when not being calculated, is found from a "look-up" or reference table. For example, the **half-life of carbon-14 is noted as being about 5,730 years**.

If you like, you can use "relative" fractional or percentage values for Mo and Ml. To do so, place these percent values in numerical (decimal) form. Usually, the original mass (Mo), or any mass considered as the original or "starting" mass of the system (where T is considered as 0), is considered as 100% since it has not decayed yet, and therefore
Mo = (100/100) = 1.0 will be used in the formulas. For example, if the mass left over (Ml) is 50%, this will be numerically represented as Ml = 50% = fifty parts per hindered parts = (50/100) = 0.50 in the formulas. The mathematical reason that these percent or fractional values can be used is that the ratio of the masses is also equivalent to the ratio of their corresponding percentages.

Below, another method of calculating half-life is derived, and some more generalized formulas will be developed.

After one period (T) of half-life time, the ratio of the mass or substance left (Ml) to that of the original mass (Mo) is always found to be 50% (or 0.50) in half-life situations. Since mass left or remaining is in question, this value could be called the percent remaining after each period of time.

$\frac{Ml}{Mo}$ = PR = percent remaining (PR) after any one period. Mo = mass at start of the period in question, Ml=mass at end of the period in question.

Algebraically: $M_l = M_o(PR)$

Regardless of the period in question chosen to find PR, PR will always be a constant as long as the physical decay rate is always a constant value.

	Period Number =	0	1	2	3	. . .
	Ml =	Mo	Mo(PR)	(Mo(PR))(PR)	((Mo(PR))(PR))(PR)	. . . these can be simplified to:
OR:	Ml =	Mo	Mo(PR)^1	Mo(PR)^2	Mo(PR)^3	. . .

Notice that Mo and PR are common factors of the remaining mass left (Ml) at the end of each period. Also notice that the exponent of PR is equal to the number of the period (N) in question. Expressing this data into a general algebraic formula:

Ml = Mo(PR)^N or= $Mo\left[\frac{Ml}{Mo}\right]$^N :Mass Left Formula
(PR corresponds to the specific decay rate used, and what remains)

Notice that the physical decayed or lost value (a change or difference = mass at start of period - mass at end of period) becomes smaller and smaller as the periods increase since the same (constant) percentage (PR), when used a decimal value, is multiplied to a smaller value (the mass starting each new period = Ml). Overall, in decay situations, PR is less than 1, and any value less than 1, a proper fraction, raised to a power greater than 1, or multiplied by itself, is smaller than itself. A fraction of a fraction results in a smaller value. Therefore, in the first few periods, a relatively large decay (loss of the substance in question) will be produced, and as the periods increase, the actual physical decay values will be less and less and it will eventually appear as a very slow, prolonged or endless decay where there is always some minimal or minuscule value still left (Ml).

The actual value of the decay between the starting mass and the mass at the end of a period in question can be calculated as:

Total Decay = Mo - Ml : where Mo is mass at the start of the system, and Ml becomes the mass at the end of the period in question.

The actual value of the decay between consecutive periods can be calculated as:

Period Decay = Mo - Ml : where Mo or Mn is mass at the start of the period in question, and Ml becomes the mass at the end of the period in question (or= at the start of the next period). Perhaps, a better notation could be:
Period Decay = $(M_n) - (M_{n+1})$: n=N , the period in question

Ex. For half-life study, the ratio of Ml to Mo for each period is: Ml/Mo = PR = 0.50, and if Mo= 100g (g = grams).

Ml = Mo(PR)^N
Ml = 100g (0.5)^N

Period Number =	0	1	2	3	4	. . .
Ml =	100g	50g	25g	12.5g	6.25g	. . .
Decay (g) =	0g	50g	25g	12.5g	6.25g	. . .

(Note, only when PR = 0.50, the decay of the (last) period of time equals the mass left = Ml.)

Observe that the value of the decay is decreasing as time increases, but still, the decay rate is the same constant value of 0.50

Solving for the period (N) in question:

$Ml = Mo(PR)^N$ dividing both sides by Mo:

$\frac{Ml}{Mo} = (PR)^N$ taking the log of both sides:

$\log\left(\frac{Ml}{Mo}\right) = \log (PR)^N$ using the log (of a) power rule:

$\log\left(\frac{Ml}{Mo}\right) = N \log (PR)$ dividing each side by log (PR) and switching sides:

$N = \frac{\log (Ml/Mo)}{\log (PR)}$: PERIOD NUMBER
: this denominator is a constant for a given problem, for half-life problems, PR=0.50

Total time or age can be found using the expression: $T=NP$

Again, like the formula shown previously but now using different variable names or identifiers, the total time elapsed (t) is the product of the period time (now using T, instead of P) and the number (N) of the period in question.

$t = TN$: t = Total Time Elapsed Formula
(using either upper and lower case letter (t) for the time values)

Therefore, mathematically:

$N = \frac{t}{T} = \frac{\text{time elapsed}}{\text{time of period}}$: Determining The Period In Question Formula

The (time) units of measurement of (t) and (T) must be the same, such as seconds, minutes, hours. days, or years.

since: $Ml = Mo(PR)^N$,we can derive a more generalized formula:

$Ml = Mo(PR)^{(t/T)}$: Mass Left Formula
PR = percent remaining = 50% = 0.50 for half-life problems.
t=total time, T=half-life period time, Mo=starting mass

Ex. If you began with 270g, (Mo), of substance, and after a period (T) of 3 years, 50% of it or 135g (Ml) remains. How much will you have after a total of 12 years of elapsed time (t).

In this example the percent remaining (PR) is given as 50%, it can be calculated from:

$PR = \frac{Ml}{Mo} = \frac{135g}{270g} = 0.50$: PR after a 3 year time period, and in its usable decimal form for calculations.
Since half of the substance is remaining after this length of time, this length of time, 3 years, is also the half-life time or period.

$Ml = Mo(PR)^{(t/T)}$

$Ml = 270g(0.50)^{(12yrs./3yrs.)}$

$Ml = 270g(0.50)^4$: the half life period is 3 years, and 4 of these (3 year) periods is 3 x 4 = 12 years

Ml = 270g(0.0625)

Ml = 16.875g or = 16g + 875(10^-3)g = 16g + 875mg

Note, the ratio (PR) of Ml to Mo per period can be greater than 1. This happens when there is a growth or gain such as an account that has gained interest, growth of living things, growth of crystals, etc.

INTEREST EXAMPLE

You may have a savings account which receives periodic interest (usually as a small percentage value) that is added to the account balance or amount. The amount of interest is based on, or in reference to, the current balance in the account. The current balance or amount in the account is the initial deposit plus all the interest already received. This concept is sometimes called "compound interest", but remember, the interest rate is a still a constant percent value, and that the interest money received per period is rather increasing. Compound interest means that you will receive interest based on both the current balance and any previous interest already added to the account. If you initially deposit $200.00 and the interest rate is 5.35% (0.0535 decimal) on the net or total amount in the account after each 3 month period, what is your accounts total worth after 1 year (12 months) has elapsed?

First, you may wish to review the previous example in this book called: Half-Life Example

We were given: Mo = $200.00 : we can consider variable M as a variable for money instead of mass.
Mo = original, initial or starting value of money

$N = \frac{t}{T} = \frac{12 \text{ months}}{3 \text{ months}} = 4$ N = number of intervals or period (T) durations during the complete time duration duration (t).

After the first period:

Ml = Mo + Interest : here, Ml = Mass (of money) left = Money left or current value
Ml = 200 + 200(0.0535) = $210.70

$PR = \frac{Ml}{Mo} = \frac{\$210.70}{\$200.00} = 1.0535$: which is essentially; PR = (1.0 + interest rate) in terms of relative values
PR = "Percent Remaining" of the original starting mass, quantity or value.

Ml = Mo(PR)^(t /T)

Ml = $200(1.0535)^(12months/3months)

Ml = $200(1.0535)^4

Ml = $246.36 : after 1 year

Checking by "long-hand" or manually:

N Elapsed	Interest (at 5.35%)	Net Account	
0		$200.00	$200 + (0.0535)($200) = $200 (1 + 0.535) = $200 (1.535) = $210.70 :
1	$10.70	$210.70	
2	$11.27	$221.97	
3	$11.88	$233.85	
4	$12.51	$246.36	:checks

Below is another way to mathematically express Ml:

$Ml = Mo + (\text{change of } M)$ or for this example above: $Ml = Mo + Mgained$

If the change is a decay or a loss, as with half-life problems, this can be algebraically expressed as negative in sign:

$$Ml = Mo + (-Mlossed)$$
$$Ml = Mo - Mlossed$$

Since PR = percent remaining, assigning a variable name of PC (Percent Changed) to the percent that was decayed or lost from the 100% value:

$$PC = \frac{Change}{\text{Initial value}} = \frac{Mo - Ml}{Mo} = \frac{Mlossed}{Mo} \quad \text{: (per period), therefore:}$$

(Note, for purposes other than this immediate discussion, if you want to keep PC with a sign indicating if the change was greater or less in value, use (Ml - Mo) for the numerator above.)

$$Ml = Mo - Mlossed$$
$$Ml = Mo - Mo(PC)$$

The sum of PR and PC is equal to 100% (or 1.0). This will now be verified:

$$PR + PC = 1.0$$

$$\frac{Ml}{Mo} + \frac{(Mo - Ml)}{Mo} = 1 \qquad \text{combining fractions:}$$

$$\frac{Ml + Mo - Ml}{Mo} = 1 \qquad \text{combining terms in the numerator:}$$

$$\frac{Mo}{Mo} = 1 \qquad \text{: checks}$$

From: $1 = PR + PC$: Here, 1 is the decimal equivalent of 100%, therefore:
$PC = 1 - PR$ and:
$PR = 1 - PC$

Ex. When $PR = 90\%$:
$PC = 1 - PR$
$PC = 100\% - 90\%$
$PC = 10\% = 0.10$

$Ml = Mo - Mo(PC)$ factoring out the HCF of Mo:

$Ml = Mo(1 - PC) = Mo(PR)$: Formulas For Money or Mass Left For A Single Period

Therefore, the formulas for the money (such as in an interest account) or mass left (such as of a decaying mass), can be expressed in terms of either the percent remaining or the percent changed.

From: $Ml = Mo(PR)^{(t/T)}$
$Ml = Mo(1-PC)^{(t/T)}$: Money or Mass Left Formulas (decays)

If the change was an increase, such as from a growth or interest account, this value is algebraically noted with a positive sign.

$Ml = Mo + (\text{change of } M)$
$Ml = Mo + (+\,Mgained)$
$Ml = Mo + Mgained$

When the ratio of Ml to Mo is greater than one, PR = percent remaining will be greater than one. PC will be a growth rather than a loss, and then PR = 1 + PC. This will now be verified since it may not obvious:

$PR = 1 + PC$

$PR = 1 + \frac{Mchanged}{Mo}$: when there is a growth, $Ml > Mo$, $PC > 0$, $PR > 1$

$PR = 1 + \frac{Ml - Mo}{Mo}$ combining fractions (LCD = Mo):

$PR = \frac{Mo}{Mo} + \frac{Ml - Mo}{Mo}$

$PR = \frac{Mo + Ml - Mo}{Mo}$ combining terms in the numerator:

$PR = \frac{Ml}{Mo}$: checks

$Ml = Mo + Mgained$ Since $Mgained = Mo(PC)$:

$Ml = Mo + Mo(PC)$ factoring out the HCF of Mo:

$Ml = Mo(1 + PC) = Mo(PR)$: Formulas for Mass Left After A Single Period

$Ml = Mo(PR)^{(t/T)} = Mo(1+PC)^{(t/T)}$: Mass Left Formulas (growths)

A more generalized formula which accounts for decaying (-) or growing (+) substances in terms of percent remaining (PR) or percent changed (PC) per period is:

$Ml = Mo(PR)^{(t/T)} = Mo(1 \pm PC)^{(t/T)}$: Mass Left Formulas (decays or growths)

However, we know algebraically, that we can use a more generalized formula as long as the proper sign for the value of PC is always accounted for:

$Ml = Mo(PR)^{(t/T)} = Mo(1 + PC)^{(t/T)}$: Mass Left Formulas (decays or growths)
(use proper sign for PC)

Ex. If a substance decays by 5% each period:

$PC = -5\% = -0.05$: assigned the negative sign since its a decay or loss
$PR = (1 + PC) = (1 + (-0.05)) = (1 - 0.05) = 0.95$:95%

Many times the "natural" constant of (e), about 2.718, is used in mathematical formulas for (natural and continuous) decays and growths. Here is a derivation where (e) can be used for half-life study:

At the end of the first (1) half-life period (T):

$$M1 = \frac{Mo}{2}$$

From the concepts of logarithms:

If e^x = 2, then: x = loge 2 = ln 2, therefore:

e^x = e^(ln 2) = 2 and:

$$M1 = \frac{Mo}{2} = \frac{Mo}{e^{(\ln 2)}} = Mo\, e^{(-\ln 2)}$$

: Often, a negative exponent indicates a decaying function or value rather than a growth. Here, e^(-ln 2) is actually a numerical coefficient (a multiplying factor to) of Mo. It will cause the value of Mo to decrease or decay.

By the end of the second half-life period:

$$M2 = \frac{M1}{2} = \frac{\frac{Mo}{2}}{2} = \frac{Mo}{2^2} =$$

$$\frac{Mo}{(2)(2)} = \frac{Mo}{(e^{\ln 2})(e^{\ln 2})} = \frac{Mo}{(e^{\ln 2})^2} = \frac{Mo}{e^{(2 \ln 2)}} = Mo\, e^{(-2 \ln 2)}$$

Notice that at the end of each half-life period in question (n), that the numerical coefficient of the exponent of (e) is the same as the period. Expressing this in a formula:

$$Mn = Moe^{(-n \ln 2)}$$

: Formula For Mass Left After A Decay , (expressed with e), where the decay is 50% for each period. (n) is the period number.

Here's how to express the formula for times in between periods, and hence, at any time in question:

Since total time (t) is the number of periods (n) gone by times the time-length or duration of each period (T), as shown previously:

$$t = nT \quad \text{therefore,} \quad n = \frac{t}{T}$$

Substituting this for (n) in the formula we get:

$$Ml = Mo\, e^{(-t/T \ \ln 2)} = Mo\, e^{(-0.69314718\ t/T)}$$

: Mass Left After A Decay Formula (for 50%, "half-life" decays)

Notice that the formula can be written using the associative law as:

$$Ml = Mo\, e^{(-t \ \ln 2/T)}$$

The value (ln 2/T) is a constant for the given problem, and therefore it only needs to be calculated only once. For example, if the half-life period is 10,000 years, perhaps for a half-life analysis using carbon-14 dating:

$$\frac{\ln 2}{T} = \frac{0.69314718}{10000} = 0.000069314$$

and the resultant formula is simply:

$$Ml = Mo\, e^{(-0.000069314\ t)}$$

Ex. In this example, a person gives you the following equation that looks similar to those just discussed, and you are asked if you can algebraically solve for T, hence create a formula for the mathematical relationship between T and all the other values.

$Vl = Vo\ e^{(-\,0.69314718\ t/T)}$ The equation can also be expressed as:

$$Vl = \frac{Vo}{e^{(0.69314718\ t/T)}}$$

solving for the time of each period: T
In this example T will be the time of the half-life or value.

$$e^{(0.69314718\ t/T)} = \frac{Vo}{Vl}$$

taking the natural log. of both sides:

$$\ln e^{(0.69314718\ t/T)} = \ln (Vo/Vl)$$

after using the log exponent rule, and some simplifying:

$$0.69314718\ t/T = \ln (Vo/Vl)$$

after multiplying each side by T, and then isolating T:

$$T = \frac{0.69314718\ t}{\ln (Vo/Vl)}$$

: T = the "half-life" period of time. This is the time taken or needed for Vl to be equal to half of Vo. T is a constant for the specific system.
t = the time taken for some change to take place, such as the time needed for Vo to change (here decay) to Vl.
Vo = the starting or initial value that will be decreasing or decaying naturally
Vl = the current value left after the natural decrease or decay of Vo

Ex. One of the most common formulas for a savings account where compound or compounding interest is added to an account is shown below. Compound interest is simply a method where the interest is calculated on the current total or net (accumulated, gathered) savings balance, and this balance includes any interest that was previously calculated and added to it. The interest rate value is usually a constant or fixed value, and is not "compounded" in value.

$$T = M (1 + I)^n$$

M = Starting deposit
T = Total = M + Total Interest
I = Interest rate per period
n = nth period, or nth interval of interest being added into the savings account balance,
This is the specific interest period or interval number in question.

Of course, for this formula to hold true, it is assumed that there are no withdrawals from the savings account. A derivation of this formula will now be presented:

$T0 = M$: the total at the start or at interval or period 0

$T1 = T0 + \text{Interest of } T0 = M + MI = M (1 + I)^1$: the total after the end of the first interval

$T2 = T1 + \text{Interest of } T1 = M (1 + I) + M (1 + I) I = M (1 + I) (1 + I) = M (1 + I)^2$

$T3 = T2 + \text{Interest of } T2 = M (1 + I)^2 + M (1 + I)^2 I = M (1 + I)^2 (1 + I) = M (1 + I)^3$

Clearly, the exponent of the (1 + I) factor corresponds to the interval of the savings. This pattern confirms the formula. Since total time, (t) = (Time of a period)(n periods), you can use this formula for (n):

$n = t / T$: t = total time, T = Period of the interest rate **:**

TOTAL = M (1 + **I**)^(t / T) : total savings in an account with compound interest of **I**
M=starting balance, t=total time elapsed, T=time between interest payments or payment interval time

Ex. If the initial deposit into a savings account was \$25, and with 5% compounded interest every 4 months, how much will the account grow to after 12 months of time?

Here, t = total time elapsed = 1 year = 12 months
T = period of calculating the interest rate = 4 months
TOTAL = M (1 + **I**)^(t/T)

TOTAL = \$25(1+ 0.05)^(12months/4months) = \$25(1.05)^3 = 25(1.15$\underline{8}$) = \$28.95

A gain of: (\$28.95 - \$25) = \$3.95

Next, a general discussion about paying interest on a loan will be included in the example given. Again, observe how algebraic formulas can be created.

LOAN EXAMPLE

A bank gave a person a $15,000 loan (Mo) to be paid in full by 1 year after 12 interval (N) base payments (B). With each base payment, the bank also charges you a 2% interest (I) on the remainder (Ml = money left to pay) of the loan not yet paid back. This is similar, in a reverse type of manner, to the bank paying you interest on the total amount you have in the bank.

Defining variables to be used in the algebraic formulas:

Mo = Original amount of the loan, and in this example, it is $15,000.
Ml = Amount of the loan left or remainder of the loan yet to be paid back. Obviously, after each base payment, the value of Ml is less, and therefore, the interest on that amount will be less.
I = Interest rate, use the decimal equivalent for the formulas, here, it is 0.02
B = Base payment which is the interval payment due on the loan. This is a constant value. This does not include the interest to be paid on the remainder (Ml) left to be paid.
P = Interval payment which is the sum of the base payment (b) and the interest payment (I). This value will be smaller for any next interval(s) since the interest payments will be less since the remainder of the loan (Ml) to be paid back is less.
N = Interval in question, here, the total intervals or number of payments is Nt = 12

The total you will eventually pay back to the bank is:

Total = Loan + Total Interest   expressing this algebraically:
$Mt = Mo + It$: Total Formula

The base payment of the loan is simply the total value of the loan divided by the total number of interval or base payments to be made.

$B = \frac{Mo}{Nt}$: Base Payment Formula, also, algebraically:

$Mo = NtB$: Loan Value Formula, substituting this into the Total Formula:

$Mt = NtB + It$: alternate Total Formula

The payment (P) due for each interval (letting n=N) in general terms is:

Payment = Base payment + Interest payment   and algebraically:
$P = B + In$

Each interest (I) payment at interval n=N is the remainder of the loan yet to be paid times the interest rate. That is,

In = (remainder of loan)(interest rate)
$In = (Ml)(I)$

Algebraically, here you may also note: interest rate = $\frac{In}{Ml\text{=remainder of loan at N intervals}}$

Interval Payment = Base payment + (remainder)(interest rate)   algebraically:

$P = B + MI\ I$: basic Payment Formula

The remainder or amount of the loan left to be paid (without regard to any interest) can be equated or expressed as the total amount of the loan less the amount already paid back:

From: $Mo = \text{loan paid back} + MI$
$MI = Mo - \text{loan paid back}$

Since the amount of loan paid back can be calculated in terms of the base payment (B) and the number of intervals (N) or times it was paid, payment (P) can be calculated in terms of an interval in question:

from: $\text{loan paid back} = (\text{base payment})(\text{intervals})$: $= Mo - MI$
$\text{loan paid back} = BN$: (without adjustment, see below)

When calculating the loan paid back at the start of a new interval, N must be reduced by 1. For example, starting when the loan was first taken out, this is considered interval 0 since no (0) payment or interest is yet due. When the first payment is due, interval 1 is entered and the next payment will be due at the end of this interval or start of interval 2. In other words, the intervals and-or time actually start at 0, and not 1. Therefore, when the first (1) payment or "interval 1's" payment is due, no amount of the loan has yet been paid back. To correct the loan paid back formula, an adjustment must be made, and that is to subtract 1 from N:

$\text{loan paid back} = B(N-1)$:loan paid back at the interval (N) in question

$MI = Mo - B(N-1)$:this will be substituted into the Payment Formula, but first:

Here is another derivation of the remainder (MI) of the loan to be paid:

Payment N	MI in which interest for a payment is to be calculated with.					
0						
1	Mo					: payment due at the start of the interval
2	$Mo - B$	=	$Mo - B$	=	$Mo-1B$	
3	$(Mo - B) - B$	=	$Mo - B - B$	=	$Mo-2B$	
4	$((Mo-B)-B) - B$	=	$Mo-B-B-B$	=	$Mo-3B$	
(and so on)						

Observe that for each interval or payment, B, the base payment, is to be subtracted [algebraically adding (-B) since the subtraction of a value really represents an addition, or combining with, of a reduction or loss, (ie. a negative value)] from the remaining part of the loan (MI). We also observe that this is essentially adding (-B) to Mo, (N-1) times. In short, the coefficient of the B term is 1 less than the interval in question. Expressing these facts algebraically for MI, we see that this checks with the equation previously shown.

$MI = Mo - (N-1)B$ or $MI = Mo - B(N-1)$: by using the commutative law

$P = B + \text{Interest}$
$P = B + MI\ I$
$Pn = B + (Mo - B(n-1))\ I$: n=Nth (interval) Payment Formula

Since $Mo = NtB$, we can get an alternate payment formula:

$Pn = B + (NtB - B(N-1))I$ factoring out the common factor of B:

$Pn = B + I(B(Nt - (N-1)))$
$Pn = B + BI(Nt - (N-1))$: alternate Nth Payment Formula

: Here, the value of the loan, Mo, need not even be known or used

Notice the factor BI in the last derivation is a constant value,therefore only needs to be calculated once for a given problem. This value of BI can be known as the "Base Interest" for or per each interval. To calculate the interest payment due at a certain interval payment, simply use that part (here, the second term) of the above expression that represents it:

$In = (Mo - B(N-1))I = BI(Nt - (N-1))$: n=N , Interest Payment N Formulas (*)

To find out the total amount that will be paid on the loan, the total interest must be calculated:

Total = Loan + Total Interest or in a more algebraic sense:
$Mt = Mo + It$: Total Formula, also, algebraically:

It = sum of interest payments for all the intervals

$$It = I(N=1) + I2 + I3 + I4 + \ldots + I(N=Nt)$$

$$It = MoI + (Mo-1B)I + (Mo-2B)I + (Mo-3B)I + \ldots + (Mo-(Nt-1)B)I$$

Distributing (I):

$$It = MoI + Mo\,I - BI + Mo\,I - 2BI + MoI - 3BI + \ldots + MoI - (Nt-1)BI$$ OR:

$$It = MoI + MoI - BI + MoI - 2BI + MoI - 3BI + \ldots + MoI-(Nt-1)BI$$ Factoring (I) from each term:

$$It = I(Mo+Mo-B+Mo-2B+Mo-3B + \ldots + Mo -(Nt-1)B)$$

Combining like terms in the multiplying factor of (I):

First, notice that there are Nt=12 like terms of Mo and that each numerical coefficient of Mo is one (1). Summing up the numerical coefficients of Mo is essentially repeated addition of one (1), twelve (12) times. The numerical coefficient of Mo in an algebraic sense is therefore:

$(1)(12) = (1)(Nt)$ or simply $Nt = 12$ Expressing this in the general algebraic formula:

$$It = I(NtMo -B -2B -3B - \ldots (Nt-1)B)$$

To make things easier, we will "divide through" the B terms by (-1) so that the coefficients of B will all be positive. A general format example will be shown first:

Given -B, dividing by -1:

$$\frac{-B}{-1} = +B$$ and therefore:

$-1(+B) = -B$:checks with the given value of: $-B$

This is basically the same as factoring (-1) from each variable B term:

$$It = I(NtMo -1(B +2B +3B + \ldots +(Nt-1)B)$$ or simply:

$$It = I(NtMo - (B +2B +3B + \ldots +(Nt-1)B)$$

We can combine the terms that contain B by summing up B's numerical coefficients by hand or we can use a general formula for the sum of integers from 1 to (Nt-1):

The general formula for the sum of the first N integers from 1 to N is:

$$\text{Sum} = \frac{N^2 + N}{2} \quad \text{or} \quad = 0.5N^2 + 0.5N = 0.5(N^2 + N)$$: **sum of the first N integers from 1 to N**

Here is a simple verification/derivation of the above formula:

Ex. We are to sum (S) up (from an initial sum of 0) the first 4 integers (1, 2, 3 and 4), hence letting N=4 in the above expression.

$$\begin{array}{rrl} & S & = 1 + 2 + 3 + 4 \\ + & \underline{S} & \underline{= 4 + 3 + 2 + 1} \\ & 2S & = 5 + 5 + 5 + 5 \end{array}$$

: this is N=4 terms, adding the sum to itself, we will have S + S = 2S:
: remember, addition is commutative, so the sum (here S=10) should still be the same regardless of order, and here, it's a descending order of values.

The right hand side can be represented with multiplication since multiplication is basically a repeated addition of the same value. Notice that each term is algebraically (N + 1) = (4 +1) = 5, and that there are N terms, and expressing this with multiplication:

$$2S = (N+1)(N)$$ solving for S:

$$S = \frac{(N+1)(N)}{2}$$ clearing grouping symbols by distributing N:

$$S = \frac{N^2 + N}{2}$$ substituting the given value of N:

$$S = \frac{4^2 + 4}{2} = \frac{16 + 4}{2} = \frac{20}{2} = 10 = 1 + 2 + 3 + 4$$

Checking:

$$\begin{aligned} 2S &= 5 + 5 + 5 + 5 \\ 2(10) &= 20 \\ 20 &= 20 \end{aligned}$$: checks

Extra: Here's the sum of the first 100 integers from 1 through 100:

$$S = \frac{100^2 + 100}{2} = \frac{10000 + 100}{2} = \frac{10100}{2} = 5050$$

For terms which are not necessarily integers, and-or don't have a difference between them of 1, a similar derivation and more generalized formula can be found in the study of mathematical progressions and series.

In the interest example, the highest coefficient of B is (Nt -1) = (12 - 1) = 11. The sum of the first eleven integers is:

$$\frac{11^2 + 11}{2} = \frac{121 + 11}{2} = \frac{132}{2} = 66$$

checking: 1+2+3+4+5+6+7+8+9+10+11 = 66

Substituting the algebraic expression for the coefficient of B into the total interest formula:

$It = I(NtMo - (B + 2B + 3B + . . . + (Nt-1)B)$

$It = I\left(NtMo - \left(\frac{(Nt-1)^2 + (Nt-1)}{2} \right) B \right)$: Total Interest Formula or:

$It = I\,(NtMo - ((Nt-1)^2 + (Nt-1))\, 0.5B)$: Total Interest Formula or:

$It = NtMoI - ((Nt-1)^2 + (Nt-1))\, 0.5BI$: Total Interest Formula

Substituting the arguments or actual values used in the initial problem given at the start of this discussion, and also the derived or calculated arguments, we can find the total interest that will be paid to the bank.

$It = (12)(\$15{,}000)(0.02) - ((12-1)^2 + (12-1))\,(0.5)(1{,}250)(0.02)$ we find:

$It = 1{,}950$ dollars $= \$1{,}950$

Manually checking this result will also give it a check, and give an algebraic verification to the total interest formula:

Payment Number	MI	I = (MI)(0.02)
1	$15,000	$300
2	$13,750	$275
3	$12,500	$250
4	$11,250	$225
5	$10,000	$200
6	$ 8,750	$175
7	$ 7,500	$150
8	$ 6,250	$125
9	$ 5,000	$100
10	$ 3,750	$ 75
11	$ 2,500	$ 50
12	$ 1,500	$ 25

$It = \$1{,}950$:checks

Notice that the interest payment for each interval is reduced by a constant equivalent to (BI). This value is seen in the (In) formula shown previously and is marked with an asterisk symbol (*). Therefore, each payment (P = B + I) will be reduced by (BI). In the example shown, the reduction in interest will be ($1,250)(0.02) = $25 for each payment. A certain bank might allow the average of the total interest charge to be added to each base payment so that all of your payments are the same value or constant.

$Iav = \frac{It}{Nt}$: Average Interest Payment Formula

For the example shown:

$Iav = \frac{\$1{,}950}{12} = \$162.50$

Therefore, the average payment will be:

$Pav = B + Iav$: A "Constant Payment", or "Average Payment" Formula

For the example shown:

Pav = $1,250 + 162.50 = $1,412.50

Since there are Nt average payments, the total you will have to pay back to the bank can be found by:

Total = Mt = Loan + Total Interest = NtPav : Total Payment Formulas

Mt = $15,000 + $1,950 = (12)($1,412.50) = $16,950

REFLECTION EXAMPLE

A certain type of mirror reflects 90% (or 0.90) of the incident (incoming) light. If a beam of light is reflected to and off of a series of five (5) of these mirrors, what percent of the original beam will be reflected off of the last (5th) mirror?

Letting Mo = Starting light beam value, quantity or intensity
Mn = Value, quantity, or intensity of the beam after reflecting off of the nth mirror.
I = Percentage of incident beam reflected off each mirror and available for the next mirror.

Here, $I = PR = \frac{Mn+1}{Mn} = 0.90$: 10% of the light is lossed due to absorption and scattering at the mirror (reflective surface).
PR = percent remaining, as used in a previous example

After reflecting off of the first mirror (n=1), the remaining light beam is:

$M1 = (Mo)I$

After reflecting off of the second mirror, the remaining light beam is only 90% of the first reflection:

$M2 = (M1)I = (MoI)I = MoI^2$

By observing the correlation (relationship, likeness, similarity) between the value of the stage (n) or interval (physically each mirror reflection) of the reflection series, and the exponent of (I), we can generalize this and express it into an equation:

$Mn = Mo\ I^n$

Since the numerical value of Mo was not given we can consider it the whole (numerically as 1) starting value, or 100% (= 100/100 = 1) of the original beam. This is sometimes referred to as doing calculations in percentage, portion, or relative terms. For this example, the ratio of Mn to Mo will always be the same for a given value of (n) since the loss is a "simple loss" and not compounded like interest.

$Mn = MoI^n$ for the 5th mirror:
$M5 = (1)(0.90^5)$
$M5 = 0.59049 = 59.049\%$

Checking: If Mo has a value of 34 units, the value of M5 is:

$M5 = (34 \text{ units})(0.90^5)$
$M5 = (34 \text{ units})(0.59049)$
$M5 = 20.07666 \text{ units}$ and:

$$\frac{M5}{Mo} = \frac{20.07666}{34.0} = 0.59049 = 59.049\%$$

Checking: If Mo only had a value of 15 units, the value of M5 is:

$M5 = (15 \text{ units})(0.90^5)$
$M5 = (15 \text{ units})(0.59049)$
$M5 = 8.85735 \text{ units}$ and:

$\underline{M5} = \underline{8.85735} = 0.59049 = 59.049\%$: the same ratio value, checks

Mo 15.0

From Mn = MoI^n algebraically:

$$I^n = \frac{Mn}{Mo}$$: here, I^n is the percentage of the initial or incoming light reflected off mirror n.

The problem could have been stated or interpreted that there is a 10% loss after each step or period, and an alternate method to solving problems, such as the above one, is given below, and it is similar to those already presented and will yield the same formula as above.

M1 = M0 - loss : Or in general, Mn+1 = Mn - loss
For problems with gains, use: M0 + gain , or M0 + interest

M1 = M0 - (0.10)M0 Factoring out the H.C.M.F = M0 from the right side terms:
M1 = M0 (1 - 0.10)
M1 = M0 (0.90)

M2 = M1 - loss
M2 = M1 - M1(0.10) using substitution:
M2 = M0(0.90) - M0(0.90)(0.10) : H.C.M.F. = M0(0.90)
M2 = M0(0.90) (1 - 0.10) : note, as shown previously, PR = (1 + PC), and here, PC = -0.10
M2 = M0(0.90)(0.90)
M2 = M0(0.90)^2

Hence, this leads to the general formula:

Mn = M0(0.90)^n : M0 = Mo , and n = mirror and-or reflection number, which here is a counting number

Extra: **This is the technical description of what a reflection is, and how a mirror functions.** A shiny, rust free, metal surface has many free electrons (unbound electrons, no longer orbiting the nucleus of an atom) on it since it is where the repulsion force by other electrons inside that metal is weakest, and until the surface cannot place any more there due to repulsion by the accumulated negative charge of the electrons there on that that surface. A metallic surface will appear to **reflect** an incident or incoming ray(s) of light, and at an angle equivalent to that it received. The reflection is actually due to the electrons absorbing the electromagnetic energy from the light and gaining kinetic energy, causing oscillations (ie., vibrate and move a short distance of movement) and releasing or re-radiating that energy as an electromagnet wave of the same frequency, here, particularly as visible light. The more electrons in motion in a particular direction, the more the electromagnetic (EM, electric and magnetic field, essentially photons of EM ("light") energy). Any energy not transmitted was due to some of the energy being converted to thermal energy and-or radiation and some of it being absorbed by the surface atoms of the metal. As you can imagine, light striking a non-metallic, non-crystalline surface is rather re-radiated in in a wider angle than that of the angle of incidence due to the greater probability of internal reflections of that material and-or its atom structure. Non-metals tend to absorb many wavelengths of light and apparently only re-radiate one specific color or frequency depending on the specific surface elements or coating (such as paint) of that light and at a reduced intensity in the viewers direction.

GROWTH OF ORGANISMS EXAMPLE

If a certain type of organism divides into two organisms after about every 20 minutes, how many organisms will be present after 4 hours if given just 1 organism to start with?

Let's work out the basic data first and then try to derive a formula from that data. First let each growth interval (n) have a period (T) of time of 20 minutes long. Also, for this analysis, we do not know the average life span of the organism, so therefore, we will not consider any possible organisms that have died into the equations. The analysis is therefore more correctly for how many organisms have been born.

The basic formula between successive intervals or periods is:

organisms at n+1 = (organisms at n) (2) : after each interval, the number of organisms is twice the previous interval

n	0	1	2	3	. . .	
organisms	1	1 x 2	(1 x 2) x 2	((1 x 2) x 2) x 2	. . .	which could be expressed as:
organisms	2^0	2^1	2^2	2^3	. . .	

Mathematically, we see that the number of organisms is actually a power of 2 whose exponent is equal to the interval or period number. Expressing this we have:

organisms n = 2^n : basic growth formula in terms of the interval elapsed

Since each interval is a 20 minute long time period (T), the total time (t) for this growth process can be expressed as the number of intervals times the time of each interval:

$t = n T$ therefore, algebraically:

$n = \frac{t}{T}$ expressing this into the basic growth formula we have:

organisms n = 2^(t/T) : basic growth formula in terms of time

Substituting the values given we have:

organisms = 2^(4 hr./20 min.)

Since the units of time must be the same here, we must convert one to the other. We will convert 4 hours to an equivalent time of minutes:

$\frac{60 \text{ min.}}{1 \text{ hr.}}$ as= $\frac{x \text{ min.}}{4 \text{ hr.}}$ after solving for x min. :

$$x \text{ min.} = \frac{(4 \text{ hr.})(60 \text{ min.})}{1 \text{ hr.}} = 4\ (\ 60 \text{ min. }) = 240 \text{ minutes}$$

organisms = 2^(240 min. / 20 min.) = 2^12 = 4096

If you want to express the formula for the number of organisms using (e), you can convert the value of 2 to its' equivalent

power value of (e):
Let 2 = e^x solving for x by taking the log of both sides:

log 2 = log e^x : arbitrarily using the common log base = 10, though any base such as (e) could also be used

log 2 = x log e

$$x = \frac{\log 2}{\log e} = \frac{0.30102995}{0.434294481} = 0.69314718$$

Therefore, e^0.69314718 = 2 , and substituting this into the formula:

organisms = (e^0.69314718)^(t/T) = e^(0.69314718 t/T)

MUSIC EXAMPLE (FREQUENCIES AND FRET SIZES)

This is an advanced example, and the reader may skip over this topic if uninterested, or till another time. The author has previously experimented in the field of lutherie (lute or string instruments) and has some helpful concepts to contribute and share in terms of math. These concepts presented are also useful for anyone interested in sound and music study. In modern times, the fundamental music scale is normally divided up into 12 acceptable sounds or tones or "notes", and the 13th note, or the first note of the next higher pitch (sounding or frequency) scale, is called an octave note since it is similar in sound to the first note of the scale but twice its frequency or pitch. The higher the frequency, the higher it sounds. This fundamental music scale is often called the chromatic music scale. In ancient times the (chromatic or "stepped") musical scale only had 8 successive notes, and today, the range from a frequency to double that frequency is still called an octave, and for example, there is 8 tones or notes in any "major scale". The mathematical relationship between successive notes in the chromatic scale is a geometric relationship. With this type of relationship, there is a constant ratio between each successive frequency value of the notes. Therefore, this ratio value can be used as a constant multiplier to find the frequency of any next note in the chromatic or 12-note, divided "octave" scale. Let's give an algebraic identifier name or variable of (R) to this ratio value. In this example we are now going to find many things such as the actual value of the successive note or frequency ratio of R.

Some other important facts:

Any chromatic scale of 12 notes is usually said to contain 7 pleasurable sounding notes in reference to the first, fundamental or "root" note of that chromatic scale. The first note, for example "C", chosen also defines the name of the entire scale that is based on that note. Each successive note or sound in the chromatic scale increases in "pitch", that is, it is higher in frequency. Frequency is a measure of how frequently or often the pulses or waves of sound are. The units for frequency are cycles or vibrations (pulses) per second. This composite unit is sometimes called hertz (hz = cps = cycles/second), and which is the name of the scientist who first described these things.

If each note position was represented as a point on a line (or actually on a vibrating, sound producing string of a "stringed instrument" such as a lute [origin of the word "luther" for lute maker], violin, or guitar), each successive next note or point will be a less distance apart. This is due to the physical relationship of vibrating structures, where the relationship of physical size (such as lengths, and volumes) and resulting natural frequency is an inverse relationship. A small bell or tuning-fork produces a high pitch or frequency sound. A big bell or tuning-fork produces a low pitch or frequency sound. In a pseudo equation, this mathematical relationship could be noted as: (frequency or pitch) = 1 / (size or length)

$R = \frac{\text{next note}}{\text{note}}$: using frequencies of the notes, therefore:

next note = note (R) or=: note1 (R) = note2

Given an initial note or frequency (F1), the frequency of higher pitched notes of the scale can be calculated as:

F1 : 1st note
F2 = F1(R) = F1R^1 : 2nd note
F3 = F2(R) = (F1R^1)R = F1R^2 :3rd note
F4 = F3(R) = (F2R)(R) = (F1R^2)(R) = F1R^3 :4th note

Notice the correlation of the indicated power of R to the n_{th} note in question, and the indicated power of R is one less. Writing an algebraic formula to express this:

frequency of note n = (previous notes frequency)(R) = (first notes frequency)(R^(n-1))

Fn = F(n-1)R = F1R^(n-1) : Frequency of the nth note of a common (chromatic, or 12 steps or notes) musical scale

At the 13th note, or octave note, the frequency is always twice the first note:

$$2F1 = F1R^{(13-1)} = F1R^{12}$$

Now, R can be completely solved for since the F variable can be eliminated. After dividing both sides of the equation by F1, and switching sides:

$$R^{12} = 2$$

Here, we can use the concepts of logarithms to solve for the base (here R) of the (indicated) power. Taking the logarithm of both sides of the equation using any base you choose:

$\text{Log } R^{12} = \text{Log } 2$ Using the "log power rule":

$12 \text{ Log } R = \text{Log } 2$

$\text{Log } R = \frac{\text{Log } 2}{12}$ Hence, by the definition of logarithms:

$R = 10^{((\text{Log } 2)/12)}$ again, using a log base of 10:

$R = 10^{(0.301029995/12)}$

$R = 10^{0.025085832}$

$R = 1.059463094$: (R), Ratio Of The Frequencies Of Successive Notes (of the common 12 note, "chromatic" musical scale)

Checking: If F1=1000hz, the 13th note, or "octave note", should be twice this frequency or 2000hz:

$F13 = F1R^{12} = 1000\text{hz}(1.059463094^{12}) = 1000\text{hz}(2) = 2000\text{hz}$: checks

Given a frequency of 500hz, the frequency of the next (or second "step" in the chromatic scale) note is:

Since: $R = \frac{\text{next note}}{\text{note}} = \frac{Fn+1}{Fn}$ algebraically:

$$Fn+1 = FnR^{(n-1)} = FnR^{(2-1)} = FnR^{1}$$

$F = Fn+1 = Fn(1.059463094)$

$F = 500\text{hz}(1.059463094)$

$F = 529.7\text{hz}$: (roughly 530 hz)

Given a scale which spans one complete octave, rather than speak in terms of frequencies for the notes of a scale, musicians speak in terms of the symbols and steps such as that given for each successive step or note of the chromatic scale. The successive notes are usually given a text character symbol with names (from A to G) of:

1 , 2 , 3 , 4 , 5 , 6 , 7 , 8 , 9, 10 ,11 , 12
A, A#, B, C, C#, D, D#, E, F, F#, G, G#, A (A = the 13th note in the chromatic scale, or the octave note of an 8 note modern scale)

(# = "sharp" , this is a note raised or increased to the next note (typically called a half-tone or half-step) of a whole entire step such as from A to B.)

Note that the notes are identified with the first letters of the alphabet and that there is no note identified as "H" or by any other letter. Further notes are identified by the same repeating or periodic series of letters since these higher pitched notes (in a next higher octave range or "pitch") sound similar due to that their corresponding frequencies are a multiple (often 2, twice, etc.) of the frequencies corresponding to those notes.

The first note of a certain defined and pleasing scale composed of selected notes from the chromatic scale can be any one of the above notes, for example. If the initial or "root" note of the scale is G, the 12 notes of the G (chromatic) scale in order are:

G, G#, A, A#, B, C, C#, D, D#, E, F, F#, G (the 13th note a the scale = first note of the next higher pitched scale)

As mentioned previously, these twelve notes, semi-tones or half-steps are formally called the notes of a chromatic scale. It is possible to create a scale of either less or an infinite number of notes. The chromatic scale selects the more humanly discernible tones, and is therefore more manageable and reproducible by other musicians. Usually, other formally defined and more pleasing to hear scales contain only some of these notes of the chromatic scale. These notes can be played and heard one after the other in any desired timing and order, and including at the same time with any other of the pleasing notes in that scale. Playing two or more notes at once is called a chord of notes, or simply a chord. For example, the Major scale that is used in a modern or "Western" sounding, or type of music, consists of these 7 selected notes or steps from the 12-note chromatic scale:

1, 3, 5, 6, 8, 10, 12, 13 : with the 8th note (being the 13th note of the chromatic scale) of this scale being the octave, these 8 notes formally comprise an octave (oct is a prefix meaning "eight") range of notes or tones

For example, The C-Major scale is:

C, D, E, F, G, A, B, C : This is typically called the "key" (octave, or scale) of C-Major.
1, 2, 3, 4, 5, 6, 7, 8 : Corresponding tone or note numbers of the 8 note or octave scale, and these numbers help someone to easily reference and "transpose" (move or change position, convert) a scale to a similar higher or lower pitched (ie., in frequency) scale or key.

A peculiarity of the C-Major scale is that it was defined so that it does not formally contain any sharps (#) or flats (b) and is therefore often chosen when simplicity and-or a clearer understanding is needed. A "sharp" or "sharped note" is where a note is changed to a semi-tone or half-step higher in frequency which is essentially the next note in the chromatic scale. A flat (b, ex. Eb = "E flat") is where a note is change to a semi-tone or half-step lower in frequency. Sharps and flats can result in the same note, for example, the A# = A-sharp note is equivalent to the Bb = B-flat note. Both have the same frequency. Note for example that this scale starts at (C) and the next note is (D) which is an increase of two semi-tones or notes of the chromatic scale: C, C#, D. Such an increase of two semi-tones (or half-steps) is often called a whole-tone or whole-step. The notes of any scale, or selected notes of a scale are often generalized by noting or speaking in terms of whole-tones and half-tones rather than always use specific notes (such as C then D), numbers or frequencies. For example, this will allow a song to be easily transposed to another key. For a major scale:

1, 3 , 5 , 6, 8 , 10, 12, 13 : tone numbers of the chromatic scale
1, 2 , 3 , 4, 5, 6, 7, 8 : tone numbers of "major scale".
Fundamental or "Root" Tone, W, W, H, W, W, W, H : W = whole-tone or step
: H = half-tone or step

Knowing how to calculate the frequencies of the notes of a scale can be very handy for people such as computer programmers and some musical instrument designers and makers. Stringed instrument makers are often called luthiers, and the etymology (word source) of this word is derived from the stringed instrument called the lute.

From the study of physical science (physics), the "fundamental" or "natural" frequency of a vibrating string or wire can be calculated from the formula:

$$\text{Fhz} = \frac{1}{2\text{Lm}} \sqrt{\frac{\text{Tn}}{\text{M kg/m}}}$$

: Formula by **Marin Mersenne** (1588-1648) from France, a part of 'Mersene's Laws'. Similar types of equations were later developed by Christian Huygens for pendulum motion, and Isaac Newton for the laws of gravitation. He was also an associate of Galileo Galilei. Ts = 1 / Fhz = 1 / cps

L = Length of the string with meters (m) as the units of measurement

T = Tension (Force) applied to the string, and here it is essentially a "stretching" force.

Force = (mass of an object)(acceleration of an object) = ma. In simple terms, a force is the application of energy. The units of force are commonly newtons (N), 1N = (1 kg)(1 m/s^2) = (mass)(acceleration) = force

A force of 1N constantly applied to a 1K mass will accelerate (an increase in speed) it by 1 meter faster per second. Note that when a force being applied, there must be an acceleration or change, otherwise the force is not being applied. This force applied to a musical instrument string is usually adjusted by turning a tuning knob, and therefore adjusting the tension and natural (ie., "resonant", inherent) frequency of that string. Strings are subjected to some increased tension when pressing down on it to play a note, and the frequency heard could be slightly higher than expected. This is more noticeable on the thicker strings, and the design of the instrument may increase those string lengths so as to effectively reduce the frequency to the correct frequency. This concept is called something such as "bridge compensation" and "intonation". This may then create a problem that the "open" (unfretted) or full length string will have a note that is then slightly in error, and some instruments do consider this.

M = Mass of the string in kilograms per unit (meter) length. This is also called the linear or length density of the string. "Deep", "low" or "base" sounding stringed instruments usually have thicker and heavier (ie. more mass/length) strings so as to produce lower frequency waves and-or sound more efficiently. F is inversely related to L and M and directly related to T. The units of mass = M used here are (kg / meter of length = kg/m)

As a basic verification to the above formula, here is a derivation of a similar formula: Work = **Energy** = (force)(distance) = (f)(v)(t) = (Mass)(acceleration)(distance) = (M)(a)(d) = (M)(d/t^2)(vt) = (M)(d/t)(v) = (m)(v)(v) = mv^2 = m (d^2/t^2) = md^2 / t^2, and after dividing both sides by (d), we have: Force = md / t^2 , if we use M=m, and Tension for force we have: T = Md / t^2 , solving for t, we have: t = sqrt (Md / T) , and taking the reciprocal of time, we have frequency = = f = sqrt (T / Md) = sqrt (T / M Length)

Right now, we will be mainly interested in the relationship between the length of the vibrating string and frequency produced. These variables in the radical, for all practical purposes, will remain constant for a given situation, such as of a particular string. The radical factor (which resolves to a constant for our particular study here) can be completely eliminated since it is theoretically possible to have a tension of 1 newton applied to a string which has a mass of 1 kilogram per meter, and the square root of 1 is always 1. The formula is then reduced to just the fundamental (inverse) relationship of the frequency (f) and length (L) variables:

$$\text{Fhz} = \frac{1}{2\text{Lm}} = \frac{1}{t} \quad \text{solving for L:} \quad \text{Lm} = \frac{1}{2\text{Fhz}} = \frac{1}{2\,\frac{(1)}{(t)}} = \frac{t}{2} \quad \text{and} \quad t = \frac{1}{\text{Fhz}} \;:= 2\text{L} \text{ for this string where } \text{T=1N and M=1kg/m}$$

Clearly, frequency and length of the string are mathematically inversely related. In general, each is half (1/2 = 0.5) the reciprocal of the other. If Lm increases by a factor of (n), F will decrease by that same factor (here a divider) of (n) and which would be the same as multiplying by the reciprocal of (n) or (1/n).

A stringed musical instrument maker or player can alter the note (ie. frequency) heard by effectively shortening the length of the vibrating portion of the string. As indicated in the formulas above, this will increase the frequency of vibration and the tone heard will be "higher". This is usually accomplished by the stringed instrument players by using their finger(s), or a combination of a fret and finger as for fretted guitars and bases. A fret is an aid so that the note (ie. string length and frequency) is always the same regardless of slight position or finger misplacement, and therefore making the instrument easier to learn and-or use (ie., "play"). In the sketch below, the nut and bridge hold, fix, set, bound and define the ("open", longest, "unfretted", "natural" or "initial") specific length of the string allowed to vibrate.

Below, the numbers indicate the position of the frets and notes in a chromatic scale beginning at 0 as the note produced by the entire string. A violinist will try to position and hold their finger in these locations, but for fretted instruments such as guitars, the player will position and hold their fingers anyplace between the previous fret and the desired notes corresponding fret so as to allow the fret to physically set the proper string length for the note. [FIG 60]

```
                                                                                       string
Fret  0        1         2        3        4       5       6      7      8     9    10  11 12       .   .   .            |
     o-|----------|-----------|----------|---------|--------|-------|-------|------|-----|-----|----|---|----  - - - - - - - - - - - - - -  ---------------|-o
       |                                                                                  |                                                  /
     Nut                                                                             Half length                                         Bridge
```

Using the formula for R given above, we can calculate the frequencies of the notes in a scale and see where each fret (or finger as for unfretted instruments such as for violin-like instruments) should be placed using the length formula.

If the fundamental or "natural" frequency of the entire string is set to 262hz (which happens to be the usually defined frequency associated with the "standard" C note):

Note	Frequency (hz)	String Length (m) = 1 / (2Fhz)	
C	262	0.001908396	The higher the note frequency, the shorter the string length:
C#	277.5793306	0.001801286	: C# = (C)(R) = CR^1 = (262hz)(1.059463094) ~= 277 hz
D	294.0850565	0.001700188	: D = (C#)(R) = (CR^1)(R) = CR^2 ~= 294 hz

Taking the ratio between the string lengths of successive notes, we find a constant ("geometric") ratio and relationship: successive notes and string lengths:

$$\frac{\text{C\# length}}{\text{C length}} = \frac{0.001801286 \text{ m}}{0.001908396 \text{ m}} = \mathbf{0.943874313...}$$

: **Fret Size Ratio = FSR** (of the distance length, size or space between successive frets, and is also the **ratio of string lengths of successive notes** of the standard 12-note chromatic scale)

$$\frac{\text{D length}}{\text{C\# length}} = \frac{0.001700188 \text{ m}}{0.001801286 \text{ m}} = 0.943874313...$$

Hence, given a string of length L, at the first fret where the next successive note of the chromatic scale is located, the ratio of this string length to the previous notes string length should still be 0.943874313.

If the (open or unfretted) string or entire possible "scale length" is 25 inches, the length of the string where the first fret should be placed is:

$$\frac{\text{Length of string at Fret 1}}{25\text{inches}} = 0.943874313 \qquad \text{algebraically:}$$

Length of string at Fret 1 = 0.943874313(25in) = 23.59685783in

Hence the difference in string length, or the fret size (length or space) for the next note on that 25in long string is:
25.0 in - 23.59685783 in = 1.403142175 in :first fret size

Due to the constant ratio of successive string lengths of successive notes, their is a constant ratio between successive note or fret positions. The length of string between those two successive notes is also known as the "fret size" to musical instrument makers. Given just a fret size, the distance to the next successive fret, and so on, can be calculated without knowing or calculating the frequencies of notes and their string lengths. For example, once the first fret size has been calculated for a length of string, the next fret size and others can be calculated from that.

$$\frac{\text{second fret size}}{\text{first fret size}} = 0.943874313$$

second fret size = 0.943874313 (first fret size) Using the above value for the first fret size for a 25.0 in string:
second fret size = 0.943874313 (1.403142175in) = 1.324389856 in

Likewise, the size of the third fret can be calculated using the size of the second fret:

third fret size = 0.943874313 (second fret size)
third fret size = 0.943874313 (0.943874313 (first fret size))
third fret size = 0.943874313^2 (1.324389856 in.) = 1.250057565 in.

Finding all these fret sizes can be done quickly with either a computer with this equation programmed into it, and-or with a calculator. Since many calculators retain the last input "function" or operation (here, multiplication), it is simply a matter of pressing the "equals" or "enter" key so as to find the next successive result (here, fret size) of using the last displayed result or "output value" as the operand of that same function.

Notice that in order to calculate the (n)th fret size, that the exponent of the FRET SIZE RATIO (FSR) is one less than the (n)th fret size in question, and that the first fret size for a given string length or "(complete, possible) scale length") can be used as a constant factor for successive fret sizes. Expressing this in a formula:

Fret Size n = (1st fret size) FSR^(n-1) = (1st fret Size) 0.943874313^(n-1) : **Fret Length (size, space) Formula.**
1st fret size = (FSR)(string length)

Incidentally, and very conveniently, note that FRET SIZE RATIO = 1/(Note Ratio) = 1/NR , and this is verified below where NR is the ratio of the frequencies of successive notes in the standard chromatic 12-note (per octave, or frequency doubling) scale:

Letting L2 be the string length of the next higher note in the chromatic scale, and produced on a string of length L1:

$$\text{FRET SIZE RATIO} = \frac{L2}{L1} = \frac{\frac{1}{2(F2)}}{\frac{1}{2(F1)}} = \frac{2F1}{2F2} = \frac{F1}{F2} = \frac{F1}{F1(R)} = \frac{1}{(NR)}$$

$$\text{FRET SIZE RATIO} = \text{FSR} = 0.943874313 = \frac{1}{1.059463094} = \frac{1}{NR}$$

: **FSR and NR are reciprocals of each other**.
: NR = ratio of frequencies of successive notes

NR = Note Ratio = 1.059463094 = the ratio of frequencies of successive ascending notes in the chromatic scale. This value is slightly greater than 1, and the frequencies and tones heard of the next successive note is higher. NR is essentially the frequency ratio (FR) of successive notes.
NR = (next note frequency in the chromatic scale) / (note frequency) . NR =~ 1.06 =~ 1 / 0.94

FSR = Fret Size Ratio = 0.943874313 = Ratio of successive fret spacing sizes or string lengths of successive notes in the chromatic scale. This value is slightly less than 1, and as the fret size spacing and string length get shorter, the frequencies and tones heard of the next note are higher due to NR being greater than 1. FSR can also be called a "Fret Scale Ratio". Wind or "pipe" instruments also have corresponding note and pipe lengths based on FSR.

Since NR > 1, each note or frequency will increase in value, and this is an ascending or increasing series or steps.
Since FSR < 1, each fret length will decrease in value, and this is a descending series or steps.

Ex.	Chromatic Scale #	Note Name	Major Scale #	Ex. Frequency in hertz = cps	F ratio F/F1	Fractional or Relative Value Of The Total String Length = L , From Bridge	Fret #
	1	C	1 (root)	F1 = 262	1.0	1.0 L = 100% of L = full string length	0 (open string)
	2	C#		278	1.06	0.943874313 L ~= 0.95L	1
	3	D	2	294	1.12	0.890898718 L ~= 0.90L	2
	4	D#		312	1.19	0.840896416 L ~= 0.85L	3
	5	E	3	330	1.26	0.793700527 L ~= 0.80L	4
	6	F	4	350	1.34	0.749153530 L ~= 0.75L	5
	7	F#		370	1.41	0.707106782 L ~= 1 / $\sqrt{2}$ ~= 0.70L	6
	8	G	5	392	1.5	0.667419928 L ~= 0.65L	7
	9	G#		416	1.58	0.629960526 L ~= 0.63L	8
	10	A	6	440	1.68	0.594603559 L ~= 0.6L	9
	11	A#		466	1.78	0.561231026 L ~= 0.55L	10
	12	B	7	496	1.89	0.529731549 L ~= 0.53L	11
	13	C	8 (octave root)	524	2.0	0.5 L : half the string length = 50% L	12

Extra: Also note that the 13th note of the chromatic scale is twice the frequency of the 1st note, and the 7th note is $\sqrt{2}$ times the frequency of the 1st note. At the 13th note of the chromatic scale, the string length is half of the length of the string, and that 0.5L is equal to (0.707106782)^2 L as of the 7th note in the chromatic scale The frequency of the 8th note of the chromatic scale is equal to the average of the 1st and 13th note which has twice the frequency as the 1st note. Note also that 0.707106782 = Sin and Cos of 45 degrees and is located in the center of the octave or scale in terms of the number of half-steps.

The 6th note frequency of F6 is: (F1) + (F1 / 3)
The 7th note frequency or F7 is: (F1) 1.414213562 = F1 / 0.707106782
The 7th note frequency or F7 is: (F13) (0.707106782)
The 8th note frequency or F8 is: (F1) + (F1 / 2) = (F1 + F13) / 2

As seen in the above chart, many of the frets are spaced at a difference of 0.05L., except that between 0.5 and 0.55 or 0.56, there is also 0.53, and between 0.6 and 0.65 or 0.66, there is also 0.63. This could be 0.6 called a "5-hundredths rule", and may be used for quick calculations with reasonable results.

For reference, one-sixteenths of an inch = 1in / 16 = 0.0625 in , and this is slightly greater than 0.05.

Given a frequency number, Fn, then: F(n+6) = Fn (1.4142135562) , then mathematically:
F(n-6) = Fn (0.707106782)

When marking where the frets should be placed onto the fretboard, measure the length(s) in the **middle of the fretboard**., and this itself may be a topic for a disscussion amongst luthiers since the outer strings will have slightly longer fret spacings, and also knowing that the nut and the frets are set to be parallel to each other.

The most common scale and-or string lengths are: 24.75", such as for many guitars by the Gibson guitar co., and the 25.5", such as by the Fender guitar co. and Martin guitar co. A short scale guitar has a string length of 20" to 24". A short scale bass guitar, such as the Hofner co., violin shaped electric bass guitar is said to have a 30" scale length, and the neck feels somewhat like a standard electric guitar neck. A Fender Co. style Precision Bass and-or Jazz bass has a 34" scale length. A recent and helpful discussion about playing guitar and music notation was placed near the end of this book, and for luthiers, it includes the fret spacings of some common scale sizes.

There are various inexpensive kits available for many instruments, particularly for the electric guitar and electric bass guitar, and of various scale lengths. Some relatively inexpensive "guitar packages" often include a small amplifier and cord (plug) to it, and some may include a pick(s) and some type of guitar tuner (audio, sound) device. If a guitar tuner is not included, some audio players can generate tones at a desire frequency, and-or some computer and-or phone apps, and videos have some reference notes and-or tuning available. A metal tuning fork is low tech, but is reliable. A note played on another tuned instrument can be utilized as a reference note so as to tune other instruments.

EXAMPLES OF CHANGING THE PERCENTAGE OF A SUBSTANCE IN A MIXTURE

Ex. If a bleach solution for household use is noted as being 6% chlorine bleach per volume (say 1 cup of volume = 8 fluid ounces (fl. oz) of that solution is being used for this example) and it is diluted (ie., combined with, and will reduce a value) with 1 cup of water, what percent of that total mixture or solution will be chlorine bleach?

Since plain water substance is being added into this volume of solution, it will reduce or dilute the percentage of any other substance (here chlorine bleach) in that total volume.

6% chlorine bleach of 1 cup or 8 ounce is: 8oz (0.06) = 0.48 oz of each cup is chlorine bleach

Total volume of the mixture or solution = 1 cup of bleach solution + 1 cup of water solution = 2 cups =
= 8oz + 8oz = 16oz

This 16 oz of solution still contains only 0.48 oz of chlorine bleach, and the percentage of bleach in this total solution or mixture is:

$$\frac{\text{0.48 oz chlorine bleach}}{\text{Total mixture or solution}} = \frac{\text{0.48 oz}}{\text{2 cups}} = \frac{\text{0.48 oz}}{\text{16 oz}} = 0.03 =$$

3% of this mixture is chlorine bleach, regardless of the volume used. "a 3% solution of chlorine bleach". (Total mixture) must be > 1 unit volume.

Note, the total mixture contains: 2 cups = 1 cup of bleach solution + 1 added cup of water .

This formula will also work if the reference volume, here cups, is some other reference volume unit such as a for example 1 to several fluid ounce measuring cup, and where the bleach solution will still be 6% per that volume.

We can create an equation for the number of total number of (generic, non specific in size) volume units of solution needed so as to create a solution with a desired percentage (or dilution) of the chlorine bleach:

$$\frac{\text{6\% chlorine bleach per unit volume}}{\text{Total mixture solution in volume units}} = \text{Desired percentage in total volume},$$

from this, we mathematically have:

$$\text{Total mixture solution in volume units} = \frac{\text{6\% chlorine bleach per unit volume}}{\text{Desired percentage in total volume}}$$

Here, 1 volume unit will from the original 6% chlorine bleach mixture, and the amount of water to add into this solution will be = (Total mixture solution in volume units) - (mixture solution of 1 unit volume). The desired percentage in the total volume must also be 6% or less, since all the solutions will be a diluted ("thinned", less of a percentage of chlorine bleach) solution.

Ex. 6 units of total volume = 6% solution / 1% desired solution , : hence add (6-1)units = 5 units of water so as to create a 1% chlorine bleach solution

Rather than always use 6%, the above formula can even be made more generic or useful by using a variable such as P for the % of the substance in the original or given undiluted volume. Pharmacists and chemists use similar formulas. For the formula use entire and generic volume units, rather than a specific volume such as 8 fluid ounces. Later, you can then convert each volume unit to its actual associated units.

Extra: Volume is a different concept than weight. Fluid ounces is a measure of volume (ie., space having length, width, and height, hence a 3 dimensional structure or shape such as a cube) with units called a fluid ounces (fl. oz. = volume ounce), because 1 ounce unit of weight of water was defined as having a volume of 1 fluid ounce. 1 fluid ounce of other substances or elements will weigh more or less per unit volume. For example, liquid lead or liquid mercury weighs much more than 1 fluid ounce of liquid or fluid water, yet their volumes are still the same at 1 fluid ounce. In general, fluid ounces should not be considered as the corresponding weight of the substance unless it is water.

Ex. This example is more advanced and may be skipped over by new readers. A certain mixture or solution consists of two substances, let's say substance A and a substance B. Given a mixture where 5% of it is substance A, make the mixture to where only 3% of it is substance A. Given this data, the other substance(s) (here, substance B) in the mixture must then comprise (100% - 5%) = 95% of the solution. Substance B might be water, and if we dilute (ie. add in another substance or ingredient so as to reduce the percentage of some other substance(s) in the mixture) the mixture with some more water, the net percentage of the mixture that is substance A can effectively be reduced. In a way it could be said that substance A will be diluted, lessened or weakened, in the mixture. This method was chosen to be done here since any amount of substance A cannot be easily or cheaply removed from this specific mixture, and it is faster to just add more water to effectively decrease the percentage of A in it. Note that this is only a reduction of A's percentage of the entire mixture, and not a reduction of the specific volume, weight or amount of A, since this same volume or amount of substance A will still be in both (starting and final) mixtures since no amount of A will actually be removed or taken out of the mixture. If A was one gram or ounce in the starting mixture, there will still be one gram or ounce of A in the final mixture. The amount (ie., mass) of substance A per unit (of) volume and-or weight will decrease. Once the percentage, or "**concentration** (in the mixture)" of A is effectively reduced to 3% of the mixture, the amount of substance B will then comprise (100% - Substance A %) = (100% - 3%) = 97% of the solution, hence more of the mixture will then be substance B.

Let's look at several mathematical concepts and solutions:

Though we can solve the problem above with just the data given, it can help if we give a value to the starting quantity or volume of the mixture. Lets say the starting volume was 1 liter = 1L = 1000cc , (1cc = 1cubic centimeter and weighs 1 gram if the substance is water). 5% of this 1000cc mixture is substance A:

$$\frac{\text{volume A}}{\text{total volume}} = \frac{\text{volume A}}{1000\text{cc}} = 0.05 \qquad \text{therefore:}$$

volume A = 0.05 (1000cc) = 50cc : 50cc = amount of substance A (in both the starting and final mixtures)

We know that this 50cc value will become only 3% of the final diluted solution or mixture of:
(starting amount + added in dilution amount) = (1000cc + Xcc) Xcc is the (unknown for now) amt. of water to add in to the mixture so as to dilute, lessen and-or weaken the amount of substance A in it. Expressing this in an equation:

$$\frac{50\text{ cc}}{(1000\text{cc} + X\text{cc})} = 0.03 = 3\% \qquad \text{therefore, mathematically:}$$

$50\text{cc} = 0.03\,(1000\text{cc} + X\text{cc})$ using distribution:
$50\text{cc} = 30\text{cc} + 0.03\,X\text{cc}$ transposing 30cc:
$20\text{cc} = 0.03\,X\text{cc}$ after Dividing both sides by 0.03 to isolate Xcc:

$X\text{cc} = 666.6\underline{7}$: the amt. of water to add into the entire mixture
Note that this is a relatively (with respect to 1000cc) large amount of water needed to effectively reduce A's percentage or "concentration" by just a few (here 2) percent from 5% to just 3% of the entire mixture.

1000cc + 666.67cc = 1666.67cc : total volume of final mixture

5% of 1000cc = 50 cc : amount of substance A in the original or starting mixture
3% of 1666.67cc = 50cc : A's percentage or portion of the entire new mixture is now reduced, yet the physical amount of A in the new mixture remained the same.

95% of 1000cc = 0.95 (1000cc) = 950cc : amount of substance B (water) in the starting mixture
97% of 1666.67cc = 0.97 (1666.67cc) = 1616.67cc : amount of substance B (water) in the final mixture

Also: starting B + added B = ending B

950cc + 666.67cc = 1616.67cc : total volume amt. of water in final mixture

New amt. of substance A + New amt. substance B = New amt. of total mixture
50cc + 1616.67cc = 1666.67cc

Now we will look at some various other ideas and solutions, in particular, using fractions for the percentages:

A's volume in starting mixture = A' volume in ending mixture

100%A = 100%A : A's physical volume or amount is the same in both the starting and ending mixtures.

$(0.05)(v1) = (0.03)(v1 + x)$: v1 is total starting volume, x is amt. to add to total volume. Notice that in order to keep this equation in balance, as one factor decreases (here 0.05 decreased to 0.03), the other factor to that total decreased value must increase (here, v1 increases to (v1 + x)).

We could assign or let v2 = (v1 + x) = ending volume:

$(0.05)(v1) = (0.03)(v2)$ Solving for v2 we would get: v2 = 1.667v1.
Note here the "reverse ratios": (v1 / v2) = (0.03 / 0.05)
If we let v1=1=100% of the whole or initial starting volume, then x essentially becomes the percent increase in volume:

$(0.05)(1) = (0.03)(v2)$ solving for v2:

$$v2 = \frac{(0.05)(1)}{0.03} = 1.66\underline{7}$$

: hence the starting volume must be increased by this factor, where: $v2/v1 = 1.66\underline{7}/1 = 1.667 = 166.7\%$, also:

$(0.05)(1) = (0.03)(1 + x)$ solving for x:

$0.05 = 0.03 + 0.03x$
$0.05 - 0.03 = 0.03x$

$0.02 = 0.03x$

$$x = \frac{0.02}{0.03} = 0.666\underline{7}$$

v2 = v1 + x   Using relative or percentage values:
v2 = 1 + 0.6667   : x = 66.67% increase from 1 = 100%
v2 = 1.666$\underline{7}$: v2 = 166.67% the volume of v1

If we knew the volume of A as 1 (fluid) ounce = 1oz:

A = 1oz = (0.05)(v1)   : v1 = volume 1, the initial or starting volume before adding any water. Mathematically:

v1 = A / 0.05 = 1oz / 0.05 = 20oz   In the final mixture, A is also:

A = 1oz = (0.03)(v2)   :v2 = volume 2, the initial or starting volume plus the added water volume
v2 = (v1 + x),   v2 = the ending volume

v2 = A / 0.03 = 1oz / 0.03 = 33.3333   hence:

1 oz = A = (0.05)(20oz) = 0.03(33.3333oz)   : A is 1 oz in both the starting and ending mixtures. Mathematically:

$\frac{33.3333}{20.0}$ = 1.6667   : ratio of ending mixture to starting mixture   hence:

33.3333 = 20 (1.6667) = 20 (1.0 + 0.6667) = 20 + 20(0.6667) = 20 + (a change of 66.67% of 20)
= (starting volume + (66.67% of starting volume))
= 1.667 (starting volume)

From: starting volume + added volume = ending volume

ending volume - starting volume = added volume

33.3333oz - 20oz = 13.3333oz   : extra water to add into the mixture so as to dilute it. For a more general (algebraic) formula:

From: v2 = v1 + water added into the mixture

v2 - v1 = water added into the mixture
v1(1.667) - v1 = water added into the mixture   : from v2/v1 = 1.66$\underline{7}$, hence v2 = 1.667 v1
Factoring v1 from each term:
v1(+1.667 - 1)
v1(0.667)   Formula for the amount of water to add into the mixture for similar problems with various starting volumes of the same starting mixture with 5% substance A, and 95% substance B (water), so as to have a 3% substance A in the mixture:

v2 = v1 + v1(0.6667)   : ending volume for the 3% solution or mixture only , or:

v2 = v1 + v1(1 - (starting percent A / new percent A))   : Formula only for lowering percent A by adding in water. Percent A cannot be increased by adding in water, but only by adding in more A and-or removing water, but removing only water with A already dissolved in it may not be practical or easy. To increase A from 3% to 5%, simply add in (5-3)% = 2% of the total amount of water volume or weight in the mixture.

The concept of proportions will not work for the problem or example above, basically since we are not making a similar mixture or construction with the same proportions or fractional parts of substances. Substance A will be 5% in one mixture or construction, and only 3% in the ending mixture or construction being made. The percentage of water in both mixtures is also a different value. Whereas one percentage (here, of water) will increase, another percentage (here, substance A) will effectively decrease and this is not a direct mathematical relationship but an inverse mathematical relationship. Also, whereas the physical amount (here, volume) of water increases, the total physical amount (volume) of substance A remains the same in both (non-mathematically similar, or non-proportional) mixtures or constructions.

This below was briefly mentioned above, and will be mathematically explained further here:

Consider for example that: 2 is 2% of 100 and 2 is 1% of x

The solution to this considers that to keep the same value (here 2) but only reduce the percentage that is of the whole or total, then the whole or total must be increased. This is an inverse mathematical relationship.

$2 = 2\%$ of $100 = 1\%$ of x : here 100 is the starting quantity or "whole entire value". This can be expressed as:

$(0.02)(100) = (0.01)\,x$ this can be expressed as two equivalent and inverse ratios: solving for x:

$\frac{0.01}{0.02} = \frac{100}{x}$ in pseudo: $\frac{\text{(new percent)}}{\text{(old percent)}} = \frac{\text{(old total)}}{\text{(new total)}}$: notice the "inverse" ratios

$x = \frac{(0.02)}{(0.01)}100 = (2)100 = 200$: the percent ratio decreased by a factor of (0.02/0.01) = 2, and the whole value increased by that same factor of 2. Or in other words:
(0.01/0.02) = 0.5 and the reciprocal of 0.5 is: (1/0.5) = 2
The percent was multiplied or "increased" by a factor of 0.5, and the whole value was multiplied or "increased" by the reciprocal of that factor = 1/0.5 = 2

Here are some common cooking examples involving percentages:

Ex. A recipe for a certain type of bread requires 1/4 = 0.25 = 25% of the total flour mixture to be whole wheat. This can be easily done by using 3 measurements (scoops, cups, bags, etc) of white flour, and 1 of the same measurement of whole wheat. This will create a flour mixture with a total of 4 measurements, and with 1/4 being whole wheat flour. 1/4 could be thought of as 1 part being whole wheat of 4 total parts. If the recipe was for 1/3 = 0.33 = 33% of the flour mixture being whole wheat, for each 2 measurements of white flour, use 1 measurement of whole wheat flour. 1/3 could be thought of as 1 part being whole wheat of 3 total parts. For a 1/5 = 0.20 = 20% whole wheat mixture, use 4 measurements of white flour, and 1 measurement of whole wheat flour which makes 1 part of the 5 total parts. For a 1/10 = 0.10 = 10% of the whole mixture, use 9 measurements of the main ingredient(s) and 1 measurement of the ingredient that will compose a 10% of that entire mixture.

Ex. A recipe states to use 2 and 1/4 cup flour = 2.25 cups of flour. If you decide to use 25% = 1/4 of the total flour mixture with whole wheat flour, how much whole wheat flour will you need, and how much regular white flour will you need?

whole wheat flour = 25% of the total flour mixture
whole wheat flour = (0.25)(2.25) cups
whole wheat flour = 0.5625 cups

total flour = white flour + whole wheat flour
2.25 cups = white flour + 0.5625 cups
white flour = 2.25 cups - 0.5625 cups
white flour = 1.6875 cups

Since 25% is whole wheat flour, the remaining portion: (100% - 25%) = 75% is white wheat flour:

(amount of white wheat four) / (total amount of flour) = 1.6875 cups / 2.25 cups = 0.75 = 75% : checks

(0.5625 cups) x (8oz/1cup) = 4.5 fl. oz (dry, equivalent, fluid volume) white wheat flour
(1.6875 cups) x (8oz/1cup) = 13.5 fl. oz (dry, equivalent, fluid volume) whole wheat flour

Ex. If you have 15 cups of regular white wheat flour, how much whole wheat flour would you need to add or combine to that amount of white wheat flour so as to create a flour mixture that is 1/3 = 0.3333... = 33.3% whole wheat flour. Two methods will be shown to solve this problem.

First note that it is a common, but incorrect, thought to simply calculate the amount of whole wheat needed as just 33% of 15 cups:

(0.3333)(15 cups) = 5 cups : nice try, but it is the incorrect amount of whole wheat

The correct amount requires a different calculation:

$$\frac{\text{Z cups whole wheat}}{\text{(X + Z) total cups}} = 0.3333 = \frac{\text{Z cups whole wheat}}{\text{X cups white wheat + Z cups whole wheat}} = \frac{\text{whole wheat cups}}{\text{15 cups white wheat + Z cups whole wheat}}$$

0.333 (15 cups white wheat + Z cups whole wheat) = Z cups whole wheat
5 cups white wheat + 0.333 (Z cups whole wheat) = 1 (Z cups whole wheat) : Consider: 1 = 100%
5 cups white wheat = 1 (Z cups whole wheat) - 0.333 (Z cups whole wheat)
5 cups white wheat = 0.667 (Z cups whole wheat)

5 cups of white wheat / Z cups of whole wheat = 0.667 , mathematically using just the numbers in the ratio:

$$\frac{\text{5 cups}}{\text{Z cups}} = \frac{5}{Z} = 0.667$$ mathematically:

$$\text{Z cups} = \frac{\text{5 cups}}{0.667} = \text{7.75 cups}$$: use 7.5 cups of whole wheat in the mixture

(X + Z) total cups = X cups white wheat + Z cups whole wheat , (X + Z) = (15 + 7.5) = 22.5 :
22.5 cups = 15 cups + 7.5 cups

whole wheat / total cups = 7.5 cups / 22.5 cups = 0.333 = 33.3%

white wheat / total cups = 15 cups / 22.5 cups = 0.667 = 66.7% , The relative sum of portions of the whole (1) are:

% white wheat + % whole wheat = 0.667 + 0.333 = 1.0 = 100%

This problem can also be solved using: If 15 cups is to 66.7% then x cups is to 33.3%:

66.7% = 100% - 33.3% = 1.0 = 0.333 : Total % = % white wheat + % whole wheat , therefore:
% white wheat = Total% - % whole wheat = 66.7% = 0.667

$$\frac{\text{15 cups}}{0.667} = \frac{\text{x cups}}{0.333}$$, after solving for x: , x = 7.5 cups

Ex. A certain product for sale is a mixture of 60% of substance A, and 40% of substance B.
total mixture = substance A + substance B
total mixture = 100% (total mixture) = 60% (total mixture) + 40% (total mixture)

In decimal equivalent of these relative or percentage values, and regardless of the actual volumes, weight and-or mass used:

total mixture = 1 (total mixture) = 0.60 (total mixture) + 0.40 (total mixture)

If this mixture is then modified so that substance B is only 30% of the total mixture, how much water must be added into this total mixture to dilute it for this to happen. Let us call the water as substance C, and it is also possible either substance A or B is also water, but they might be other substances also.

Since an amount of water will be added into the total mixture the volume, mass and-or weight of the resulting total mixture will be more. The resulting volume will be larger, but still, in the relative sense, it can be considered as 100%= 1. Since substance C will now occupy some of that 100%, the percentages of both substance A and substance B in the total mixture will decrease.

Let us reduce the amount of substance A and substance B, by the same percentage in the mixture so that they then account for (100% - 10% due to substance C) = 90% being due to substance A and substance B in the mixture.

In the original mixture: B / A = 40% / 60^ = 0.4 / 0.6 = $0.66\underline{7}$, and we will try to preserve this ratio of B to A in the final mixture.

We will then have this formula and-or calculation for the mixture:

total mixture = 1 = 100% = A + B + C
100% = (< 60%) + (30% < 40%) + C

For keeping the same ratio (r) of: $\frac{B}{A} = r = \frac{0.30}{A} = 0.66\underline{7}$, $A = \frac{0.30}{r} = \frac{0.30}{0.66\underline{7}} = 0.45 = 45\%$

100% = 45% + 30% + C
100% = 75% + C , after solving for C, we have:
C = 100% - (A + B) = (100% - 75%) = 25% of the modified, final and-or new total mixture

New total mixture = 1 = 100% = A + B + C = 45% (total mixture) + 30% (total mixture) + 25% (total mixture).

Ex. If the original total mixture was 1L before adding in substance C, then A = (1000 mL)(0.60) = 600 mL and B = (1000 mL - 600 mL) = 400 mL. , The final volume = FV = (1L + C liters) = (1L + 0.25 FV) , then FV - 0.25 FV = 1L , then 0.75 FV = 1L , then **FV** = 1L / 0.75 = **1.333L** , **C** = (FV - Original Volume) = (1.3333L - 1L) = 0.333L = **333 mL** , checking: 0.333 / 1.333 = 0.25 = 25% , As an example for the volume of A, using a proportion or equivalent fraction: 0.25 / 0.333 L as = 0.45 / X liters , X = 0.6 L = 600 mL = A
A / FV = 600 mL / 1300 mL = 0.45 = 45% FV , also (45% < 60%)

Extra:. If the new total mixture is 1L = 1000 mL , then A = 450 mL , B = 300 mL , C = 250 mL : 1mL = 1 cc
A = (1000 mL) (0.45) = 450 mL

Extra: If the percent of substance A was to also remain the same at 60% in the new mixture then consider this for C:

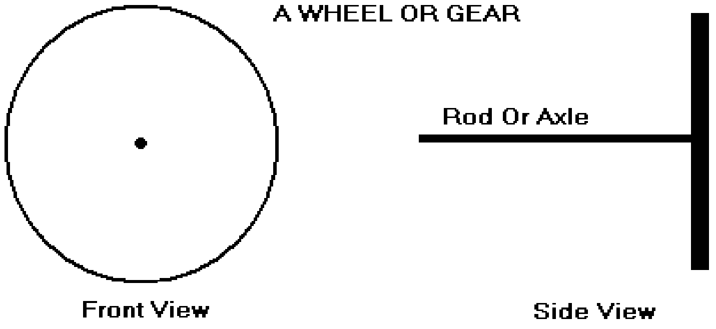
New total mixture = 1 = 100% = % being A + %B + %C = 60% + 30% + C = 90% + C =
C = (100% - 90%) = 10% , 1 = %A + %B + %C = 0.60 + 0.30 + 0.10

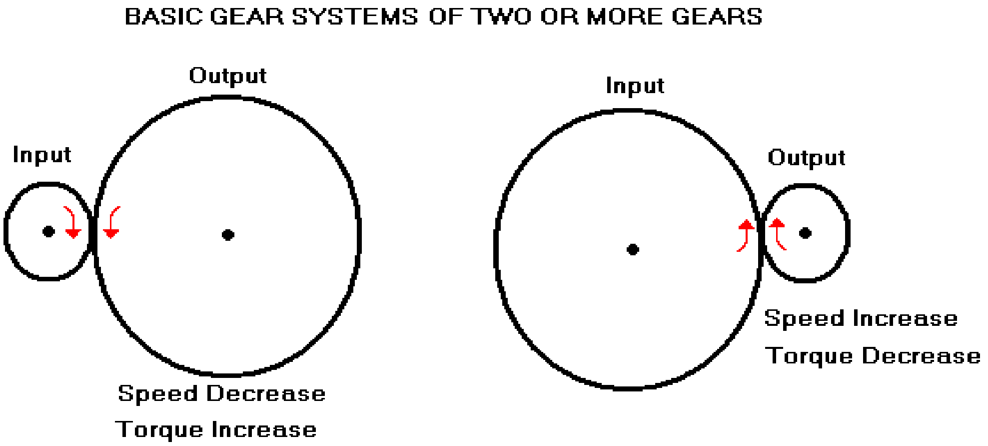
The ratio of B to A is then: 0.30 / 0.60 = 0.50 = 50% , and this is now less than 66.67%

Extra: If the percent of substance C was to be 15% , then : 1 = 100% = %A + %B + %C = A + 30% + 15% = A + 45%, and A is therefore: A = (100% - 45%) = 55% = 0.55 of (total mixture) , and B / A = 0.30 / 0.55 =~ $0.54\underline{5}$

GEARS EXAMPLE

This example and explanation will show how a simple gear system of two or more connected rotating gears or wheels of different sizes can be used to change the resulting rotational speed or the torque (a force that cause a turning or rotation about a point, hence torque is a rotating force or force of rotation) of one of those wheels or gears. The appendix also contains a few defined terms relevant to this example that you may optionally review if needed. [FIG 61]





The rod ("drive shaft" or connector) or axle is placed at the center of the wheel and can be used to hold the wheel in position for it to rotate with stability and efficiently, and-or to apply or transfer power (from elsewhere, perhaps a hand-crank or motor) to the wheel or gear so as it can rotate about it's center ("hub"). For a given rotational speed per unit of time, the larger the wheel and its circumference (ie., distance, length), the greater the distance a vehicle would travel per unit of time. It's also possible that the wheel can be used to apply power to the axle, such as in a water powered wheat grinding or saw mill. A large water wheel does not rotate very fast but it collects the high input force of the water to turn it, and this speed or revolutions per minute (rpm) of this can be changed later by using gears if needed.

Many vehicles have gearing to change the speed or torque of its wheel(s) so as to improve the vehicles movement in certain driving situations or needs. Many other machines also use some type of gearing to alter (change) the speed or torque of some moving part so as to improve it's usefulness and efficiency in some way.

A gear is much like a wheel, however the rim or edge of it has what is called the teeth of the gear, and these evenly-spaced rim protrusions are generally somewhat square and-or triangular in shape and allow efficient contact with another gear with the same size (but generally not necessarily the same number) and shape of teeth, and so as to transfer (via., contact and force) mechanical power from one to the other without slipping past each other like two wheels might. In general, the number of teeth on a gear is proportional to its size (ie., circumference, diameter, radius). The smaller each gear tooth is, the greater then number of teeth on the rim or edge of the gear and-or on the wheel. If the teeth are too small, there is a risk of gear slippage (non contact, lack of power transfer) and-or teeth wear due to friction (mechanical resistance due to the two parts [masses] and the forces in the opposite direction) and-or collisions. In general, the ratio of the gear teeth of two interconnecting or corresponding gears is the same as the ratio of their physical dimensions such as circumference, diameter and-or radius. The faster a gear spins or rotates also increases the amount of wear per amount of time and-or revolutions of it and it will then need to be replaced.

Gears or wheels of the same or different sizes (ie., due to their radius and-or circumference values) can be used to mechanically (ie., a force due to the energy of a mass and motion or movement (ie., a velocity), and then contact) transfer an input power from one to the other, and this could be described as the gears or wheels being like mechanical energy transferers (ie., like a mechanical circuit, linkage, conveyors) and-or "transformers" in terms of any torque and speed changes. Torque (rotating or twisting force) can be increased at the cost (loss, trade-off, "price") of reduced speed of the output gear. Rotating speed can be increased at the cost of reduced force (torque) at the output gear. Either way, nearly all the energy or power put into this system is "conserved" or maintained, that is, the energy just doesn't disappear, but nearly all of it is transferred from one gear to the other. No system is perfect and some small fraction of the available energy or power will be lost due to friction (surfaces in contact with each other while in motion, a resistance to motion), vibration, heat, sound, etc. This will reduce kinetic energy to the output, and therefore motion. For our basic analysis, here of a simple wheel or gear system, we will not consider these small losses. If the two gears are of the same diameter, radius and-or circumference, then there will be no increase or decrease in either speed or torque, and the gears are used to just transfer power from one location to another.

A wheel and **axle** (ie., the rod a wheel or gear can spin or rotate about, much like a perpendicular axis to the plane or disk of the wheel) is a simple machine, and of which can be used to modify (increase or decrease) the input force so as to provide some "mechanical advantage". In general, a wheel by itself provides load bearing support, and if several are used such as for a cart or car, the load or weight being moved is then distributed to each wheel. Wider wheels will have more surface area and will make less pressure (= F / A) on a surface, and this helps prevent the wheels and-or load from being stuck into soft surfaces such as soft dirt and-or gravel, and where much energy will then be wasted due to this type of friction and-or impedance to then overcome by additional force. Wider wheels will distribute the weight of the load to a wider area of which the wheel is moving upon.

Since steel metal is very hard, a drill-bit will need a high torque or force to be able to cut and drill through the metal. A "power drill" or "power driver" will likewise need a high torque or force so as to be able to place (ie., "twist") in or remove a screw from wood. In both cases, gears will be used to convert a high rotational speed from an electric motor into a slow rotational speed, but with a high output torque necessary for the situation.

Energy Out = Energy In or Power Out = Power In
100% = 100%
1 = 1

: Energy is the ability or potential to do work.
A common unit of energy is a joule (J).
Power is a measure of work done over a time, hence it is a measure of the energy used up or transferred over time so as to get the work done. A common unit of work is therefore:
joules (J) per second = J / s = Watts, hence 1J = 1Ws

If the (mechanical, power transfer) system of wheels or gears has a torque magnification factor = x, then the corresponding speed magnification factor is the reciprocal of this value = 1/x, and vice-versa. This will be verified below.

Using up or transforming energy is called work, and both energy and work have the same units of joules since energy = work, and-or energy used = work done   Power is the total amount of energy or work used during an amount of time. Power is a (average) rate of using energy and-or doing work (using energy). The units of power are **joules per second** which is also called watts (w). In terms of torque, power (Pw) = torque x rotation speed. The S.I., System International or International System (ie. metric) units of force are usually called **Newtons**, and the units of power or energy used, applied or needed is: **Newton-meters (Nm)**, hence a measure of **force** applied through a distance. Below, we see that in the equation of input and output power, or power transfer, that torque and speed are mathematically inversely related for a given (fixed, constant) amount of Power. Note that even though they are inversely related, they are generally not mathematically reciprocal in value to each other. Only the "magnification factor" of the ratio of the two torque values, and the "magnification factor" of the ratio of the two speed values, are mathematical reciprocals. For each input and output wheel or gear, the available power (P) is the same value:

P input gear = P output gear : with conservation of energy, P input / P output = 1

(input torque)(input speed) = (output torque)(output speed) :speed =angular velocity =w= radians per second
1 rev / s = (2)(pi) rads / s ,
revs = revolutions or rotations of the wheel
Speed can be thought of as a faster application
of a force or torque per time, hence more
energy being applied per unit of time,
and power = energy / time

For a constant or given amount of power, torque and speed are reciprocals.

Clearly, and strictly mathematically, to keep the equation in balance, if the value of one variable (ex. torque) is to be increased (by a multiplying factor) on one side of the equation, the other variable (here a multiplying factor, ex. the speed) on the same side of the equation must then be decreased (ie. divided by that same factor value) so as to keep both sides of the equation in balance and also have conservation (ie., same net sum of input and output values, no loss, maintain) of energy. Mathematically, from the equation we have these ratios:

$$\frac{\text{input speed}}{\text{output speed}} = \frac{\text{output torque}}{\text{input torque}}$$

: = same "magnification or gain factor" or
ratio value of these inverse ratios or
proportions

Given two fixed (having a constant circumference) sized wheels or gears, the speed or torque can be altered (changed, increased or decreased) in the output gear when it's size is not the same size as the input gear. If the size of the output gear is less or is decreased, it's speed (revolutions per second, rotation or angular speed, or velocity) will increase.

Without knowing the specific value of the applied forces (torque) or speeds of any gear, we can calculate the corresponding magnification or "gain factor" in either the speed or the torque by knowing the size of the two gears and calculating their ratio (ie., the mathematical relative, fractional, or portion of one with respect to the other). For gears and wheels, and considering speed and torque, the size value is either the circumference, diameter or radius of the gears. Given two gears or wheels, the ratio (r) of the corresponding values chosen will be the same as any other corresponding values chosen:

$$\frac{\text{circumferenceA}}{\text{circumferenceB}} = \frac{\text{(2)(pi)(radius A)}}{\text{(2)(pi)(radius B)}} = \frac{\text{radius A}}{\text{radius B}} = \frac{\text{(pi)(diameterA)}}{\text{(pi)(diameterB)}} = \frac{\text{diameterA}}{\text{diameterB}} = \text{size ratio of two circles, wheels and-or gears}$$

When a larger sized input gear is applying power (ie. force, torque) to a smaller sized output gear, the smaller gear will then rotate more (per unit time), and to help understand this, consider that a point on its circumference must and will travel and equal the same circumference or distance length as that of a point that travels on the larger input gear when it rotates just once. Expressed another way, due to the "junction", "connection" or contact point at both wheels, both wheels will actually rotate the same amount of distance, point per point, along their circumference per unit of time, however with the smaller wheel or gear, that distance corresponds to a much larger central angle and its amount of degrees. In short, when a larger input gear spins (ie., rotates) once, a smaller output gear will spin more than once. This also means that the smaller gear will rotate "faster" or more times per amount of a given time, hence its rotational or "angular" speed or velocity is more. [For a potential future reference, you may consider this equation: ¢2 = ¢1 (factor), and that this factor is equal to (C1/C2) or= (r1/r2) or= (d1/d2) , and mathematically: C1 ¢1 = C2 ¢2 , and: (¢1 / ¢2) = (C2 / C1) , which are "reverse ratios".].

Circumference = (pi) Diameter = (pi) 2 Radius = 2 (pi) Radius , and when given two wheels or gears:

larger wheel size / smaller wheel size = (x) = wheel size magnification factor of the larger wheel or gear. This value will be >1 when the numerator is larger.

therefore: (smaller wheel size) (x) = larger wheel size
or: (smaller circumference distance)(x) = larger circumference distance

Consider that 1 rotation is equal to the circumference length or distance, therefore:

(1 smaller distance)(x) = 1 larger distance

These distance values correspond to (whole or fractional) rotations of each wheel or gear:
(1 rotation of small wheel)(x) = many rotations of small wheel = 1 rotation of large wheel

Therefore, a smaller output wheel or gear will correspondingly rotate (x) times more or faster so that a point on it's circumference will travel a distance equal to a point traveled on the circumferences of the input gear or wheel. It will then be said that the speed (number of rotations or revolutions per second), also known as "angular speed or velocity" of the smaller gear (in this two wheel or gear system) is more (greater), and is sometimes, somewhat incorrectly noted as being "faster" (even though it, and-or a point on its circumference would actually travel the same (linear) distance as the larger gear or wheel would in the same amt. of time).

output speed / input speed = gain in speed : gain means a magnification, amplification or increase factor (from the input or start, to the output or end) and is expressed as a multiplier to the input to solve or determine the output value. It is also very possible that it is less than 1 (or < 1) such as when there is a reduced speed and-or torque gain at the output.

output torque / input torque = gain in torque Generally: gain in speed /=/ gain in torque , and these values are rather inversely related, and are generally not reciprocal in value to each other.

If the output gear is smaller, that is, it has a smaller radius (ie., lever arm) and circumference than the input gear, it's speed (of rotation) will be faster, and it's available torque (on its shaft, or perhaps to be applied to even another gear) will be less since the effective lever-arm (ie. its radius value) of that (smaller) gear or wheel is smaller. In short then, in a wheel or gear system, a smaller output gear will spin faster but have less torque.

A larger output gear will spin slower, but will have more torque because the effective lever-arm distance (ie. the radius distance) to the center of that wheel or gear is longer, and a force applied to a longer lever-arm will increase or magnify that force. Torque = Force x Lever-arm = (F)(L), and therefore has units of Nm. We see in this equation that the lever-arm distance is essentially a force multiplier. For example, at twice Lever-arm distance, the Torque will be twice as high. The magnification (of force, distance, and speed) is also mentioned ahead in this book in the analysis of vertical angles and the sides of such constructions in the topic of: A Simple Device To Measure Small Distances

As indicated previously, corresponding input and output speed and torque (T) values are generally not reciprocal in value for a gear or wheel system, however, the specific gain or magnification (factor value) in speed and torque are mathematical reciprocals of each other and they will always have a product of 1:

input power = output power : For torque situations: Power = P = (T)(v) = (F)(L)(v)
T = torque=rotational , amplified force at or about the axis of rotation, and F = linear force, L = lever arm or radius from the center or axis of rotation. v=velocity

(input torque) (input speed) = (output torque)(output speed) , mathematically:
(input torque) / (output torque) = (output speed) / (input speed)

(input torque) / (output torque) = gain in speed taking the reciprocal of both sides:
(output torque) / (input torque) = 1 / gain in speed or:

gain in torque = 1 / gain in speed : the gains in speed and torque are reciprocals

gain in torque x gain in speed = 1 **:** Torque and Speed Gain Relationship , and mathematically:
gain in torque = 1 / gain in speed = 1 / (input gear size / output gear size) , hence:

gain in torque = 1 / gain in speed = **(output gear size / input gear size)** : **gain in torque, by gear sizes**
gain in speed = 1 / gain in torque = **(input gear size / output gear size)** :**gain in speed, by gear sizes**

Ex. Given a rotating gear that has a certain amount of power (due to speed and torque) available, what should be the size of a connected gear so as the available torque in it is twice (double = 2) that of the input or source gears torque value?

Since specific values were not given, we will be working with generalized or relative values.

From: gain in torque = output gear size / input gear size

output gear size = (input gear size)(gain in torque) and for this specific example:

output gear size = (input gear size) (2) : the output gear size should be twice (2) the size of the input gear

Note that since torque in this specific system will be increased, that the associated speed will be decreased by the reciprocal of this gain (increase, magnification factor) in torque:

gain in speed = (1 / gain in torque) and for this specific example:

gain in speed = 1 / 2 = 0.5 : the rotation speed of the output gear will be half (1/2) of that of the input gear

If for example the speed of the input gear was 100rpm = 100 revolutions per minute of time, the output gears speed would be:

From: output speed / input speed = gain in speed mathematically:
output speed = (input speed) (gain in speed) or:
output speed = (input speed) (1 / gain in torque) and for this specific example:

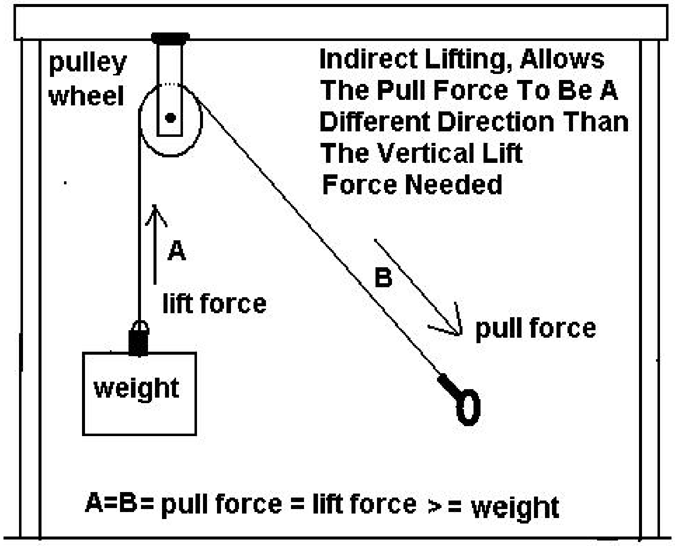
50rpm = (100rpm)(0.5)

It is possible that two gears or wheels of different size can be on the same rotating shaft or axle. They will both rotate at the same speed or angular velocity (ie., rotatonal velocity, ex. degrees per second) but a point on the circumference of the larger gear will have a greater linear velocity. This type of simple machine is much like a **pulley** described below, and is essentially the reverse of a wheel and axle system and where here, the input force or power is applied to the larger wheel rather than the smaller diameter shaft or axle. This system is sometimes often seen in some simple hand powered (ie. cranked, rotated, spun, turned [torqued]) machines that get water from a deep well more easily with less input force needed, but may also be seen in pulleys for raising objects up to a height, such as into a barn. This machine may be sometimes called a compound wheel system. The gain in input force is equal to the ratio of the radius of each wheel and is essentially like the ratio of two lever arms. The larger "input wheel" applies a larger torque upon the axle and-or upon any other smaller wheel on that axle. This system is often called a "wheel and axle" system.

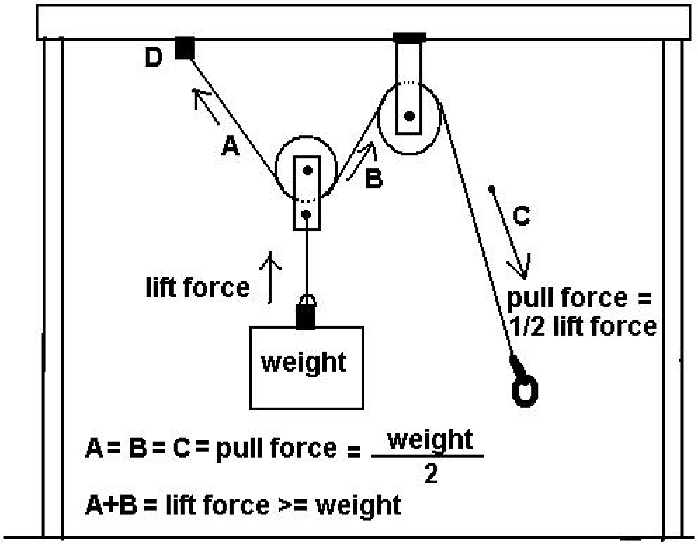
A common example where torque (force) will be increased mechanically is by pulleys (a rope or chain, and wheel system), and electric winches which contain an internal gear system so as to pull (apply force) heavy loads. A **pulley**, like a lever, is considered as a simple mechanical (force driven) machine that provides a "mechanical" or force advantage (ie., a greater output force than the input force) . A basic ("fixed") pulley consisting of just a wheel affixed to an above height and rope to apply ("pulled, tension) forces does not offer any mechanical advantage, but essentially changes the directions of the input and output forces, and the object is still essentially pulled, but in an upward direction instead of along the ground. See the figure below. Once an object is raised to a height, it can be set fixed at that height by "anchoring" the rope to the ground or to a heavy object. If the pulley wheel is not affixed to a height, and the object is affixed to the pulley on the rope, this pulley can still be used to lift the object to a height. One end of the rope is affixed to a height, and the other end is where the user can apply force. The advantage of this system is that anchored or affixed end of the pulley will support half the weight of the object being raised to a height. With a "compound pulley" or "movable pulley system" [also contains another pulley(s) non-fixed or movable along the rope or chain] with many pulleys working together, a larger portion of the object weight will be held by the pulley system and its fixed support, and therefor creating an improved mechanical advantage and making it even easier to lift an object, but requiring more distance and-and time by the user. The total work required to lift an object a height will still be the same as that without using a pulley, but it could be said that the work is easier and-or less stress on the body with the pulley:

Work In = (Force) x (Distance) = Work Out = (Force) x (Height) , since Distance = (Speed)(Time)
Work In = (Force) x (Distance) = (Force) x (Speed) x (Time)

Car mechanics can slowly lift a very heavy metal engine into and-or out of a car by using a compound pulley ("block and tackle" or "hoist") system. The input force applied and the speed of the object being raised is less, therefore the height will be achieved slower as the amount of time needed will increase. Essentially, if the input force is divided by (n = the "mechanical advantage" or force gain, multiplier or amplification), the length of time needed to raise an object to a height is increased by that same factor (n). [FIG 61A]



A Simple Pulley System Without Any Mechanical Advantage



A Pully System With A Moveable Pulley Where Half The Weight Is Supported At D

An **inclined plane** or "**ramp**" is another example of a **simple machine** that is said to provide "mechanical advantage", ease or gain. With a ramp a heavy object can be more easily (ie., less input force needed since the incline is now supporting some of the weight of the object, perhaps half of it) raised or lowered to an amount of height, but the path and its distance taken is longer than the height distance it is raised or lowered to and therefore the time needed is longer. A lever is another example of a simple machine.

Is the required or input energy less with a simple machine?

No, it will take the same total amount of energy or Joules to move an object to the same height. The input energy (J) and-or power (W=J/s) needed will be less per second and this helps the worker and-or machine which may have a "low power" and-or force ability, but when it is applied for a longer time, there is no actual saving of the total energy required and-or used. For example, 1 watt (ie., 1w = 1J/1s) applied for 10 seconds is a total of 10 watt-seconds, and this value is equivalent to 10 watts of power applied for 1 second. In both cases a total of 10 w-s of energy or= 10 Joules (1J = 1w-s) of energy were required and-or used to complete this work or task. A basic formula for how much of the weight of the object is supported by the incline is:

(amount of weight supported by the incline) = weight (cos ¢ of the incline)

,therefore, the effective weight that you need to move will be: **effective weight** = weight - (amount of weight supported by the incline) = weight - weight (cos ¢ of the incline) = **weight (1 - cos ¢ of the incline)**. To move the object horizontally, assuming no friction to overcome with extra force, you must apply a force, and to move or lift the object vertically, you must apply a force greater than or equal to the effective weight (ie., the objects effective amount gravitational force to overcome, much like friction to overcome) of the object. Placing the object to be moved into a carrier with wheels will greatly reduce any surface friction to overcome, and so as to reduce wasted force and energy. The larger the force applied, f=ma, the greater the acceleration (a = f/m = change in velocity per unit of time) and resulting velocity, and the less time needed to move the object a certain distance (d=vt). To say that something is accelerating, is to say it is both speeding up and going faster at the same time. For an object to o accelerate, a force needs to be applied, and once the force stops, the acceleration will stop, and it will remain at its current speed or velocity when the acceleration stopped.

The goal, assistance and practicality of using the inclined plane is to use less input force to move an object vertically.

For a measure of the work and-or energy involved, the basic equation for work is: work = energy = (force)(distance), and for this inclined plane system, the total (ie., sum) or final amount of energy required to lift an object a height will be the same as without using it, since even though the effective force is less than the weight of the object, the distance is longer: work = energy = (a lower force applied)(through, over, or during a longer distance) = (effective force)(total distance). This also ensures a "conservation of work and-or energy" where the input energy = output energy. For a given amount of energy, if one of the variables, or factors of a mathematical product increases by a factor of (n), the other variable or factor must decrease by that same factor of (n). If the effective weight decreases by a factor of 2, the total distance needed will increase by a factor of 2. Note that when an object is raised a height with kinetic energy (KE), that input energy is transferred to the object and stored as potential energy (PE) available.

Although in a gear (transfers power) system, the applying force can be greatly amplified for the output force, the number of revolutions (per same amount of time) or speed of the output gear is greatly reduced by the same factor. Therefore, a point on the circumference of a larger output gear will travel or move much slower than that of the input gear or wheel, and therefore, more time will be required to move the same distance (such as a height) as that of a point on the input gear's circumference would travel in one revolution of that input gear. Winches are slow (longer, require more time) to move something a certain distance, however, they are still able to move objects of great weight when needed.

Two gears that are used to transfer power from one to the other will rotate in the opposite (rotational) directions with respect to each other: clockwise=CW, or counter-clockwise=CCW.

As indicated above, a pulley is an example of a "simple (mechanical, with motion and force) machine" or mechanism to assist (called a "mechanical advantage") in doing something, but as we can see by the numbers, that there is also a "trade off" or "cost" of having an increase in one variable, and that there is a decrease in another variable(s). For an electric winch or pulley, the advantage is a gain in force, but the disadvantage (ie. a mechanical disadvantage) is that it will take a corresponding gain in time to go (ie. lift up to the same unaided height, or pull the same unaided distance) the same distance because speed has decreased by the same factor:

From: distance = speed x time

time = distance / speed

We see that time and speed are inversely related. For a fixed distance, if speed is decreased by some factor, then the corresponding time value necessary to go that same distance will increase by that same factor.

This note is mentioned further ahead in this book when discussing power and torque, and it is also included here due to its importance:

In terms of torque: power = (Pw) = (torque) x (rotation speed) = (force)(Lever arm)(rotation speed)

The units of force are usually called Newtons, and the units of power are Newton-meters (Nm). We see in this equation of power, that torque and speed are mathematically inversely related for a given (fixed, constant) amount of power as such for the input and output power of gears or wheels. Note that even though they are inversely related, they are generally not mathematical reciprocal in value to each other, however it is important to note that in a gear system, that the specific corresponding gains (increases, multiplying factors) or losses in torque and speed are mathematical reciprocals of each other. Please also see the article: **An Extra Note About Torque And Power** in the Extras And Late Entries section of this book.

Closely related to gear analysis is lever analysis of which an article is presented further ahead in this book. Consider a smaller output wheel, it has a smaller radius, and therefore, it essentially has a smaller leverarm. Since **Torque = (force)(leverarm)**, if leverarm decreases, the torque (T) decreases, but its speed (ie., angular velocity = degrees per time) will increase such as for a smaller gear being powered by a larger gear. Consider this mathematical relationship:
Power In = (Tin) (Angular Velocity in) = Power Out = (Tout) (Angular Velocity out)

When a wheels or gears increases its rotational or angular speed, the effective linear velocity of a point on its circumference (C) also increases by the same factor. Given a wheel with a circumference of C1 powering a wheel with a circumference equal to (n C1) = C2, it will take (n) rotations of C1 to rotate C2 once. If the time of each rotation of C1 is (t1), the time needed to rotate C2 is (n t1), hence a reduction in angular rotational speed. The linear speed of a point on C2 will be (n) times greater than that of C1.

For an example of where gearing is used to increase torque is that when a vehicle is going up a hill and it will need more force to do that than as compared to a flat or level road. This can be accomplished by using a larger power output gear so as to increase the torque (ie. [rotating] force) of the wheels, but of course it will be at a lower speed, but still, is will make it much more possible for that vehicle to reach the top of the hill. A vehicle at rest will initially need more torque to get it moving to overcome friction and to get it to its desired velocity. It takes a force (ie., torque) to alter the speed of an object. Once the vehicle is at the desired traveling speed, it will slow a little due to the wheel friction (ie., resistance, drag) with the roadway, and it will take only a relatively small applied input power and force to maintain that desired speed.

With any two or more wheel or gear system, given a system or motor that is turning just one output wheel such as for a vehicle, if that wheel size is increased, the speed of the vehicle will increase. If that wheel size is decreased, the torque of that wheel will increase.

The maximum amount of torque can be measured by using weights suspended on a string around the rotating shaft, and the weight can be lifted vertically upward. It is also possible to use a common weight or mass scale to measure torque in a mechanical type of linkage and-or manner. According to **Power = (torque)(rotational speed)** , mathematically: torque = Power / (rotational speed). Theoretically, if the input power to a very efficient motor is:

Pw = (V)(A) = Pmotor, The max. torque of an electric motor can be calculated by: **torque = (V)(A) / (rotational speed)** , and by this equation, the slower the rotational speed, the greater the torque created. Note that a motor may not be 100% efficient, but perhaps 90% efficient, and due to that some power will be lost (ie., not available as output torque) as heat energy due to the resistance of the internal coil wire and the friction of the bearings, etc. The faster a motor rotates, the greater the back-emf produced in that certain motor design, and this will reduce its power output - mainly that the rotational speed will have a maximum value. With a back-emf, the net or resulting voltage to the motor is reduced.

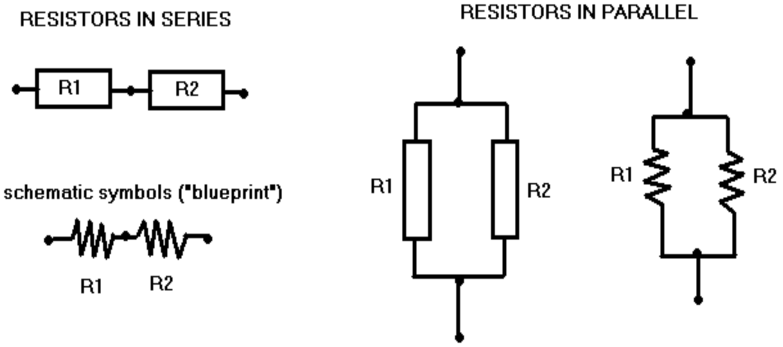
Gears transfer energy and-or power mechanically. Though gears are circular and provide a rotational and-or periodic (ie., repetitive) motion and timing, there are mechanical "linkages" or "cams" which can either turn a gear, or the gear moving these such as to create a linear (ie., straight) back and forth motion. Before the invention of high power motors which can be used wherever electricity is available, flowing water and wind power were used to power some machinery such as saws and grinding mills. One special gear is called a worm gear which has a screw shape, and which is sometimes used to convert between rotational and linear motion. Bevel gears can be used to change the direction of rotation such as from horizontal to vertical. If gears are separated by some distance, power can be transferred from one to the other using a shaft or rod, a belt or a chain. There are many gears and linkages already known about, and you can purchase the various books about them. New discoveries are always being thought of and made into reality. Some machinists specialize in gear creation from solid wood, plastic or metal blocks, and typically of standardized dimensions, however custom sizes can still be considered for prototypes of things being built and tested. The welding of metal is now a possibility so as to fix a broken metal gear. Gears can also be made by using hard, low friction plastics such as nylon. A common gear in most automobiles ("cars") is the **differential gear** system used to transfer the engine power and-or then a certain fraction of it to each (left and right) wheel of the car. This gear is a now considered a necessity for the car for it allows each wheel to rotate at a different rate (ie.,angular velocity, hence also the linear speed or speed on the roadway surface) as the car is turning left or right, and where one wheel is then acting as nearly a pivot or point of rotation for the other outer or more distant wheel wheel. For example, when the car is made to turn right, less power is applied to that right wheel, and the left wheel and car will then attempt to rotate about the center point of the right wheel.

[This space for book edits.]

ELECTRICAL RESISTANCE EXAMPLE

This example is of the electronics or electrical realm, and shows some mathematical examples for reciprocals, and (relative) generalizations using percentages rather than specific numerical values. Near the end of this example is some further mention of the rate of changes, or the slope, between variables. If the reader is not interested, they may skip over this material and-or possibly review it at some other time.

Electrical, electric resistance or resistivity is anything which will reduce the flow of electrical current which is usually charged (with energy, and therefore has ability to help do things) electrons. Even a plain wire has some resistance, and it is therefore said as not being a "perfect conductor" (which in theory would have none, or 0 resistance) of electricity. The greater the resistance, the greater a given current will be reduced. Hence, current and resistance are inversely mathematically related and this is reflected in the (Georg) **Ohm's Law formula for electricity: current = voltage / resistance**, or in symbolic form as: I = V/R. There are electronic parts or "components" created specifically to have some measure or value of resistance, and they are naturally called resistors. Resistors have many uses in electronic circuits, for example, as current limiters (ie. to reduce current or set its maximum value permissible for that circuit), and to set voltage levels such as in a (resistive) "voltage divider" circuit. The common letter symbol or variable for resistance or a resistor is: R, and is often used mathematically as a variable for the measure of the specific resistance value of a resistor. [FIG 62]



If you were to take a wire and cut its length in half, each half of that wire will then have half the total resistance of that original wire since each is half as long. This is because resistance is directly related to the length of the (uniform sized) material. If the length is twice as long, the resistance will be twice as much. If the length is half as long, the resistance is half as much. This leads directly to the formula for the sum of two or more resistances:

Rt = R1 + R2 + R3 . . . : formula for the total resistance of resistors in series (one after the other, like two pieces of wire connected together)

Even though various resistors of various values can be in series, the same amount of current will flow through all resistors that are in series since there is no other conductive path for the current (ie., "electricity") go to travel through. This is so since the voltage (v or V) or electrical pressure or force is applied to the starting and ending points of the resistors that are in series as if it was one single resistance "seen", affecting or applied to by that voltage. The specific amount of current (It) will be determined by the total (effective) series resistance (Rt): It = V / Rt Though the current is the same through each series resistor, it does take more electrical force or pressure to force that same current through a higher resistance, and this is seen as a higher voltage across resistances of higher value. This is what causes the voltage divider effect for resistors in series, where the largest resistance will correspondingly have the largest voltage "drop" or "loss" developed across it.

By mathematically rearranging the Ohm's Law equation, we find that the voltage across a resistor (r) is equal to the current through that resistor, times the resistance of that resistor: Vr = Ir Rr A voltage across a resistor is often said to be a "voltage drop", "voltage loss" and-or a "power loss" since energy or power is "used up", lost or wasted as current is forced through a resistor, and that power is then unavailable to be used by the rest of the circuit. Though unavailable to the rest of an electric circuit, the energy or power (a measure of available or energy used. Power = voltage x current = P=VI, and units of power are called watts) wasted in and through a resistor is not actually lost but was rather converted to other forms of energy such as: heat from a resistor, motion from a motor, sound from a speaker, and-or light from a light bulb. From this concept, it is said that energy is "conserved", "not lost", or "is maintained" and that no amount of energy actually disappears. The sum or total output energy is equal to the sum of total input energy, and this is called "the conservation of energy".

So that a formula can be developed for the total (effective) resistance of two or more resistors in parallel to each other, the topic of conductance needs to be considered. Conductance (G) is a measure of the ability to pass or allow current for a given voltage or emf, and is equal to: $G = I / V$, and it is therefore, the exact opposite or inverse to the concept of resistance: $(R = V / I)$, and conductance is therefore mathematically expressed as the inverse or reciprocal of resistance: $G = \text{current} / \text{voltage} = I / V = 1 / R$

$G = \frac{1}{R}$: the units of conductance are often called **siemens,** or **mhos** which is derived from the word "ohm" spelled backwards, and that resistance and conductance are electrical opposites or inverses of each other.

If you consider a wire as like a pipe to carry or allow the conduction or flow (ie. current) of water, and if you had two pipes in parallel (along the side length of each other), you will have a greater ability or more "room", "space" or area to allow more flow, perhaps for filling up some container with water. In relation to a wire, you would have more current ability, and hence this is described as having more conductance. Total conductance is simply expressed mathematically as the sum of each (parallel) resistors conductance ability. When conductance increases, resistance decreases. When resistors are placed in parallel, the effective or total conductance of that system will increase, and the resistance will decrease. When resistors are placed in series, the total resistance increases and the conductance will decrease.

Note, it may now seem that the total resistance of parallel conductors or resistors is: $Rt = 1/G1 + 1/G2 + 1/G3 + \ldots$, but this is actually just another expression for the total resistance of series resistances or resistors. To find the right expression for parallel resistors, first consider this expression for total conductance of parallel resistors:

$$Gt = G1 + G2 + G3 + \ldots = \frac{1}{R1} + \frac{1}{R2} + \frac{1}{R3} \ldots = \frac{1}{Rt}$$

: conductance of a system of parallel conductors or resistors. Mathematically:

$$Rt = \frac{1}{Gt} = \frac{1}{G1 + G2 + G3 + \ldots} = \frac{1}{\frac{1}{R1} + \frac{1}{R2} + \frac{1}{R3} \ldots}$$

For only two parallel resistors, the formula reduces to a simple expression to memorize:

$$Rt = \frac{1}{\frac{1}{R1} + \frac{1}{R2}} = \frac{1}{\frac{R1 + R2}{R1 \times R2}} = \frac{R1 \times R2}{R1 + R2}$$

: Formula for two parallel resistors. Their product, divided by their sum.

A common example is using two of the same valued resistors in parallel, and the total effective resistance is simply half of that common value. Note that parallel resistors always create a lesser total or effective resistance because the total or effective conductance increases when two resistors are in parallel.

If R1 = R2:

$$Rt = \frac{R1 \times R1}{R1 + R1} = \frac{R1^2}{2R1} = \frac{R1}{2} = 0.5\,R1$$

: Rt is half of the common resistance value

Some considerations on the value of the effective or total resistance of two parallel resistors:

As a parallel resistor R2 increases from 0 ohms to infinity ohms, the effective parallel resistance will increase or rise from 0 ohms and approach (become nearly equal to) the value of R1, but never greater than R1. In short, a very high or "infinite resistance" (such as even the resistance of air) in parallel to R1, t than the effective resistance is practically equal to R1.

Given a parallel resistor R2 being either smaller or larger than the first resistance R1, the effective parallel resistance will always be less R1, and never greater than R1.

If a parallel resistor is the same value (or 100% of that first value), the total resistance Rt is 1/2 or 50% of that resistor.

If a parallel resistor R2 is only half (1/2) or 50% of that of the first resistor R1, the parallel effective resistance is 33.3..% , or 1/3 of R1.

If a parallel resistor R2 is only 1/3 ("one-third", or 33 percent = 33%) of R1, the total effective resistance is 25% or 1/4 of R1.

If a parallel resistor R2 is only 1/10 ("a tenth") or R1, the total effective resistance is approximately 90% or R2.

Ex. R1=10ohms in parallel to R2=1ohm, and Rt=is 0.90909... = 0.91....ohms, which is almost 1 ohm and about 90% of R2. Part of the reason this is not exactly a 10% effective resistance reduction is that values and their corresponding reciprocals don't have a linear relationship, hence their relationship is said to be non-linear, especially for small values. Also, as R2 (the parallel resistor) gets larger in value, it will cause less and less change in Rt.

If a parallel resistor R2 is double or twice that of R1, Rt = 0.667R1 or= 2/3 R1 = 66.7% of R1
If a parallel resistor R2 is triple or three times that of R1, Rt = 0.75R1 or= 3/4 R1 = 75% of R1
If a parallel resistor (R2) is nine times that of R1, Rt = 0.90 or= 90% of R1
For verification of the above results (Rt) of two parallel resistors:

From: $Rt = (R1 \times R2) / (R1 + R2)$ we can derive some "parallel resistance percent formulas".

If R2 is some known or desired fraction or percentage=P of R1 : $P = R2 / R1$, therefore $R2 = (P\,R1)$, and:

$Rt = ((R1) \times (P\,R1)) / ((R1) + (P\,R1))$: product divided by the sum. After some simplification:

$Rt = (P\,R1^2) / (R1(P + 1))$ simplifying further:
$Rt = (P\,R1) / (P+1)$ also note, mathematically, if you divided each side by R1:

$(Rt / R1) = P / (P+1)$:also remember that Rt is always less than any and all parallel resistors

If R2 is P percent of R1, the resulting parallel resistance is:

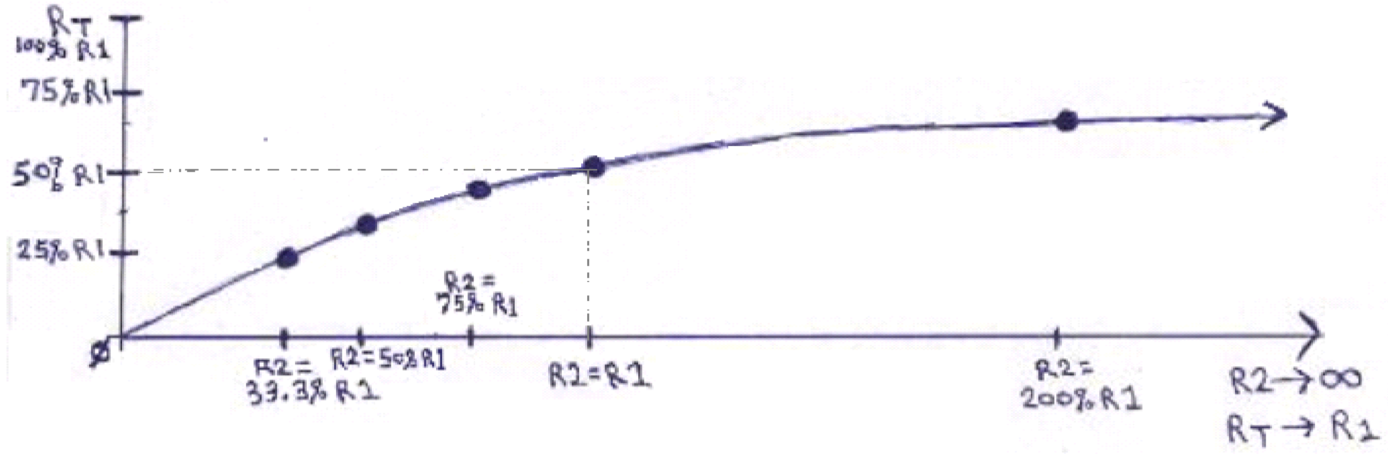
$Rt = [P / (P+1)]\%$ of R1 :Two parallel resistors, total or effective resistance percent formula.
Use the decimal value form for P, ex., for 300%, use 3.00

Ex. If R2 is 50% of R1, the parallel effective or total resistance is:

$Rt = (0.50 / (1 + 0.50))$ of R1 = $(0.50 / 1.50)$ of R1= 33.33% R1 , as mentioned above

Ex. If R2 is 20% of R1, the parallel effective or total resistance is:
$Rt = (0.20 / (1 + 0.20))\,R1 = (0.20 / 1.20)\,R1$ = 16.67% of R1

The following is a graph of the effective or total resistance (Rt) of two parallel resistors. R1 is fixed (a constant, unchanging) in value, and the value of R2 can change in value from 0 to infinity. The values of R2 are indicated on the horizontal (or "x") axis. The value of R1 is indicated on the horizontal axis. The values of Rt are indicated on the vertical (or "y") axis. [FIG 63]



As R2 increases the value of Rt (the effective parallel resistance of two or more resistances or resistors) does not change much. The slope of the curve is becoming near horizontal or level. This is due to that the rate of the changes in the corresponding values of each variable is getting less and less, and is approaching a value of 0, hence Rt is not changing by much in value with respect to the changes in R2.

Rate or ratio of changes of the dependent variable with respect to the independent variable:

$$\frac{\text{change in dependent variable}}{\text{change in independent variable}} = \text{ratio or rate of changes} = \text{slope}$$

This slope value is how the dependent variable will change when the independent variable changes.

$$\frac{\text{change in Rt}}{\text{change in R2}} = \frac{(\text{Rt.2} - \text{Rt.1})}{(\text{R2.2} - \text{R2.1})} = \text{slope}$$

Since a curve does not have a constant slope value like any line would, we can consider the curve as composed of just many small line segments, and therefore, we will make the change in the independent variable to be as small (or "close") as possible so that points chosen for this equation are as if they are on the same line or line segment, and that point or section of the curve can be analyzed like a small line segment for its slope value.

$$\frac{\text{the corresponding small change in Rt as R2 changes}}{\text{a very small change in R2}} = \text{slope of the curve at one point} = p(x,y) = p(R2,Rt)$$

The parallel resistance effect creates the condition that as Rt approaches a certain limiting value that is determined by and equal to R1, that Rt will approach (become "nearer and nearer to", or "closer and closer to") the value of R1, and that the changes in Rt, as R2 changes, get smaller and smaller until there is practically 0 change in Rt. The curve becomes near horizontal, like a horizontal line, as R2 increases.

Two, or possibly more, resistors may sometimes be placed in series or parallel so as to effectively create a third valued resistance that is otherwise unavailable.

When two resistances are in parallel, the effective or combined resistance is less than or equal to half of the largest resistance, and is slightly less in value than the smaller resistance if the difference in the resistances is large ,otherwise, it will be nearly equal to about half of any one resistor. A signal will see or be affected by the combined resistance and-or "the load". If the load resistance is low, more current can flow. If the load resistance is high, less current will flow. With impedance matching, the most electric power (= V I) is transferred.

A special resistor called a **varistor** is usually made from a semiconductor metal(s) and it can change its resistance in relationship to the applied rated max. voltage for that varistor. It is therefore a voltage sensitive, operated and-or a voltage dependent resistor (VDR). It can be placed in parallel to some electrical devices so as to protect them from excessive current due to an excessive applied voltage. It does this by sensing the applied voltage and reducing its own high internal resistance so as to conduct more and pass excessive current (ie., voltage and or current [temporary] "spikes", "surges") through it. A varistor is much like two diodes connected in reverse-parallel, and it has a non linear type of conduction conduction - essentially "on" (conducting) or "off" (not-conducting) like a diode. Due to this reasoning, a varistor is not a variable resistor. A **thermistor** is a special resistor that will change its resistance (depending on the specific type) due to the applied temperature. It is therefore very useful as a temperature sensor.

A List Of Common Metals And Their Relative Electricity Conductance

The lower the resistance, the greater the conductance and less power loss for the same size (diameter, mm^2) and length (m or cm) of wire, and at the same temperature. Room temperature is used during the measurement for the standard values. Silver has a (element specific) **resistivity constant (p)** of about 1.6 (10^-8) ohms-m = 1.6 (10^-6) ohms-cm. The values below are listed as relative values of conductance to silver which is the best know conductor with the lowest resistance. For a value of the relative conductance of a metal, use: (relative conductance) = (1 / relative resistance)

(element specific) resistivity = p = (Resistance measured in ohms) (Area in m^2) / (Length in m) ; R = p (Length / Area)

Material	**Relative conductance = (1 / Relative Resistance)**	: based on conductance and resistance are reciprocals
Silver	1.0	: an ecellent conductor , high cost , 1.6 / 1.6 = 1 = the relative resistance of silver
Copper	0.94	: an excellent conductor, relatively low cost , 1.6 / 1.7 = 0.94
Gold	0.73	: does not oxidize (ie., rust) and-or tarnish in the presence of oygen or water, very high cost if wire
Aluminum	0.60	: low cost, moderate conduction, resistance can be reduced by using thicker wire
Zinc	0.27	: this and the remaining metals listed are poor conductors having a much high resistance than silver
Nickel	0.21	
Iron	0.16	: relative reesistance of iron = 1 / 0.16 = 6.25 , 6.25 (1.6 uohms-cm) = 10 uohms-cm
Tin	0.13	: often usd in varius solder alloys, and sometmes with a small percentage of silver
Lead	0.07	: a poor conductor , but is still used mainly for fuses that melt, and electrical solder

The conductivity of silicon and germanium metal is much lower than that of lead, and they are considered as semiconductors and-or practically a high resistance. A small amount of other metals are added into these smiconductior metals so as to greatly improve their conduction such as for transistor (solid state amplifiers) devices and solarcells (solid state electricity generators).

A Note About Electromagnetic Fields

Below is a note about electromagnetic fields and current (ie., electron, matter) flow. This note ranges from basic to complex, and the reader may skip over it and review it later after viewing the more specific discussions about electricity and energy.

This book will usually describe the conventional thought about of the flow of electricity, and it is most practical and useful, such as when considering the water fluid analogy for the flow of electricity (ie., electrons). In advanced technological thought, the electrons only move a short distance and transfer their kinetic energy, usually via electrostatic (force, field) repulsion to the electron next to it in its path. This process is a chain-reaction, "one after the other" or "domino effect", and this surely gives the appearance that each electron is flowing or moving completely from one point in a closed circuit to the other. The electric force is repelling and giving the electrons kinetic energy, and these electrons will then have a motion and create a magnetic field and can be sensed by a nearby directional compass pointer ("needle") made of iron.

Stationary (static, non moving) charges such as electrons do not have a magnetic field. In a vacuum tube amplifier, electrons will travel much greater distance from one electrostatic (field, force) plate to the other before they collide with it and transfer their kinetic energy.

A voltage measurement is a measure of the electrostatic field strength between two points that are charged and are usually at different voltages, and hence the measurement is usually called a voltage (or potential energy) difference. If you were to take a resistor or long wire, the voltage difference measured between two points along it will go from say 0 to the maximum voltage value in that circuit. Lesser values of voltage can in general, always found between any two points along that wire, and that have same distance between those two points. In this case, it could be said that the electrical energy is evenly distributed.

For a traveling radio wave or light in outer-space that consists of no electrons, but both a magnetic field and an electric field, these expanding and traveling fields contain, store and convey the radio wave energy. These fields can be thought of as pure forms of, and the storage of electromagnetic energy without any moving charge carriers (ie., physical matter "storage containers" or "vessels") such as electrons which also have their kinetic (motional, mass) energy.

Radio waves and other electromagnetic energy, including light, travel at the speed of light in a vacuum, and slower in other mediums such as glass and metal wires. When electrons collide or repel with each other due to their electric charge field, they loose energy and transfer it to another electron of which it will take time to accelerate towards the next electron. It is incorrect to think that light travels instantaneously to everywhere, but it rather travels at the known speed of light, about 186000 miles / s =~ 300000 km / s per second in a vacuum (ie., no air or any other interfering, resisting and limiting matter) such as outer-space. It is currently (2021) thought in science that radio wave energy is a form of and identical to light or photon energy, and that photons are a "bit", "packet" or "particle" of light and having an electric and magnetic field, and no mass (ie., matter). These fields (or "pure electromagnetic" energy) travel at the speed of light in a vacuum. Electrons that have gained kinetic energy can also release that energy as a form of heat and-or light which is electromagnetic energy, and this is what happens in devices such as LED lights.

Even though the energy source to produce a radio-wave and-or light may be a relatively low frequency such as 50 hertz or 60 hertz AC from the utility company, or even DC from a battery or power supply which have a frequency of 0 hertz, the electromagnetic radiation such as the radio-wave or light produced has a very high frequency. This is due to the interactions of a huge amount of energized electrons. The electrons which have gained kinetic energy and escaped the orbit about an atom will eventually recombine with an atom needing an electron and release that gained energy as a photon (a particle, pulse, wave or bit of electro-magnetic radiation such as light) of energy. This photon is like it has released a small electro-magnetic field particle. Since the number of electrons involved is huge, the number of photons involved is huge, and the frequency of the electro-magnetic radiation depends on the amount of energy applied to the electrons. Consider a wire that is warm (ie., heat, thermal energy and radiation) due to its resistance and with some electricity going through it. If the amount of electric energy applied gets higher, that wire could radiate more heat and reddish light such as is the case for an electric heater. If the amount of energy applied gets even higher, heat and white light will be radiated, such as is the case for an incandescent light bulb. White light has also been found to be a mix (ie., a "rainbow") of colors such as red, green and blue, and with each color due to the specific frequency (ie., of a wave or pulses) of that electro-magnetic radiation, with each individual pulse or packet of it being called a photon particle. You may wish to view the topic **Common Colors Chart** further ahead in this book, and which has a figure that shows these colors. The electric and magnetic fields of each photon are at right angles to each other and are sinusoidal in amplitude (ie., intensity). The intensity of the light perceived depends on the amount of photons received per unit of area. In theory, once cycle of the electromagnetic wave corresponds to one photon of electromagnetic energy. It is often said that a photon does not carry any color information, but a wave of many of then, and which has a frequency, can then carry or convey the color seen. Obviously, the number of photons in a wave of them determines the amplitude or intensity of that light seen, and-or energy transferred. A wave will a higher frequency will carry and-or transmit more photons per unit of time, and therefore, more energy per unit of time.

More About Photons

All photons of light or electromagnetic radiation of any frequency will travel at the same speed through a given medium such as a vacuum or glass, and a single photon does not have a frequency. A series, number or wave (ie. of many, a wavefront) of transmitted photons can be transmitted at a certain frequency (ex. cycles per second, or photon or photon packets composing its physical wave per second, etc) and therefore having a certain wavelength or distance of travel per cycle of the wave. It may also help to know that a single photon normally travels in a straight line. A photon can be described as a invisible electromagnetic particle having no mass and inertia, and consisting of both an electric and magnetic field of potential energy. A photon is never at rest until it is absorbed as energy into another mass. In advanced particle physics it is considered that a photon having a high energy can collide with the nucleus of an atom and produce particles such as an electron and positron (ie., "antielectron", a positively charged electron, or "antimatter") pair. An electron and positron do have mass and of the same amount, but when they collide, they will annihilate (destroy, "disappear") each other and their energy is converted back to photon energy such as gamma rays. In each cycle of electromagnetic energy transmission, there is at least one photon, and if there are more photons in that cycle and-or wave, the intensity (ie., total energy) of that wave is greater. This book has many more articles about electricity, light and photons. albeit in a simple manner so as to not make things more complicated than they need to be.

WHEN A VARIABLE CHANGES IN VALUE

This example will show by how much one variable will change when another changes. It will also show how to consider and write some equations when there is a change by 1.

Let N=numerator or dividend , D = denominator or divisor , r = rate or quotient

$\frac{N}{D} = r$: If either N or D is a variable that can change, then (r) should not be considered as a constant. Mathematically:

$N = r D$: If (r) was a constant, this equation then has the form of a basic linear or "line" equation of: $y = mx$

In the following discussions (r) is a constant:

If D is to change in value, we can let (c) represent the amount that it will change. If D changes by a value, how much will N change by? Expressing this in an equation:

$N = r D$

$N + x = r (D + c)$ solving for x:

$x = r (D + c) - N$

$x = rD + rc - N$ since $N = rD$, using substitution:

$x = rD + rc - rD$ combining like terms:

$x = rc$: if D changes by c, N will change by rc

: If D changes by 1, then c=1, $x = rc = r(1) = r$

The above can also be expressed as:

$\frac{N + x}{D + c} = \frac{N + rc}{D + c} = r$: this is also a unique way to create an equivalent fraction, here of: (N / D)

If D increases or changes by a value (c), by what factor (f) does N increase? Expressing this in an equation:

$N = r D$

$N f = r (D + c)$

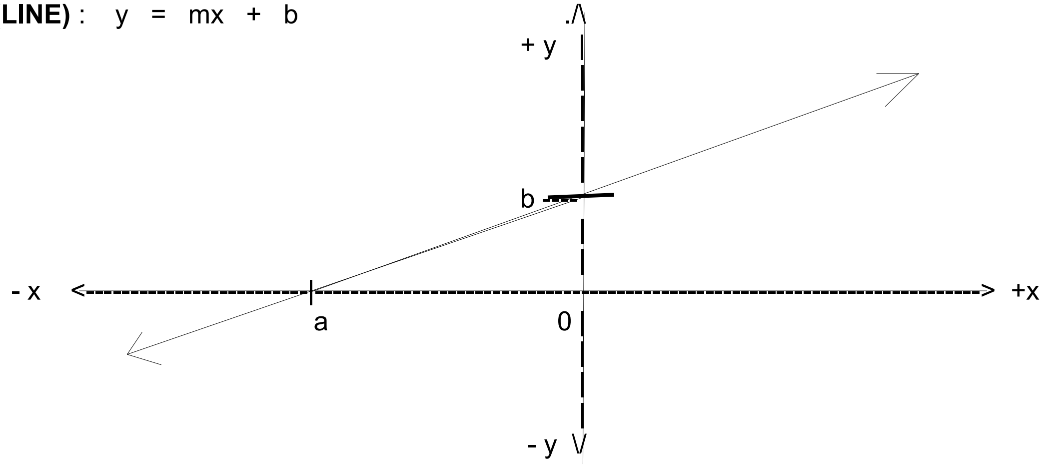
$$f = \frac{r(D + c)}{N} = \frac{r(D + c)}{rD} = \frac{D + c}{D}$$

$f = 1 + (c / D)$: if D changes by 1, then c=1, $f = 1 + (c / D) = 1 + 1/D$, also, since $D = N/r$:
$f = 1 + (cr) / N$

EQUATIONS AND SHAPES OF COMMON CURVES

For basic familiarity, below are some basic equations and a representative shape of the resulting curves when those equations are plotted on a graph. Some, such as the line, have already been discussed and others will be presented. [FIG 68]

LINEAR (LINE) : $y = mx + b$



A line is technically considered a special instance of all possible curves. As a simple verification, consider the curve or circumference of a circle being so huge that a relatively small portion of it, perhaps just a portion or arc of the circumference that corresponds to of just 1° (one degree) of rotation or movement of a point on it as it moves and rotates about the center of the circle, and is practically a line with the "bend" or curve in it being ever so slight that it is imperceptible (barely perceived or seen, very slight, small) when you are close to it. In more advanced reasoning, a very short or small segment of any curve will also resemble a line segment (a part of a line) and could be (locally, at that specific location, section, or point on the curve) analyzed as such, as for the slope of the curve at that point or location. A common example that considers this is with a concept called interpolation where an unknown value that is between two known values of an equation and-or a curve can be calculated like a point on a line or line segment.

The (y) or vertical intercept point, where x=0, is P(0, b). This can be found by substituting 0 for (x) in the linear equation and then solving for (y). To find the (x) or horizontal intercept point, where y=0, set (y) equal to 0 and solve for its corresponding (x) value. This (x) value is generally noted as variable (a) for a given line, and like (b), it is a constant for a given or certain line. The result is P(x,y) = P(xi, 0) = P(a, 0), where:

From: $y = mx + b$: setting y=0 so as to find the x-axis intercept point:

$0 = mx + b$ solving for the corresponding value of x for this point:

$mx = -b$

$$x = \frac{-b}{m}$$

$xi = a = - \underline{\ b\ }$: x-coordinate of the **x-axis intercept (i) point**, or simply the "x-intercept".

m

Algebraically, we also can find: **m = - b/a** , b= - ma , and
am + b = 0 which resembles the "slope (and, y) intercept" form of a linear equation, but this here is not actually a functional relationship of variables since all these values are constants (don't vary) for the line.
m = (change in y) / (change in x) = (0 - b) / (a - 0) = -b / a = - (b/a)

Here is a derivation of a linear equation in terms of the two (axis) intercepts or points.

From: $y = mx + b$

$mx - y = -b$ "dividing through" (each side, and hence all terms on each side) by -b:

$\frac{mx}{-b} \; (+) \; \frac{-y}{-b} = 1$ dividing the numerator and denominator of the first term by m:
(this also creates an equivalent [same value] fraction)

$\frac{\frac{x}{1}}{\frac{-b}{m}} + \frac{y}{b} = 1$ since -b/m = a , by substitution we have:

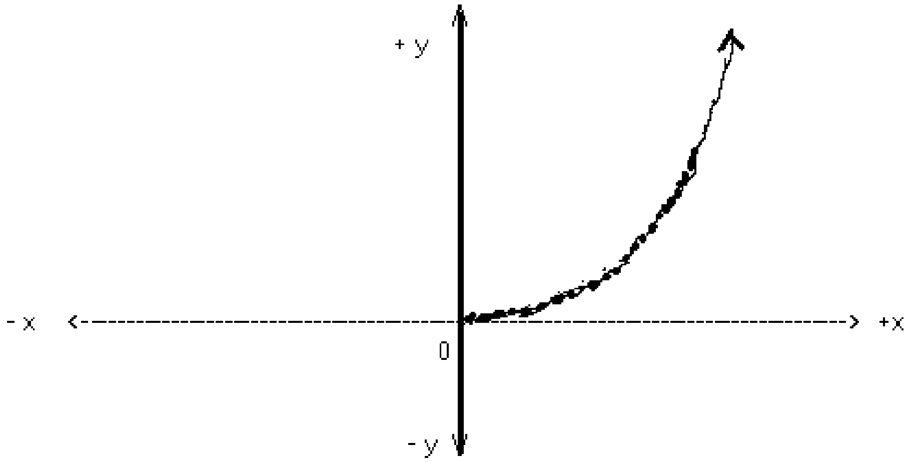
$\frac{x}{a} + \frac{y}{b} = 1$: "**dual or both intercept" form of a line**.
: Here, the slope (m = - b/a) is not explicitly indicated.
(1/a) is the numerical coefficient of (x), and
(1/b) is the numerical coefficient of (y).
(1/a)x + (1/b)y = 1 or=:
(1/a)x + (1/b)y - 1 = 0
a = x value of the x axis intercept , p(a,0)
b = y value of the y axis intercept , p(0,b)

After solving for y, we also have:

$y = b\left(1 - \frac{x}{a}\right) = b - \frac{bx}{a} = \frac{(-b)}{(a)}x + b$: this has the form of: y = mx + b
m=(-b/a) , b = (-am) , a = (-m/b)
x intercept point is: p(a,0) = p(-m/b , 0)
y intercept point is: p(0,b) = p(0,-am)

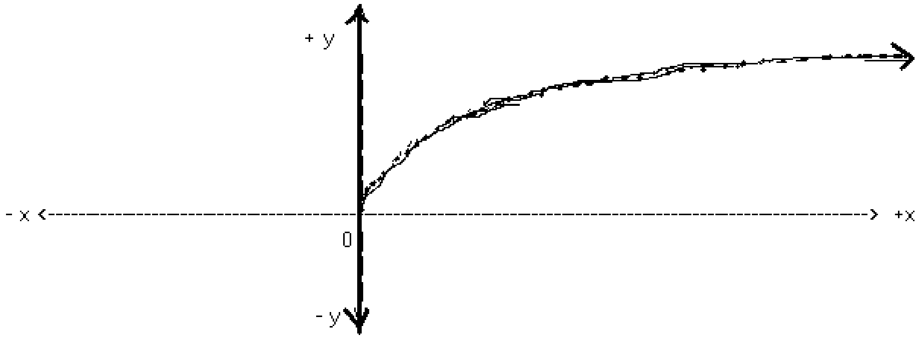
POWERS : y = x^n : a power equation is when the variable is the base value, and the exponent is constant

Ex. y = x^2 . Ex. y = x^3 . x is a variable, and x >= 0, n is a constant, and if n >= 1 , that is, the expression is not actually a root. If 0<n<1 (ie., the expression actually represents a fraction (ie., < x) amount or root of x, and with this mathematical condition, the value of y will get smaller as x increases.) [FIG 69]



For powers, is greater than 1 and gets larger, even small increases in it will cause a huge increase or change in the value of (y) which is the dependent variable. When x=1, the value of the equation y=x^n is 1. If the equation of a curve of this type (y=x^n) is unknown, it can be found such as by for example noting on the curve that when x=2, y = 8. Therefore, 8 = 2^n. Taking the log of both sides: log 8 = log 2^n = n log 2 , therefore n = log 8 / log 2 = 3 . The base of the log can be any value such as 10 or e, as long as it is used consistently. The equation of the curve is therefore: y = x^3

ROOTS : y = $\sqrt[n]{x}$ = x^(1/n) : n is the index or indicated root of the radicand x [FIG 70]



x is a variable, and x >= 0 (ie., x is not a negative radicand), n is a constant. If 0<n<1 , the expression is actually a power of x. As x grows larger in value, the curve resembles and will approaches that of a horizontal line which has a slope of 0. This means that the relationship of y to x, or the root with respect to the radicand, is not growing as much or quickly (rate) as when the radicands are lower in value. Consider x=radicands with the low values of 16 and 100.Their difference is 84, and their y=square roots differ by $\sqrt{100}$ - $\sqrt{16}$ = 10-4.0 = 6. Now consider higher value radicands of 10000 and 20000. Their difference is 10000, and yet their square roots differ only by $\sqrt{11000}$ - $\sqrt{10000}$ = 104.88 - 100 = 4.88

For indicated (ie., the index) roots greater than 1, when the independent variable is greater than 1 and gets larger and changes, then the corresponding changes or increases in the dependent variable get smaller.

Ex. y = x^0.5 : an example of a power expression, that actually results in a root of the given value, here of x.

y = x^0.5 = x^(1/2) = (1/0.5)$\sqrt{x}$ = 2$\sqrt{x}$

Obviously, variable (y) is directly related to (x), as can be seen by the graph of the curve above, but not in a linear manner.

The curve of this equation (considering both positive and negative roots) is actually that of a parabola "on it's side" with it's axis being the x-axis. To help verify this, consider $\sqrt{x}$ as equal to the perfect square of a value, say (n), then we have the quadratic equation:

y = n^2 = $\sqrt{x}$

Consider this example data:

n	y = +,- n^2	= +,- $\sqrt{x}$
1	1	$\sqrt{1}$
2	4	$\sqrt{16}$
3	9	$\sqrt{81}$
4	16	$\sqrt{256}$

: when the index is even (such as: 2, 4, 6, etc), roots, such as square (2) roots, are both positive and negative in sign, the curve will be "symmetrical" (like a mirror) with respect to a line (here, the x-axis line).

For additional verification, you can exchange the corresponding data values of (x) and (y) and find their relationship to be:

y = x^2 which is clearly a quadratic or parabolic equation.

For example, in this root equation, we will find a power equation:

y = $\sqrt{x}$ y = root = 2=index$\sqrt{\ x = \text{radicand}}$: root could be thought of as a base, and the index could be thought of as an exponent, as shown below:

3 = 2$\sqrt{9}$ therefore:

9 = 3^2 expressing this in a general algebraic sense:

x = y^2 in more of a relation to the initial equation, this could be expressed as:

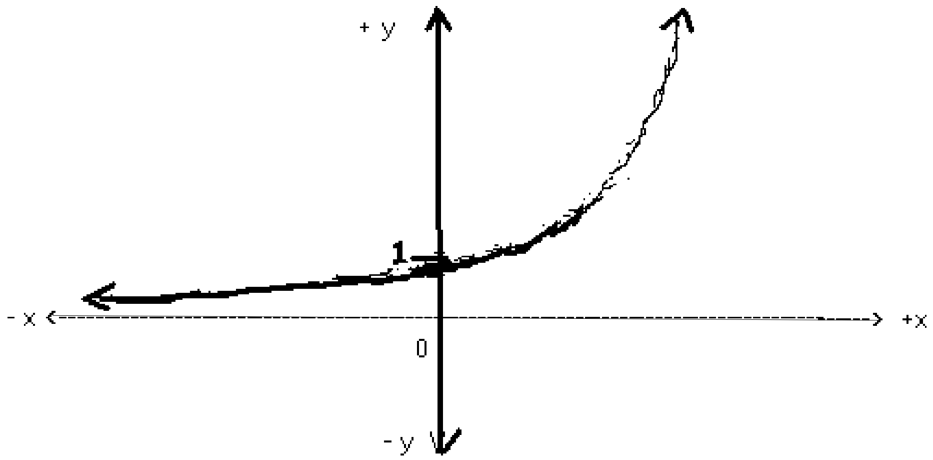
radicand = root^index this could be expressed using the more general and common relational form where y is the dependent variable, and x is the independent variable:

y = x^exponent

EXPONENTIAL : y = n^x : an exponential equation is when a variable is in the exponent, and the base is constant

Here, x, the independent variable, is an exponent, and this is why the equation is called an exponential equation. If you were to solve for (x), it is equal to: $x = \text{logn } y = \log_{n} y = \log y / \log n$

For an exponential equation, (n) is a constant. When $n >= 1$ this is the typical curve shape: [FIG 71]



When $x = 0$, $y = n^x = n^0 = 1$, and this is where the curve crosses the y-axis. Note that for a power equation as shown above, that when $x=1$, $y=1$.

Like other equations, an exponential equation may contain a multiplying constant (c):

$y = cn^x$: $c \neq 0$ so as the indicated power actually exists

The (y) or vertical intercept can be easily be found by setting (x) equal to 0:

$y(0) = cn^0$ since $n^0 = 1$:
$y(0) = c(1)$
$y(0) = c$: hence (c), the multiplying constant, is the vertical axis intercept; where $x=0$.

If the exponential equation is not known, (c) can be found by reading a graph of the corresponding data (points) of the unknown equation. If the equation is known, (c) can be easily found by:

$$c = \frac{y}{n^x}$$

Given a (y) value, the corresponding (x) value can be found by observing the graph of the equation, or mathematically by using logarithms:

$y = cn^x$ taking the logarithm of both sides:
$\log y = \log cn^x$
$\log y = \log c + \log n^x$
$\log y = \log c + x \log n$

$$x = \frac{\log y - \log c}{\log n} = \frac{\log(y/c)}{\log n}$$

If (y), (c), and (x) are known, perhaps from a graph, (n) can be solved for:

$y = cn^x$ dividing both sides by c:

$\frac{y}{c} = n^x$ taking the x root of both sides:

$\sqrt[x]{\frac{y}{c}} = \sqrt[x]{n^x} = n$ switching sides:

$n = \sqrt[x]{\frac{y}{c}}$: formula for solving for the base of an expressed power

If two or more pair of corresponding values (ie. the coordinates of two or more points) of an exponential equation are known (given, calculated or read from a graph), an exponential equation with the form of: ($y = cn^x$) can be constructed from that data:

Given two points (x,y): P(3.2 , 5.8) and P(4.7 , 8.2) that appear to be, and-or are on an exponential-like curve:

This can be expressed with functional notation as:

$y(x1) = y(3.2) = 5.8$: let = y1
$y(x2) = y(4.7) = 8.2$: let = y2, Solving for n, a base of the power, by substituting the known data into two instances of the basic exponential equation of: $y = cn^x$:

$$\frac{y2}{y1} = \frac{cn^{4.7}}{cn^{3.2}} = \frac{8.2}{5.8} = 1.413793 = \frac{n^{4.7}}{n^{3.2}} = n^{(4.7 - 3.2)} = n^{1.5}$$ therefore:

$n^{1.5} = 1.413793$ after taking the 1.5 root of each side:

$n = \sqrt[1.5]{1.413793}$

$n = 1.259671$ for the (y) values above to be shown as correct, (c) must now be solved for:

Writing equations or formulas for the above steps or procedures, we have:

$$n = \sqrt[(x2 - x1)]{\frac{y2}{y1}}$$

$$c = \frac{y}{n^x} = \frac{5.8}{1.259671^{3.2}} = \frac{5.8}{2.09325829} = 2.770799967$$

The exponential equation is therefore:

$y = (2.770799967)\ 1.259671^x$: this equation has the exponential format of: $y = cn^x$

Notice in the original stated points, that the values of (y) and (x) are directly related. As (x) increased, (y) increased. Also, if you were to divide the lesser value by the greater value, you would still arrive at the correct result:

$$\frac{cn^{3.2}}{cn^{4.7}} = \frac{5.8}{8.2} = 0.707317073 = \frac{n^{3.2}}{n^{4.7}} = n^{(3.2 - 4.7)} = n^{-1.5} = \frac{1}{n^{1.5}}$$

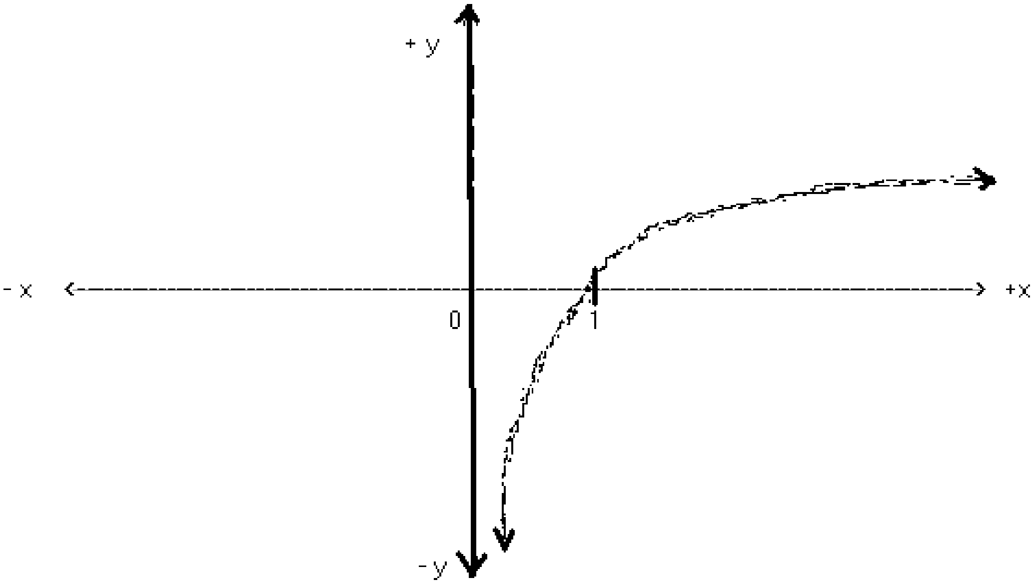
$0.707317073 = \dfrac{1}{n^{1.5}}$ taking the 1.5 root of both sides:

$\sqrt[1.5]{0.707317073} = 0.707317073^{(1/1.5)} = 0.707317073^{0.66666666} = 0.793857881 = \dfrac{1}{n}$

After solving for (n), we have: $n = 1.259671314$: checks, as shown above

LOGARITHMIC : $y = \log_b x$ [FIG 72]

When $x > 0$, and $b > 0$:



Note as (x) approaches infinity, the curve approaches the shape of a line. If you were to exchange the (x) and (y) axis of either the logarithm curve or the exponential curve, you would have each other curve. This is so since exponential and logarithms are inverse mathematical operations.

Here is a discussion and graph of the logarithm of a power of N with respect to the indicated (x, the exponent) power of N.

Given: $y = \log N^x$ using the log rules, this can be expressed as:

$y = x \log N$ or:

$y = \log N \; x$ both forms are of a basic linear equation of:
(In short, (x) the exponent, causes a multiple of log N.)

$y = m \; x$: here, $m = \log N$, and is a constant and the slope of the line

Hence the relationship between the exponent of N, which is x, and $y = \log N^x$ is a linear relationship. If (x) changes by some factor (F), (y) will change by that same factor (F). This is equivalent to multiplying both sides of the equation by F.

y = log N^x multiplying both sides by some factor (F):

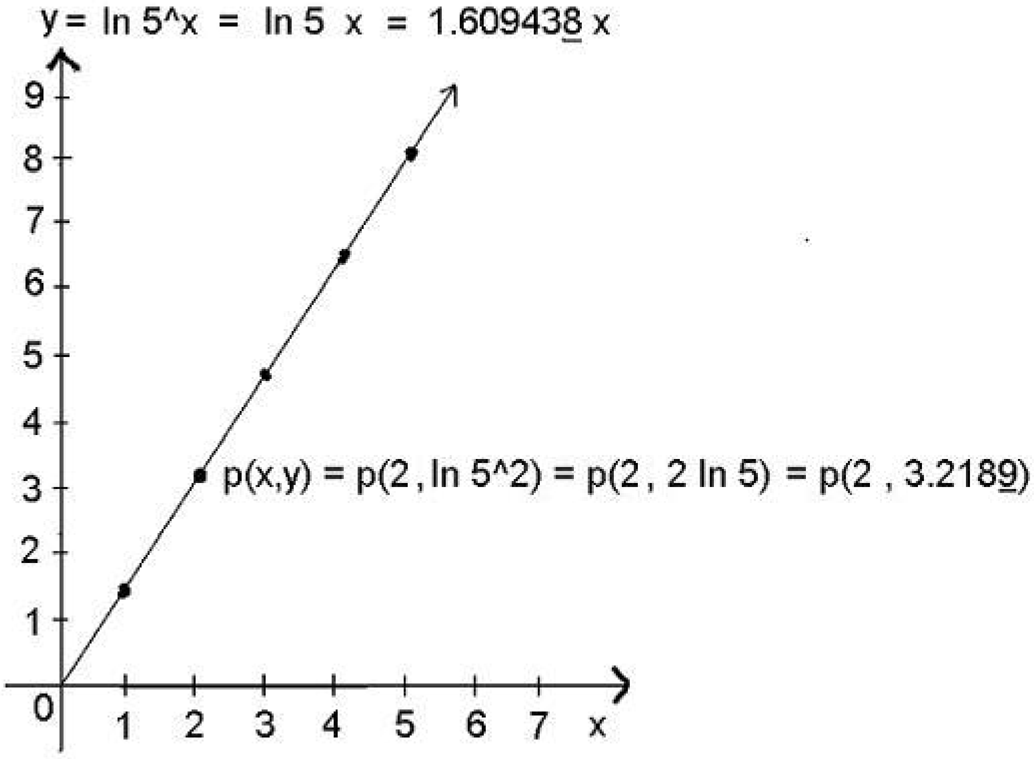
Fy = F log N^x
Fy = Fx log N
Fy = log N^(Fx)

Or, using the linear equation:

y = m x if (x) changes by some factor (F), and multiplying both sides by F to keep the equation in balance:

Fy = m Fx

Here is a graph of y = ln 5^x, the relationship between (y) and (x) is a shown to be a linear relationship and not an exponential relationship. [FIG 73]



The following curves are formally called conical curves, and are curves of various **conic sections** (cross sectional areas, "flat" planes or slices of). The word "conical" and "conic" comes from the word **cone**. A (right) cone is created when a right-triangle is rotated about one of its two "leg" sides which then becomes the central axis of that cone. These curves are the result of a planar (plane, flat), or two-dimensional, cross-sectional "slice" of a three-dimensional (right) cone. For example, when the slice or plane is at a right angle (ie., perpendicular, 90°) to the central axis of the cone, hence the slice is also being parallel to the base of that cone, the intersection of that plane and cone surface will create a **circle** or disk shape or curve. Each point on the perimeter (ie., edge, circumference) of the circular section of the cone is equidistant from a (center) point on the axis of the cone of which is also the center point of that circular shape or plane. When the plane is parallel to the side of the cone, a **parabola** shape and curve is formed at the intersection. When the plane is not parallel to the side of the cone or base, the shape and curve is an **ellipse**. If you were to take the circle section and raise one end or side up and the opposite side down, it would create an elliptical section of the cone. When the plane is parallel to the axis of that cone, it will create a **hyperbola**. The circle and ellipse are closed curves, and the parabola and hyperbola are not, but keep extending. For completeness, a point and a line can also be considered as (special, unique instances) conic sections. All of the (conic) equations that mathematically define one of the conic sections are actually a part of the general quadratic equation which will be discussed first.

First, here is the general or formally defined linear equation:

$ax + by + c = 0$: (a) and (b) are numerical coefficients (possibly 1, but not 0) of the (x) and (y) variables. (c) is an arbitrary constant (possibly 0).

Ex. After computing the resulting value (here 2) from two variables, the following equation was created:

$6x - 2y = 2$ expressing this in the general form:
$6x - 2y - 2 = 0$: by observation, and with respect to the general linear equation: a=6, b=-2, c=-2

Solving for (y), we will have (y) expressed in terms of (x), and hence an equation showing the relationship or function between the two variables:

$$2y = 6x - 2$$

$$y = \frac{6x - 2}{2} = \frac{6x}{2} - \frac{2}{2}$$

$y = 3x - 1$: this equation has the basic linear equation form of: $y = mx + b$: here b = -1

Given the general linear equation shown previously, and for the sake of simplicity, we will assume that the numerical coefficients ((a) and (b)) are 1, and letting f = c, a placeholder for an arbitrary constant, we now have:

$$(x + y + f)^1 = 0$$

By squaring the general first degree or linear equation, we will have the general second degree or quadratic equation:

$$(x + y + f)^1 (x + y + f)^1 = (x + y + f)^2 = 0$$

By using distribution and combining like terms on the left side, we have:

$$1x^2 + 2xy + y^2 + 2fx + 2fy + f^2 = 0$$

Dividing each term by (f) and assigning variables to these newly created numerical coefficients of the variables, we have the general or formally defined second degree or quadratic equation of:

$ax^2 + bxy + cy^2 + dx^1 + ey^1 + f = 0$: General Or Formal, Second Degree or Quadratic Equation

[This space for potential edits.]

CIRCULAR (CIRCLE) : x^2 + y^2 = r^2

Notice that for this simple equation of a circle, being (part) of a conic section, that it contains only some terms of the general form of a second degree or quadratic equation, that is, it need not have all the terms of that form, especially if those terms have a value of 0. This circle equation here is a simplified or unique form of the general or full formal circle equation which would have (x^1) and (y^1) terms. More specifically, this "reduced" or "partial" equation here is for when the center of the circle is at the origin (0.0) of the rectangular coordinate (rectangular, planer, two-dimensional measuring and addressing) system when it is graphed. The equation of the circle is actually a form of the Pythagorean Theorem for right triangles, where (r), the radius of the circle is essentially the hypotenuse side, and the corresponding "legs" or leg sides of this right triangle construction are the (x) and (y) values from the origin of this measurement system and center of this circle.

Algebraically arranging the equation into a form for plotting (graphing the relationship of corresponding values as points) a graphical or visible relationship between the variables:

$y^2 = r^2 - x^2$ taking the square root of both sides of this equation:

$y = \pm \sqrt{r^2 - x^2}$

Note, for a given or unique circle, r (radius) is actually a constant value.

Ex. Place the equation of: $3x^2 + 3y^2 = 9$ into standard form.

First, with some basic mathematical processing, this is of the general form of: $ax^2 + by^2 + f$
All the terms of the general quadratic equation are not present, but this partial form of the general quadratic equation that defines a circle.

Dividing through (on both sides) by 3, we find:

$x^2 + y^2 = 3$

Note that the coefficients (here 1) of both variables are equal.

Note also that $r^2 = 3$ (not 9), therefore, $r = \sqrt{r^2} = \sqrt{3} = 1.7320...$

After dividing both sides by 3 and canceling:

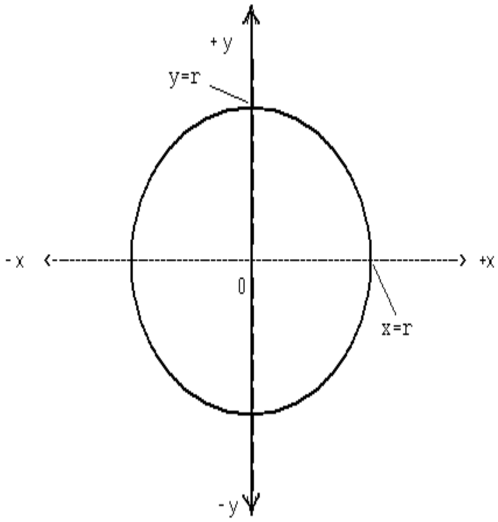
$\frac{x^2}{3} + \frac{y^2}{3} = 1$: this could optionally be expressed as: $0.333X^2 + 0.333Y^2 = 1$

Shown in this form, the square roots of the divisors (or denominators if you will) of the variables are the intercepts to the corresponding axis in the numerators. This is also the case for an ellipse curve that will be shown ahead. In general, for a circle with its center at p(0,0), the x-axis intercepts, where y=0, are clearly: $P(+- \sqrt{r^2}, 0) = P(+ - r, 0)$.

Algebraically arranging the equation for plotting by solving for (y):

$y = \pm \sqrt{3 - x^2}$

When x = 0, $y = \sqrt{\ r\ } = \sqrt{3}$.
When $x = r = \sqrt{3}$, $x^2 = 3$ and $y = 0$ [FIG 74]



All circles are similar circles to each other since the parts (circumference, diameter, radius) of each circle all have the same portion (fractional value) of that circle and with respect to each other. For example, C/D = (pi) for every circle.

Translation Of Axis And Coordinates

What if a point(s) is to be in reference to a another location and-or axis?

If a point(s), p(x,y) is to be centered about another location, say p(h, k), you must translate (ie., shift, adjust) the coordinates of each point (x, y) so as to be centered about p(h, k). The x location of each point must be increased by h, and the y location of each point must be increased by k so as to be still in reference to p(0,0).

The x coordinate value of each point in reference to this new system centered around p(h, k) will be called x**' =** "x-prime", and the y coordinate value will be called y**' =** "y-prime". p(x' , y') can also be thought of as a different reference or origin.

In relationship to the standard reference system with p(x=h=0 , y=k=0) as the origin, a translated point will have the coordinates of:

p(x , y) = p(h + x**'** , k + y**'**) or= p(x**'** + h , y**'** + k) , from this we mathematically have:

p(x**'** , y**'**) = p(x - h, y - k);

If the coordinates of a point are x = 3, and y = 2 and the center or point of reference is the standard p(0,0), and if this point is now to be in reference to, or centered about point p(10, 5), we will let h=10, and k=5:
p(x' , y') = (3, 2) and p(x , y) = p(x' + h, y' + k) = p(3+10 , 2+5) = p(13,7);

Let's write the equation of a circle that has a radius of 10, and its center point (0,0) translated to be located a p(4,6).

x^2 + y^2 = r^2 is re-expressed or translated to:

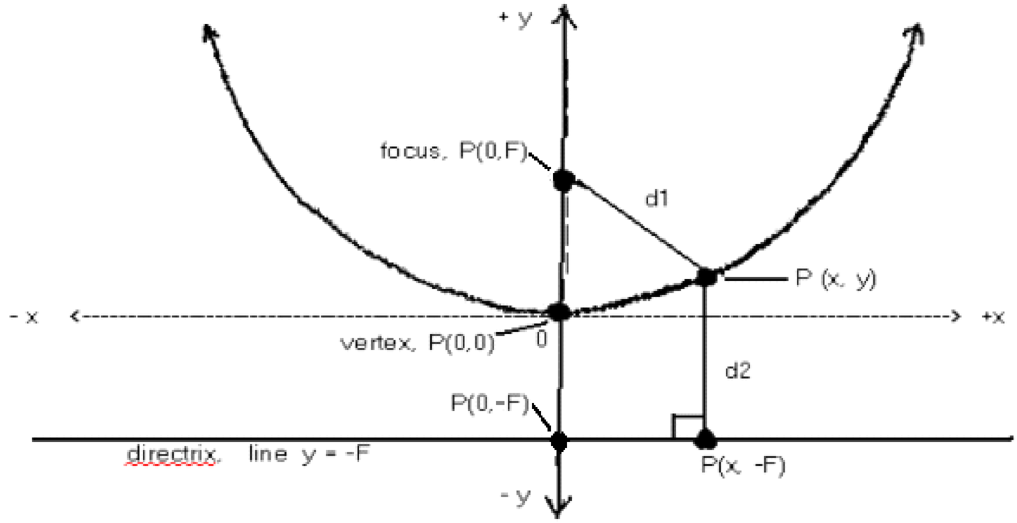
x**'**^2 + y**'**^2 = r^2 =

(x - h)^2 + (y - k)^2 = r^2 substituting the known values , if r = 10, then r^2 = 10^2 = 100 :

$(x - 4)^2 + (y - 6)^2 = 100$ and: $(y - 6)^2 = 100 - (x - 4)^2$ and $y = \sqrt{100 - (x - 4)^2} + 6$

PARABOLIC (PARABOLA) :

Observing the drawing below, a parabola curve is formed when the distance (d1) from any point on the curve to the (fixed or constant) focus point is equal to the (perpendicular) distance (d2) from that same point to an imaginary line (called the directrix) that is perpendicular to the axis of the parabola. Note, that this distance (d1 and d2) of either or both of these lines (to those points mentioned) is not constant since it changes from point to point. The focus of a parabola is located on the axis of the parabola. The parabola curve is symmetrical (ie, similar or the same in shape) about this axis and extends endlessly and appears to get wider and wider as the distance to its axis increases. The directrix line is located at the same relative distance that the focus point is from the vertex (ie. the "narrow point" and where the curve and slope changes direction and value) of the parabola, but on the opposite side of the vertex and perpendicular to the axis of the parabola. Often, the equation and shape of a parabola are constructed around an initially specified focus point. [FIG 75]



$y = ax^2$ is the equation of the above parabola curve.

The equation of a parabola when the vertex is at the origin (h=0,k=0), and the axis of the parabola is along the y-axis is:

$x^2 = 4Fy$: Where F (a constant) is the focus point (or focal length) along the (y) axis, point (0,F). If F is negative (ie., when y's numerical coefficient is negative), the parabola curve opens downward. Solving for (y) for plotting points and creating the smooth curve on a graph:

$y = \frac{x^2}{4F}$ Since 1/ (4F) is a constant (c), this also has a more general form of : $y = c x^2$, or $y = a x^2$ if we replace (c) with the typical or formal equation variable (a).

This simple equation of a parabola will now be verified. As stated above, for all points on the parabola curve:

$d1 = d2$ using the (Pythagorean or right triangle) "distance formula":

$\sqrt{(y - F)^2 + (x - 0)^2} = y + F$ after squaring both sides, to clear the radical:

$(y - F)^2 + (x)^2 = (y + F)^2$ extending the squared binomials:

$y^2 - 2yF + F^2 + x^2 = y^2 + 2yF + F^2$ transposing terms (solving for x^2):

$x^2 = 4Fy$ and solving for y:

$$y = \frac{x^2}{4F}$$

However, this equation can be expressed in another, perhaps simpler, form. Since 4F (or: 1/4F) is a constant (c) for any specific parabola:

$x^2 = (4F)y = cy$: after letting $c = 4F$, $F = \frac{c}{4}$ solving for y:

$$y = \frac{x^2}{c} = \frac{x^2}{4F}$$

$y = \frac{x^2}{c} = \frac{(1)(x^2)}{(c)(1)}$ expressing this reciprocal value of (c) as a new constant (a) :

$y = ax^2$: This is the most basic parabola equation, which is actually a (simple) quadratic equation, and also a "power (here it's 2) of x" equation. Note that if F is negative, then (a) and the (y) values will be negative and the curve will expand or open downwards.

Note: $a = (1/c) = 1/(4F) = 0.25/F$ and therefore, $F = 0.25/a = 1/4a$:the focus point for this equation and parabola would be: $F(0, 1/4a)$

Ex. Given : $y = 0.025x^2$, find the focus point of this parabola.

This has the expressed form of: $y = ax^2$, where $0.025 = a$, and $b=0$ which is essentially the vertical offset of the curve.

Since: $a = \frac{1}{c} = \frac{1}{4F}$, (c) is the reciprocal of (a):
Also of note: $F = (1/4a) = (0.25/a) = (c/4)$

$$c = \frac{1}{a}$$

Taking the reciprocal of the numerical coefficient (a) of the squared variable (x):

$$c = \frac{1}{a} = \frac{1}{0.025} = 40$$

Hence $y = ax^2 = \frac{(1)}{(c)}\frac{x^2}{1} = \frac{(1)}{(4F)}x^2 = \frac{x^2}{40}$: here, expressed in the general parabola form. Note also that: $a = (1/40) = 0.025$

Here, $c = 4F = 40$, solving for F:

$F = \frac{c}{4} = \frac{40}{4} = 10$: note also that $F = 0.25/a = 0.25/0.025 = 10$

$F = +10$: the focus of this parabola is at point: $P(0,F) = P(0,+10)$

Given the original equation of a parabola: $x^2 = 4Fy$, and taking the square root of both sides:

$$x = \pm \sqrt{4Fy}$$

This shows that for each (y) or vertical value, there are two (x) or horizontal values, one positive and one negative in sign, but both are the same in absolute value. These two points with the same (y) value or y-coordinate are on opposite sides of the axis of the parabola. Clearly then, the axis of this parabola is the vertical or (y) axis, and the parabola will be symmetrical about it.

The equation of a parabola when the vertex is at the origin, and the axis of the parabola is along the x-axis is of an identical form that has the variables switched:

$$y^2 = 4Fx \quad \text{and} \quad y = \sqrt{4Fx}$$

To graph a parabola point, you will obviously need more points than you do with the graphing of a simple straight line. Some other key (significant, helpful, guiding) plotting points of the curve are the x-axis intercepts (where y=0) which are the roots of the quadratic or parabolic equation, the y-axis intercept (where x=0) which is easily found to be P(0,c). It is possible that the curve does not cross the x-axis, and for such a case, the roots are "imaginary". Another key point is the vertex point of the parabola. Other names for this point are either the minimum or maximum point which both go by the general name of the "extreme point" of the curve. As derived ahead in the discussion about derivatives, the x-coordinate of the extreme point of a parabola is:

$$x = -\frac{b}{2a}$$

: x coordinate of extreme point of a parabola.
These variables correspond to those of the
standard quadratic equation: $y = ax^2 + bx + c$

Variable (a) cannot be 0 since anything multiplied by 0 is 0, and this would then eliminate the x^2 term and the equation would no longer be a quadratic equation. Also notice that the bx^1 term can only be 0 when (b) is 0, and then the x^1 term is not present. To find the corresponding (y) value of the min. or max. point, you can substitute this points (x) coordinate into the original equation given. Algebraically, it is found by substituting this (x) value into the general quadratic equation:

$$y = ax^2 + bx + c \qquad \text{by substitution:}$$

$$y = \frac{a}{1}\left(\frac{-b}{2a}\right)^2 + \frac{b}{1}\left(\frac{-b}{2a}\right) + c \qquad \text{after distribution:}$$

$$y = \frac{b^2}{4a} - \frac{b^2}{2a} + c$$

The first two terms have a factor of b^2 in the numerator and (2a) in the denominator. We can factor out those values:

$$y = \frac{b^2}{2a}\left(\frac{1}{2} - \frac{1}{1}\right) + c \qquad \text{combining}$$

$$y = \frac{b^2}{2a}\left(-\frac{1}{2}\right) + c \qquad \text{distributing:}$$

$$y = -\frac{b^2}{4a} + c$$

: y coordinate of extreme point of a parabola

The coordinates of the extreme point Pe are therefore:

Pe (- b/2a , - b^2/4a + c) : "extreme point" of a parabola is the max.("highest"), or min. ("lowest") point on the curve of a common parabola or quadratic equation.

Notice that variable (x) plays no role in the expression for the coordinates of this point since this extreme point is fixed, that is, it is a constant for the given equation and parabola, and does not depend upon any (x) variable value.

What is the effective "rim to rim", or "curve to curve" distance of a line, parallel to the directrix line, of the parabola at the height of the Focus point? If we set y=F, we can solve for its corresponding x value, and then double this x value:

From: y = x^2 / 4F , if y=F : F = x^2/4F , x^2 = 4F^2 , $x = \sqrt{4F^2}$ = $x = \sqrt{4}\ \sqrt{F^2}$, x = 2F and 2x =4F

All parabola curves are essentially similar when considered as being just magnified versions of each other, while still having the same exact parabolic curve shape. For a mathematical verification to this, consider that the distance from the focus (F) point to the curve at the height of the focus is always 2F. This point is always of the form: p(x,y) = p(2F,F). At great distances from the vertex, the two "arms" or sides of the parabola will be practically parallel to each other as they get nearly vertical when the slope of the curve becomes a very high value.

If a plane parabola shape or curve is rotated about its (symmetry or symmetrical) axis line, the three dimensional solid or volume created is called a paraboloid. Cross sections or planar "slices" parallel to the directrix will be circular.

Here is a short discussion about the different basic forms of a quadratic or parabola equations and their curves.

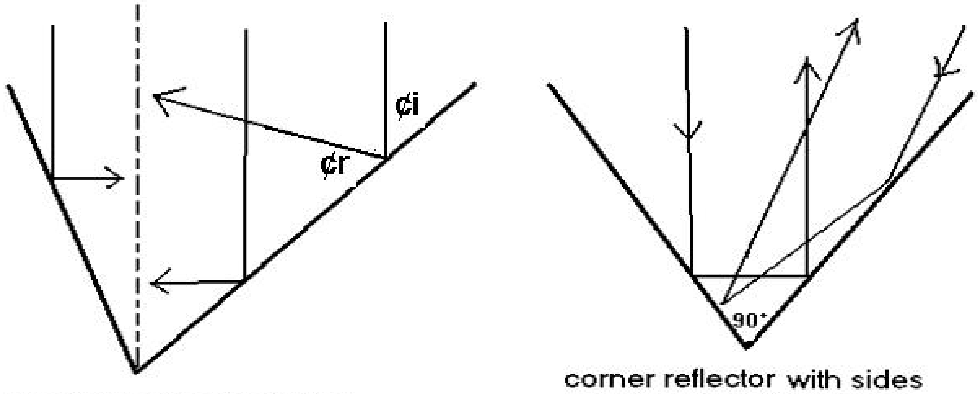
y = x^2 : This parabola curve will have a point, here the extreme or minimum point, at (0,0). When x is less than one, it's square will always be a smaller value since this is essentially a fraction of a fraction. The curve is "slow growing" for these values. When x is greater than one, the "exponential effect" of squaring of a value, is easily seen as the change in y values grows larger and larger for each change in x. The curve becomes "fast growing". Since the (rate of) change is not a constant as for linear or line equations, the equation and the relationship of the variables of a parabola equation is said to be a non-linear. When the x^2 term is negative: y= - (x^2) = - x^2, the curve will open downwards and have a maximum point. The value of x^2 without the -1 multiplier is always positive in value for all values (both pos. and neg.) of x. y=-(x^2) can also be expressed as y=(-1)(x^2), and we see its the same as the equation of: y=(x^2) but each value of y is essentially converted to its corresponding negative value by the (-1) factor. As the values of x increase more and more , the corresponding values of y will decrease more and more, and produce the inverted or "upside down" parabola curve.

y = x^2 + c : Here, a constant is added into the most basic quadratic equation. The effect. like as in a line equation, will shift the curve vertically. The vertex or minimum point of the parabola will no longer be at (0,0), and any part of that curve will not cross at that point either since for this equation, when x=0, y=c. This constant (c) is much like a "lead value".

y= x^2 + x^1 : Here, with the addition of the variable to the first power will shift the axis of the parabola horizontally (left and right). This will change the origin and vertex of the parabola and it will no longer be: (h=x=0, k=y=0). Still, the curve will cross through this point since when x=0, y=0.

y = x^2 + x^1 + c : This will be similar to the equation above, however the curve will be shifted vertically along the y-axis, and it will not cross through point (0,0) since for this equation, when x=0, y=c. (c) will not change the shape (and therefore, it also wont change the slope) of the curve, and it will have the same shape as that of: y = x^2 + x^1

Extra: If the sides of the curve were not a parabola shape, but flat or straight shape, there would not be a common single focus point of the incoming or collected rays of light as an example. A common line or plane placed between the two reflective sides could be called the focus line or focus plane instead of a focus point. The incoming rays need not even be parallel to strike this line. In a "corner reflector" (ie., right angle or 90° reflector) often used for indicating objects in dim or dark conditions, the two reflective surfaces or sides have a 90 degree angle of separation. Each reflected ray will be reflected back in the same direction or parallel to the incoming ray such as from a light source. A similar reflector is called a retro-reflector and which basically means a "return reflector". [FIG 76]



basic two sided reflector

corner reflector with sides separated by 90 degrees

. **For any mirror, the angle of reflection with respect to the surface of the mirror will equal the angle of incidence of the light or energy.**

¢i = ¢r

Several retro-reflectors have been placed on the surface of the Moon, and have been used for various purposes such as for measuring the distance to the Moon (~ 240000 mi =~ 384000 km.)

From: distance = (speed) (time) , using substitution for these values we have:

Distance to Moon = (Speed of light) ((Total time taken for light to travel to the Moon and then back to Earth) / 2) =
Distance to Moon = (Speed of light) (Time to travel to the Moon)

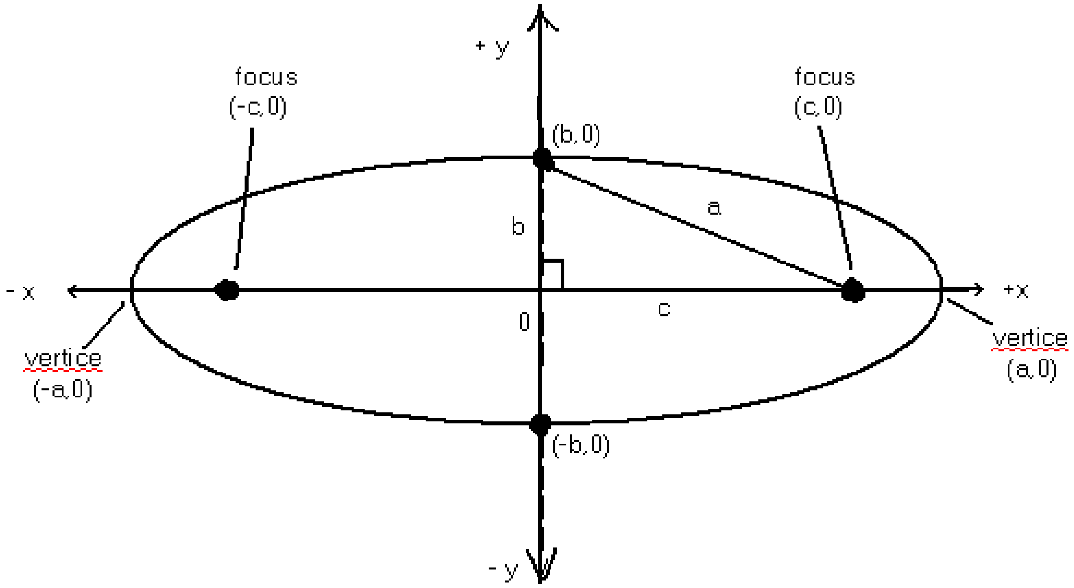
For a parabola shape: Incoming or receiving parallel light rays or other energy such as sound and radio waves that happen to also be parallel to the axis of the parabola will be reflected to and concentrated at the focus point. In a reverse manner, rays emitted from the focus point in every direction and those emitted towards the parabola's curved surface will be reflected parallel to the axis of the parabola.

The depth (or usually, vertical) distance from the edge of a parabola curve (or some other arcs) to the center of the parabola is called the **sagitta** distance. Sagitta is a word which is commonly called the "sag" of the curve or object. This distance is essentially equivalent to the distance from the arc or curve to the central point of a chord line which intercepts that arc or curve at two points. When rough grinding a parabolic mirror for a telescope, this distance can be checked so as to know when the grinding should stop and polishing should begin. The longer the focal length of the mirror, the less grinding needed, and the sagitta distance is perhaps only a few millimeters. This distance can be found using the standard parabola equation: y = a x^2 or as: height = vertical = y = a x^2 = a (horizontal distance)^2. See the full discussion above to calculate the value of (a = 1 / (4F)) which includes the focal (F) point distance. y = ax^2 = x^2 / 4F

[This space for book edits.]

ELLIPTICAL (ELLIPSE) :

The shape of an ellipse is like that of a stretched or elongated circle, hence its shape is much like an oval or an egg. If you look at a circular ring shape and tilt it away from you, it will appear very similar to an elliptical shape. Numerically, a measure of this elongation, non-circular, or "unbalance" is called the eccentricity (e) of the ellipse. Don't confuse the variable (e) used here with the ("natural") base value used in the context of natural logarithms. The longer the elongation, the greater the eccentricity (e) of the ellipse. The eccentricity of a circle is obviously 0 since the length of the horizontal and vertical axis within a circle are the same and therefore produce no elongation in any one direction. The horizontal and vertical axis lengths within a circle are obviously equal to the diameter or (half-diameter) radius value of that circle. A circle is actually a special instance of an infinite number of ellipses. The eccentricity of a circle is 0. When the eccentricity of an ellipse is 1, the ellipse is completely elongated into a line. Most planets have a near circular orbit, hence they have a low value for orbit eccentricity. Comets usually have an orbit having a high eccentricity value. Both the circle and ellipse are examples of what are known as "closed curves" since they completely define and enclose (contain, surround) a bounded region of a plane. All circles are similar, but may vary in sizes, hence they are not identical. Ellipses that have the same eccentricity value are similar, and they may even vary in size, and are therefore not identical ellipses. [FIG 77]



Orbits of outer-space objects, such as planets and comets going around the sun are actually elliptical in shape. Here, the sun is effectively at one of the two focus points of the ellipse or elliptical orbit. This orbit shape of a planet is caused by the constant pull of the force of gravity from the Sun, and will cause the object to slowly change direction and speed.

If energy (ex, sound, light) was emitted directly outward from any focus point of a (solid, physical) ellipse shape, the energy would be reflected from the inner curve edge of the ellipse to the other focus point. An egg is somewhat of an ellipsoid (three dimensional elliptical) shape where an ellipse is fully rotated about its major or minor axis.

An ellipse ("closed") curve is defined or formed when the total distance from any point on the ellipse to both foci (plural of focus) is always the same, and that distance has a value of (2a). This distance is also equal to the length of the major (ie. longest) axis of the ellipse which passes through both foci and the center or origin of the ellipse. For a circle, it's center point is effectively both focus points being in the same place. Here (r=radius or 2r) is the common distance. The more eccentric the ellipse, the more elongated it is and the farther apart the foci are, and vice-versa, however the maximum eccentricity (not a length value, but practically a ratio value) is defined as a value of 1. The focus points on an ellipse are equidistant from it's center point along the major axis. Before the standard equation of an ellipse is shown, the ellipse will first be discussed using the common circle and its equation since a circle is a special instance of an infinite number of ellipses.

Starting from the common equation of a "representative" or unit (1) circle where the radius is understood as being 1 (or 100%), the curve of an ellipse can be created and perhaps more easily understood.

$r^2 = x^2 + y^2$: basic circle equation. After solving for y^2, and taking the square root of both sides:

$y = +- \sqrt{r^2 - x^2}$: When x=0: y = +- r, and y is at its maximum or minimum value:

$y = +- \sqrt{r^2 - 0^2} = \sqrt{r^2}$

$y = +- r$: the max. and min. y value, p(0, +- r)

When r=1 (or 100% if you will):

$y = +- \sqrt{1^2 - x^2}$

$y = +- \sqrt{1 - x^2}$

Obviously, x^2 must be less than or equal to 1 for the square root of a positive radicand value to be taken. As x grows larger and approaches the value of the radius=1, x^2 becomes closer to 1, and y becomes smaller and closer in value to:

$y = +- \sqrt{1 - 1}$

$y = +- \sqrt{0}$

$y = +- 0$: the min. y value, p(x=+- r , 0)

The values of x can be negative, and the square of a negative value is a positive value. After all, the circle is symmetrical about its origin point. Also, for each value of x there are two corresponding y values as indicated in the equations above, and is due to the fact that the two square roots of a positive value or radicand are both positive or both negative in sign.

As shown above, when x is close in value to the radius, the square root of x^2 will be close to 1 and the difference of ($r^2 - x^2$), and the corresponding (y) values, approach 0 in a non-linear (non-line-like) manner due to the squared value and the square root values that always result in non-linear values. The result is the curve of the circle, or a curve of an ellipse when the maximum (y) value is no longer equal to the maximum (x) value. In particular for the ellipse, each and every (y) value (or even each (x) value) of the normal circle equation is divided by the same (constant) value (other than, or not equal to 1), or it can also be said that each and every (y) value now has a numerical coefficient (other than 1). If each (y) value is divided by a value >1, then an ellipse with a larger (x) axis (or "major axis") will be produced.

Is there a new focus point? First of all, the center of the ellipse, like the circle, will still be at the intersection of both the (x) and (y) axes (unless the curve is "translated" or moved to a new reference or origin position within the standard rectangular coordinate system). Any straight ray emitted from the center of a circle will be reflected back (from the circumference) to the center (ie. focus point) since the angle of reflection with respect to that reflective surface will equal the angle of incidence with respect to that surface. For a circle, the angle of incidence and reflection are both actually 0° with respect to a perpendicular line at that surface or circumference point. Remember, a tangent line through a point on the circumference of a circle is always perpendicular to the radius line drawn to that point. The distance the ray or beam will travel is obviously equal to a distance of (r) to the circumference, and (r) back to the focus, hence a total distance of:

$r + r = 2r$: total distance for a ray from the focus of a circle and back to the other (coinciding) focus .
This is similar to the concept and value of 2a, as for an ellipse mentioned previously.

It is fair to guess that even though for an ellipse, which is like a circle that is essentially "squashed" and-or elongated, there is still a focus along the longest axis of it (the curve shape) due to the symmetry of the curve on both sides of that axis. It is also fair to guess that there are two focus or "foci" points due to the symmetry of the curve about the other axis. This leads to a conclusion that there are two foci points which are the same distance from the center of the curve along the major axis. If a circle was only slightly "squashed" or elongated (ie., stretched) to an ellipse shape, it is fair to guess that the foci points are still near the center of that circle as before it was "squashed" or elongated very slightly. As the circle or ellipse gets more elongated, the farther the foci points will be from the center.

A ray of energy (perhaps light, radio waves, or sound) emitted from one focus point will be received by the other focus point after reflecting from the ellipse curve shape to be collected or concentrated at that receiving focus. This is obvious for a circle. For an ellipse, this can be easily verified when the point of incidence and reflection is at the y-axis interception point of the curve. By drawing a tangent line to the curve at that point, and by using the symmetry of the angles of incidence and reflection with the y-axis, and even the angle of transmission and reception of the rays at the foci, then this fact (and the constant distance of 2a) is verified. It must be noted that all the rays emitted (in various directions) from the center (not the foci points) of an ellipse will generally not pass through both foci or even back through the center.

When the (y) values are divided by a high value (this is equivalent to multiplying each (y) value by a very small constant value = [1/high-value]), they approach a value of 0, and the square of those (y) values (being less than 1) will approach a value even closer to 0:

$r^2 = x^2 + y^2$ if $y \to 0$ (read as: "if, or as, y approaches a value of 0"), then:
$r^2 \to x^2$ r^2 will approach a value of x^2, and r will approach a value of x.
After taking the square root of both sides:
$r \to x$ With substitution:

$$y = \sqrt{r^2 - x^2}$$

$$y = \sqrt{r^2 - r^2}$$

$$y = \sqrt{0} = 0$$

So regardless of the value of (x), all the (y) values will be 0 and the curve of the ellipse approaches the shape of a (horizontal) line, hence it's the line: y=0. We then also have some verification that a line (segment) is a special instance of a conic section, and in particular, an ellipse.

Given: $y = \pm\sqrt{1 - x^2}$,

If each (y) value is multiplied by a numerical coefficient, say variable (b), as discussed above for making an ellipse, the equation for each (y) value is now:

new $y = \pm b\sqrt{1 - x^2}$ squaring both sides, we have:

$y^2 = b^2 (1 - x^2)$ after dividing both sides by b^2 :

$\frac{y^2}{b^2} = 1 - x^2$ and:

$x^2 + \frac{y^2}{b^2} = 1$ after solving for x :

$$x = \pm\sqrt{1 - \frac{y^2}{b^2}}$$

If each (x) value is multiplied by a numerical coefficient, say variable (a), and after squaring both sides of this equation to rid the radical, we will have:

$$x^2 = a^2\left(1 - \frac{y^2}{b^2}\right)$$ after dividing both sides by a^2 :

$$\frac{x^2}{a^2} = 1 - \frac{y^2}{b^2}$$ algebraically we have:

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$$: **BASIC EQUATION FORM OF AN ELLIPSE**
Center is at the origin, p(0,0), of both axis.

When the center of the ellipse is at the origin (x=h=0, y=k=0) and the (major) axis of the ellipse is on the (x) axis, the equation of the ellipse is of the basic form shown above. When (a>b) the (major) axis of the ellipse is on the (x) axis. If (b>a) the (major) axis is along the (y) axis. When (a = b), the equation is actually for a circle, for example, when (a) and (b) are both 1. This form above is essentially a basic "circle equation form" where the circle is a unit circle with a radius of 1 as discussed previously. This form will also lead us to find the lengths of the major and minor axis**:** When x=0, we find the maximum (y) value of $y=b=\sqrt{b^2}$, and when y=0, we find the maximum (x) value of $x=a=\sqrt{a^2}$.

Given the following equation of an ellipse, place it in a standard ellipse equation form:

$$3x^2 + 4y^2 = 24$$ after dividing through both sides by 24 and canceling:

$$\frac{x^2}{8} + \frac{y^2}{6} = 1$$: or = $0.125x^2 + 0.166667y^2 = 1$
: note that here, $a^2 = 8$ and $b^2 = 6$

Since a=8 is larger than b=6, the major axis is along the x-axis. The coefficient of x^2 is the constant (1/a), and (a) is the length along the major axis from the center of the ellipse to the edge or vertice of the ellipse. Hence, (a) is equal to half of the major axis. This (half) portion of the major axis is often called the semi-major axis. On the other hand, the coefficient of y^2 is (1/b), and (b) is equal to the length of the semi-minor axis which is perpendicular to the major axis. Again, when both (a) and (b), the coefficients of the (x) and (y) terms, are equal in value, that the equation reduces to one of a circle.

For the above example:

$a = \sqrt{a^2} = \sqrt{8} = 2.828427125$: length of the semi-major, or half of the major axis

$b = \sqrt{b^2} = \sqrt{6} = 2.449489743$: length of the semi-minor, or half of the minor axis

Note, if given this form indicated above: $0.125x^2 + 0.166667y^2 = 1$

$0.125 = \frac{1}{a^2}$ mathematically:

$a^2 = 1/0.125 = 8$:as seen above

$a = \sqrt{a^2} = \sqrt{8} = 2.828427125$ and:

$0.166667 = 1/b^2$

$b^2 = 1/0.166667 = 6$:as seen above

$b = \sqrt{b^2} = \sqrt{6} = 2.449489743$

Using the general equation and expressing (y) in terms of (x) for plotting purposes:

$$y = \pm b \sqrt{1 - \frac{x^2}{a^2}}$$: Note that when x=0, y= +-b as should be expected, and this point (0,b) is the y-axis intercept.

You can find the focus point: F(c, 0) from a Pythagorean, right triangle, type of relationship of the distances:

$$a^2 = b^2 + c^2$$: where (c) equals the ± x coordinate of a focus point

To verify that the hypotenuse is equal to (a) = half the major axis, consider the point (b,0). According to the definition of an ellipse, the total distance to both foci points is 2a after a ray is emitted from one focus and reflected off the ellipse to the other focus. Half of this distance is equal to (a).

$c^2 = a^2 - b^2$, the focus point is: F(c , 0)

Due to the elongation (of an axis) of an ellipse, you might suggest that the formula for eccentricity (e) should be the ratio of the minor and major axis, and have resulting ratios less than or equal to 1, and then and adjustment made by subtracting this ratio from one (1) since longer elongations, where the major axis is larger, should have higher (rather than lower) eccentricity values rather than lower eccentricity values. Consider the following:

$$\frac{\text{minor axis}}{\text{major axis}} = \frac{2\ (\text{semi-minor axis})}{2\ (\text{semi-major axis})} = \frac{b}{a}$$: this is sometimes called the "compression factor" or "aspect ratio"

A "proposed formula" for (e) = $1 - \frac{b}{a}$: This specific value is associated with the compression factor is sometimes called the "flattening factor", but it is not the formal formula for eccentricity.

Combining fractions, this can also be expressed as:

$$1 - \frac{b}{a} = \frac{a}{a} - \frac{b}{a} = \frac{a-b}{a}$$ = ratio of: (difference in length values) to the longest length value

As a check on the "proposed formula" for (e), a circle is defined as having no eccentricity (e=0), the length of the major and minor axis are the same, therefore (a=b):

$$1 - \frac{a}{a} = 1 - 1 = 0$$: (e) of a circle

And for a line being defined with the highest eccentricity possible, the ratio of the minor (2b) axis to the major axis (2a) is very small (since b approaches 0), and is practically 0:

$$1 - \frac{b}{a} = 1 - 0 = 1$$: (e) of a line

This "proposed formula" seems to be a very logical mathematical definition of eccentricity (e), however, it is not the one used. (e) is actually defined in such a way as to be applicable to all conic sections. A mathematical definition of the eccentricity of a conic section is:

$$\frac{\text{distance from any point on the curve to a fixed point known as the focus}}{\text{distance from the same point on the curve to a fixed line known as the directrix}} = \text{eccentricity (e) of a conic section}$$

This ratio (e) is a constant for a particular conic section. In relation to the ellipse, the definition resolves to:

$$e = \frac{\text{distance between foci points}}{\text{major axis}} = \frac{2c}{2a} = \frac{c}{a}$$

: eccentricity of an ellipse. (a) and (c) are values on the major axis. This value is always less than 1 for an ellipse.

In the above equation we find that (c) is equal to the distance from the center to one of the foci of the ellipse. (a) is the length of the half of the major axis and-or is the distance from the center to the farthest edge of the ellipse along the major axis.

As a simple verification, when the ellipse is circular-like in shape, the distance between the foci points is 0, and (e) will be a very small value, practically and equal to 0 as defined for circles. The more eccentric the ellipse is, the distance between the foci points is greater and this distance approaches that of the length of the major axis. (c) will approach the value of (a) and therefore, their ratio is near 1 as expected for the eccentricity of a line or ellipses with high eccentricity.

Since $c^2 = a^2 - b^2$ in an ellipse, we can algebraically have:

$$e = \frac{c}{a} = \frac{\sqrt{a^2 - b^2}}{a}$$

: eccentricity of an ellipse,
Also, from this: $c = e\,a$ and $a = c / e$

The eccentricity of any parabola is 1, and the eccentricity of a hyperbola is greater than 1. The eccentricity of a line is "infinity" or a "very, very high value". In short, the lower the eccentricity, the more circular-like the curve is.

A three dimensional shape and-or volume created by rotating an ellipse along its major or longest axis is called an ellipsoid. The North American ball used for the game of football has a similar shape to that of an ellipsoid. The specific elongated shape of the football is technically called a prolate spheroid (ie., elongated or "stretched" spheroid or sphere). Imagine a construction with a shape that is someplace between that of a hemisphere of a circle, a cylinder and a cone shape and you will then have an football shape. Some seeds of plants also have a similar type of this shape. The shape of the cross sections of an ellipsoid are circles or disks. A shape that looks somewhat similar to that of an ellipsoid is that of a sphere that has been "squashed" on opposite ends and it would be the result of rotating an ellipse along its minor axis. This is technically called an oblate spheroid.

An ellipse can be drawn on a piece of paper placed on a spare wooden surface by using two tacks at the foci locatons, and a loop of string of constant length equal to: 2a + 2c = 2(a + c) is needed, and of which these lengths determine the eccentricity and vice-versa. This string will be held firmly by the pen or pencil during the drawing of the ellipse curve. The tension of the string loop will guide the position of the pen so as to draw the ellipse.

The orbit of planets is given a basic discussion further ahead in this book in the topic of sun, moon and stars. It is shown that (e), eccentricity ban be calculated in another way using named variables of the orbit that correspond to the general equation of an ellipse. Some astronomers have found the specific elliptical orbit of the planets and other celestial objects by using many observations of their positions, and then predicting and checking to see if their calculation is acceptable and-or needs to be adjusted. Due to some, relatively slight gravitational interference upon a planet from other distant planets, a planets predicted elliptical orbit will change slightly from what was expected. In reference to the above drawing of an ellipse and the forward discussion about orbits, c = a planets average distance from the Sun = major axis / 2 = 2a / 2 = a = (aphelion distance + perihelion distance) / 2. This position is actually the "center" point of the ellipse, halfway between both the major and minor axes. Half the minor axis is equal to b = the square root of (a^2 - c^2) due to the right angle and Pythagorean Theorem. e = c / a = the ratio of: (distance from center to focus) / (distance from center to farthest point). Distance from the center to focus = average distance = (aphelion + perihelion) / 2. The eccentricity = e of Earth's orbit about the Sun is very low at about e = 0.017, and is practically circular. A circle has an eccentricity = e = 0.

HYPERBOLIC (HYPERBOLA) :

The word "hyperbolic" and "hyperbole" old words containing the word prefix "hyper", and are sometimes used to describe things that are excessive or extreme, and is rooted in the meanings such as "an excessive bole [throw]". The opposite in meaning to the word prefix "hyper" is the word prefix "hypo" which means low. The equation and formal definition of a hyperbola are somewhat similar to that of an ellipse, however with a hyperbola, the difference between the distances from any point on the hyperbola curve to the two foci points is always the same. Unlike the ellipse and circle, the hyperbola is not a closed curve. It has two symmetrical (similar or mirrored) branches that extend endlessly. The two branches are due to a planar section of two identical cones connected at their vertex or "top points". Each branch is considered hyperbolic. An asteroid or comet from outside our solar system may get attracted and then have a trajectory towards near to the Sun due its gravity, and yet not orbit the Sun like objects in our solar system do with an elliptical orbit, but it will rather just pass through and out of our solar system due to its high kinetic energy. That asteroid is then said to have a hyperbolic trajectory or path.

When the center of the hyperbola is at the origin, and its axis (passes between the two vertices of the hyperbola, and is similar to the major axis of an ellipse, and where the foci of the hyperbola are located upon) is along the x-axis, the equation of a hyperbola has, or can be reduced to the basic form of:

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$$

: (a > b) when the x-axis is the axis of the hyperbola.
This equation is similar to an ellipse equation, but the coefficients of the x and y terms have opposite signs.

There is another and simpler equation of a hyperbola (though with different axis) that is often encountered, and this is:

$$\frac{x\,y}{c} = 1$$

: For this equation to be true, (c) must equal (x)(y). (c) is a constant.
Mathematically:

$$x\,y = c$$

: Both (x) and (y) are inversely related to each other. After solving for (y) for plotting, this resembles a common "division equation", where the divisor, and therefore the quotient change in an inverse manner.

$$y = \frac{c}{x}$$

: (y) is a some multiple (c) of the reciprocal of x = (1/x). y=(c)(1/x).
The equation's curve shape is shown below. Since the graph shows the relationship of how (y) changes with respect to (x), (c) must remain constant.
In general, due to the form of this equation, it could be called a "division equation" and the graph of it could be called a "division curve". If we let c=N=numerator, or dividend, and x=D=denominator, or divisor, and y=Q=quotient, we have:

$$Q = \frac{N}{D}$$

: when N=D, Q=1
: when N>D, Q>1
: when N<D, Q<1 , a result less than one is a fraction of 1

In dividing values such as successive integers: N / (N+1) is less than 1, and approaches closer to 1 as N approaches infinity:

Ex. 1/2 = 0.5 , 2/3 = $0.666\underline{7}$, 3/4 = 0.75 , 9/10 = 0.9 , 542/543 = $0.998\underline{2}$

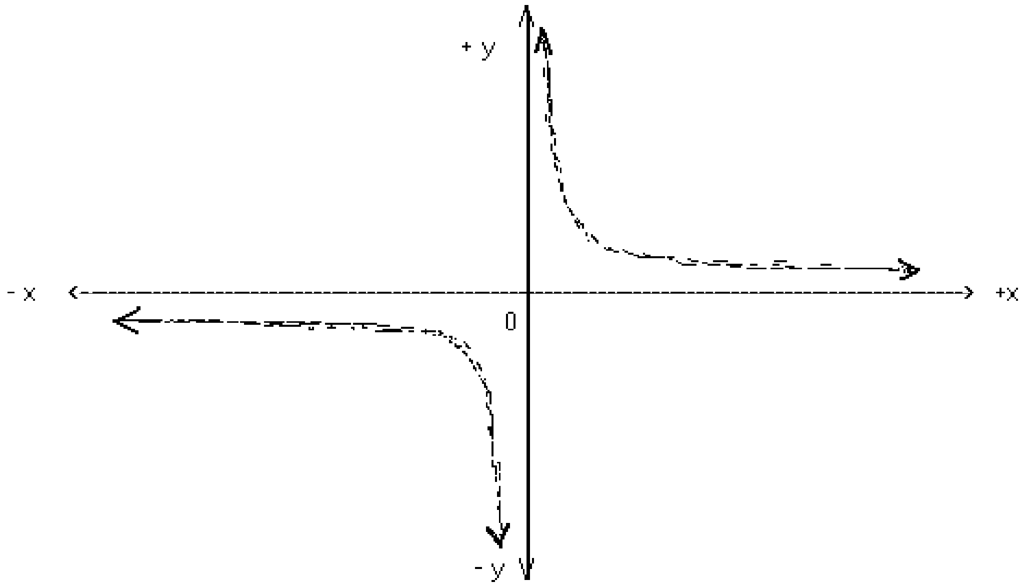
In an opposite way, (N +1) / N is greater than 1, and approaches closer to 1 as N approaches infinity.

Ex. $2/1 = 2$, $3/2 = 1.5$, $4/3 = 1.3333...$, $10/9 = 1.111...$, $543 / 542 = 1.0018...$

These quotients are reciprocal in value to the above results, since the values used were reciprocals. $(N+1) / N$ and $N / (N+1)$ are reciprocals of each other.

Ex. $3/2 = 1.5$, $4/3 = 1.333...$, $10/9 = 1.111..$, $502/501 = 1.002...$, $23510 / 23509 = 1.00004...$

When c=1, the equation $y = (c/x) = (1/x)$ could be called the "pure reciprocal equation". When the numerator is not equal to 1, you can put it into this "reciprocal form" by dividing both the numerator and denominator by the numerator (ie., canceling the numerator). [FIG 78]



The curve(s) of this equation are symmetrical to or about the origin (0,0), and to a line which passes through the origin which has a slope of 1. Note that the equation $c = xy$ may appear to have a form of a linear equation because the powers of the variables (x and y) are 1. When plotted, the curve does not resemble a line at all, but resembles, more or less, a quadratic or second degree equation. That is, this is formally a second degree equation because when variables are multiplied, the degree of the equation is the sum of the highest power of each different variable. As another example, here is a third degree equation:

$$\frac{x^2y^1}{c} = 1$$: sum of exponents = 2 + 1 = 3, hence a third degree equation

$$y = c / x^2 = cx^{-2} \quad \text{and} \quad x = \pm \sqrt{c / y}$$

A note on mathematically drawing a conic section or curve without a conic or second order equation:

You can mathematically draw a conic section on a piece of paper. Draw a line on the paper and choose a point nearby, perhaps an inch away. This line will become the directrix of the conic section or curve, and the point will be the focus (F) of the that curve being drawn.

For each point (p) on the curve being created, it will be a certain perpendicular distance from the directrix line, and a certain distance to the focus point, and the mathematical relationship (here, as a ratio) that the distance each point is from the directrix line and focus point is a constant of (e):

$$\frac{\text{(distance to focus)}}{\text{(distance to directrix)}} = \mathbf{e}$$

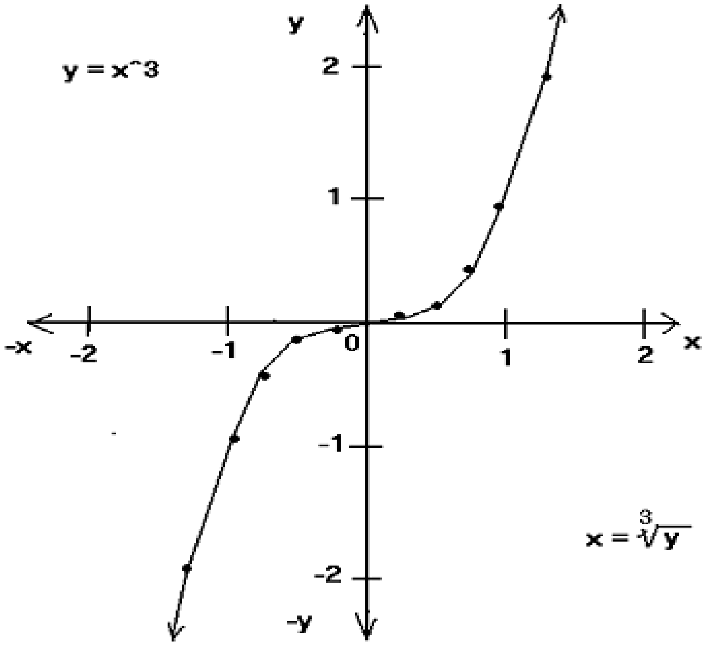
: e is a constant and is called the **eccentricity** of the conic section or curve
When (distance to focus) = (distance to directrix) , a constant, the curve is a parabola
When (distance to focus) < (distance to directrix), e<1, and the curve is an ellipse.
When (distance to focus) > (distance to directrix), e>1, and the curve is a hyperbola.

It could be said that circles have no eccentricity (e=0) or stretching, ellipses are like a circle stretched a little and have a little eccentricity (0<e<1), parabolas have moderate eccentricity (e=1), and hyperbolas have high eccentricity (e>1).

CUBE (CUBIC) , A non-conical (conic, cone) curve. This curve contains the third power of the variable.

The general cubic expression is: ax^3 + bx^2 + cx + d : constant (a) must not be 0 so as the x^3 term exists.
For a basic example: 1x^3 + 1x^2 + 1x^1 = 1 Here, the solution is about x=0.5435

There is a (somewhat complicated) formula to solve cubic equations, which can be found elsewhere if needed. Showing a graph of an example cubic function and its corresponding inverse function: [FIG 79]



If we multiply the simplest "quadratic" expression of x^2 , by x, we have the simplest "cubic" expression of:

(x^2)(x^1) = x^(2+1) = x^3

Expressing the mathematical relationship between (x) and the value or result of this expression, we have this equation:

$y = x^3$: essentially then, in this equation each (x), and the resulting (y) value of the parabola equation of: $y=x^2$ is multiplied by the factor (x).

This is similar to the graph of: $y = x^2$ except that the curve of $y=x^3$ is steeper (due to a steeper slope value) and is no longer symmetrical about the y-axis, which is essentially due to that after solving for x, we find: $x = \sqrt[3]{y}$, and here when (y) is negative in value, it produces and has corresponding negative (x) values.

A point on a graph can actually be identified by the two corresponding inverse functions, and here it would be:

$p(x, y) = p(\sqrt[3]{y}, x^3)$

Given this graph of the basic (cubic) equation of $y=x^3$, there is a specific and corresponding equation for the slope or "steepness" (from left to right, or increasing values of x) at any point of this curve, and it is:

slope at (x) = $3x^2$: Equations of this type will be discussed further ahead in the slope and derivative discussions. Technically, slope is the rate of change of (y) with respect to the changes in (x) at a given point. Because this expression has a variable, the slope value is not a constant value, but depends on the specific value of x.

Where on this curve is the steepness equal to +1? Setting this specific slope equation to 1, and solving for (x), we find:

$1 = 3x^2$, therefore: $x^2 = 1/3$, $x = \sqrt{0.3333...}$, $x = \pm 0.577...$

The corresponding (y) value is: $y = x^3 = (0.577)^3 = 0.192...$, and this point or location is: **(** ± 0.577 , ± 0.192 **)**
As (x) gets larger, the slope or rate of change increases greatly as should be expected for (increasing) values that are "cubed" (ie. number^3) or raised to any value greater than 1.

The word cube is rooted in the basic words for "elbow" (ie. a bend or angle), and possibly the words for "square", "surface", "box", and "cubit" which is a unit of measure or reference (ie, as a one-dimensional ruler for length) of the ancient world. Since a cube and other solid shapes, volumes or spaces have 3 dimensions (a length, width, and height) and therefore 3 ways to be measured, and with each having the same units of measurement, the number 3 is often associated with the words "cube" , "cubed" , and "cubic". Ex. 2^3 can be mentioned as "two cubed".

As a refresher discussion about cubed units (rather than just plain cubed numbers, ex: 5^3, without having any units):

5^3 ft is not the same as: 5 ft^3

5^3 ft = 125 ft having units of feet = ft^1, is not the same as 5 cubic-feet having units of: ft^3 = (cubic feet)

A unit of measurement: unit = unit^1 : for example, the unit of measurement or reference could be a length unit such as feet (ft), miles (mi), or meters (m), etc.
Ex: 5.23 feet

A squared unit, or a square unit: (unit) (unit) = unit^2 : Ex. 5.23 ft^2 = (5.23ft)(5.23ft) = "5.23 feet, squared"
= "5.23 square-feet"
= "5.23 feet=squared"

Ex. 2ft long, by 2ft high = (2)(2)(ft)(ft) = 4 ft^2 = "4 square-feet"
Ex. 2ft long, by 3 ft high = (2)(3)(ft)(ft) = 6 ft^2

A cubed unit, or cubic unit: (unit) (unit) (unit) or = (unit^2) (unit^1) = unit^3 : Ex. 5.23 ft^3 = "5.23 cubic-feet"
Ex. 2ft long, by 3ft wide, by 4ft high =
(2ft)(3ft)(4ft) = 24 ft^3 = "24 cubic-feet"

Ex. If considered in the shape of a cube, a million cubic feet of material would have a side or dimension length of:

$$\sqrt[3]{1000000\ ft^3} = \sqrt[3]{1000000}\ \sqrt[3]{1\ ft^3} = (100)(1\ ft) \quad \text{or} = 1\ (10^{(6/3)}\ ft) = 10^2\ ft = 100\ ft$$

That is, this cube or cubic shape of material would have a length of 100 ft, a width of 100 ft, and a height of 100 ft.

GOLDEN RATIO (In a geometric series, with a basic curve example.)

Though not often seen and-or encountered as much as the other common curves, the golden ratio (GR) is still important. For simplicity, we will use **GR =~ 0.618**

If GR was the first term of a series, and if you took 0.618 of it and of each successive term, the sum would equal:
1+GR = 1 + 0.618 = 1.618 = 1/GR = 1/0.618 :

Term :	1	2	3	4	5	6	7	. . .	
Value :	0.618	0.382	0.236	0.146	0.0902	0.056	0.034	. . .	Algebraically:
Expression:	GR	GR(GR)=GR^2	GR^3	GR^4	GR^5	GR^6	GR^7	. . .	

The value of each term (n) is: GR^n : n=term number

The sum of all the terms approaches: 1.618**...** = (1+GR) = 1/GR : as (n), the number of terms, approaches infinity

A peculiarity is that if you were to subtract each term (GR^n) from its preceding term, you would have the next term. This is similar to a (natural, basic) Fibonacci Series, if those terms above were reversed into an ascending series, and the next term was the sum of its two previous terms. Here, the next term of this series is the difference between the last two terms.

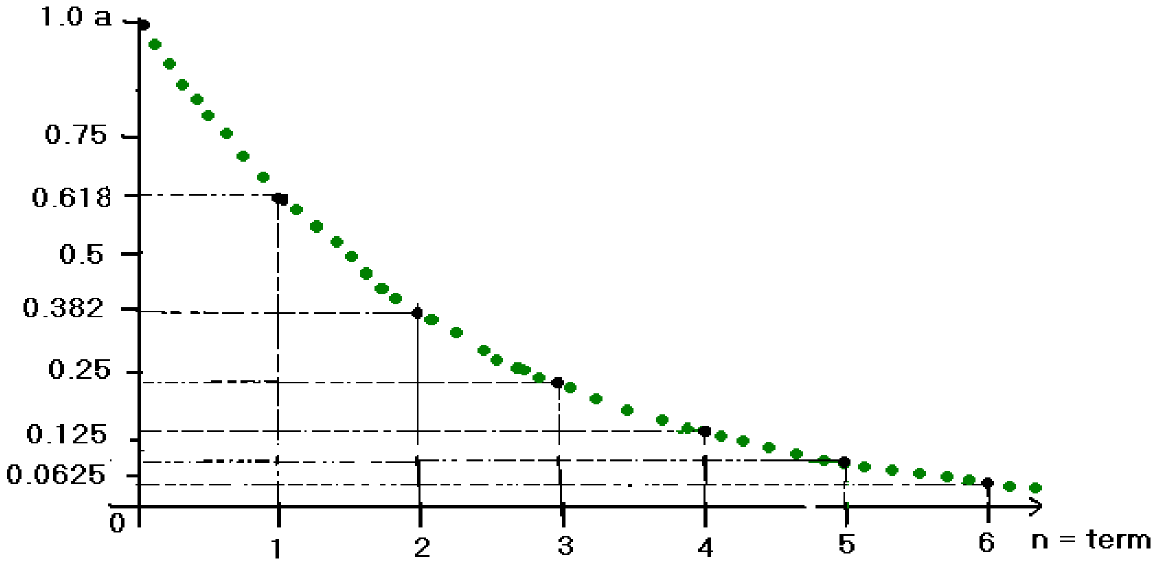
(GR)^(n+1) = (GR)^(n-1) - (GR)^n :ex. 0.236 = 0.618 - 0.382 = 0.236 , Mathematically:
(GR)^(n-1) = (GR)^n + (GR)^(n+1) Also considering just the first two terms:
1.0 = (GR)^1 + (GR)^2

If there is an initial starting term value (a), the geometric series (with multiplier r = GR = 0.618) could be expressed as:

Term:	1	2	3	. . .	
Value:	a	a(GR)	(a(GR))(GR)	. . .	with simplified expression of:
	a	a(GR)^1	a(GR)^2	. . .	**:** (a) becomes a multiplier to the value of each term above

The sum of these terms is: a + a(GR)^1 + a(GR)^2 + **...** = a (1 + GR^1 + GR^2 + **...**) = a(1+1.618**...**) = a 2.618**...**
= a(2 + 0.618...) = 2a + (GR)a

[FIG 80]



The value of each term (n) is: (a)GR^(n-1) : the term number (n) can also be a mixed number, ex. n=1.5

Ex. Given y = a GR^n , if value (a) starts out with a value of 1 (or 100%) and is processed by the formula and undergoes change in its value, and letting (y) be set to each new resulting value as (n) changes, at what term (n) will (y) be equal to half of (a's) starting value, hence where y = a/2 = 1/2 = 0.5?

Expressing the above data into the equation or formula:

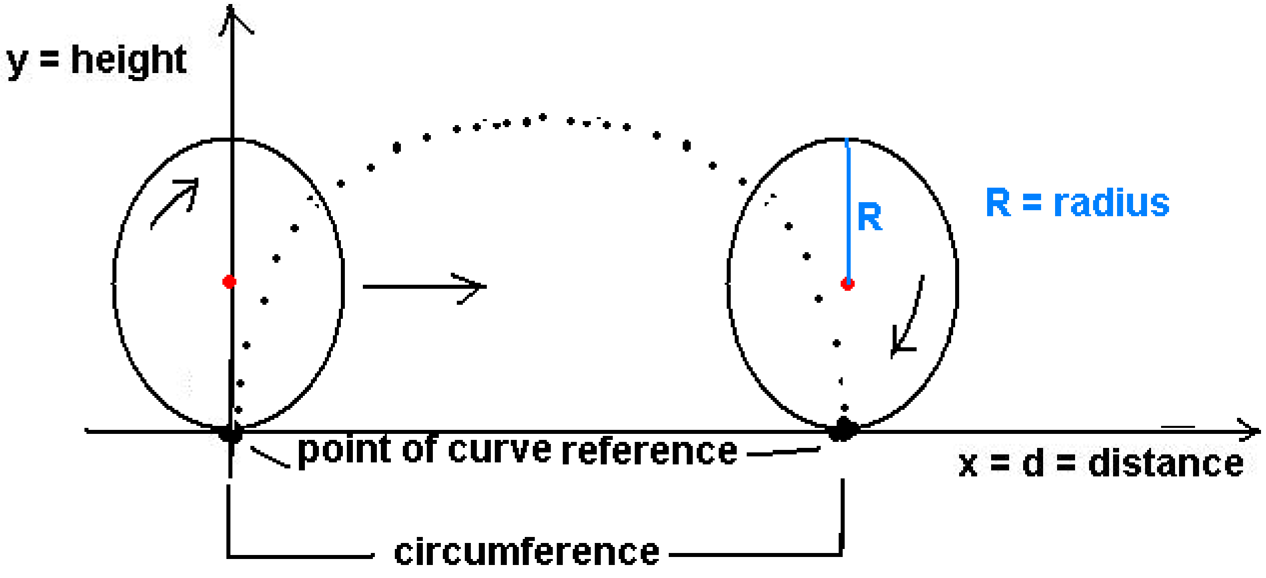
0.5 = (1) GR^n or simply:
0.5 = GR^n solving for (n) by taking the logarithm of both sides of the equation:

log 0.5 = log GR^n by using the law exponent rule:
log 0.5 = n log GR after solving for (n):

$$n = \frac{\log 0.5}{\log GR} = \frac{\log 0.5}{\log 0.618} = \frac{-0.30103}{-0.20901} = 1.4403$$

CYCLOID

The cycloid curve is a beautiful curve created when a point on a rotating wheel moving on a flat and straight surface is recorded or "traced out" for one revolution. This path or locus of this point will create a curve resembles that of a elongated half-circle and-or semi-sphere. A cycloid shape also resembles a bowl shape. [FIG 80A]



The maximum height and-or (y) value of this curve is equal to twice the radius of the circle, hence 2R, and the corresponding (x) value is equal to half the circumference of this circle.

If the distance the wheel is rotated and moved horizontally is C = 2 (pi) R, the coordinates of the max. height point are:
P(x , y) = P(circumference / 2 , 2R) = P(2 (pi) R / 2 , 2R) = P((pi) R , 2R)

Though the cycloid curve probably was discovered in ancient times, it took until Galileo Galilee to make a reasonable mathematical analysis of it. By experiments, he discovered that the area of a cycloid is three times that of the circle that was used to create it. It was later found that the arc length of a cycloid is equal to 8 times the radius (R) of the circle or wheel that created it, hence: S = 8R = 8 (D/2) where D is the diameter of the circle, hence S = 4D

A cycloid curve is one of a general class of curves called **roulettes** of which are the path traced out when one curve moves about another curve, and the resulting or third curve is the roulette of those two curves. Ways and-or patterns templates to make roulette curves have been in use for several hundred years, and possibly some since in ancient times. A modern, affordable and and very popular educational toy for mechanically drawing roulettes uses the aid of various (plastic) gears with several holes in them to place a pencil or (ink) pen for drawing (ie., "tracing out" the path or locus) the resulting curve is called the **Spirograph.** It was created by **Denys Fisher** (1918 - 2002), from England, in 1965. In this modern (2024) so called "digital world" or "virtual (simulated, as like) world", there is still much mechanical things (machines and mechanisms) still needed - both in use and-or design, and with some new ones being designed and analyzed with the aid of digital computers.

Another type of special curve is called an **involute curve**, and this is created by for example unwinding a tensioned string from a shape such as a circle, and the resulting curve is a spiral. Modern and efficient (at transferring maximum power via constant gear teeth contact any "slippage") gear teeth or protrusions are designed to have an involute of a circle. segments.

[This space for book edits.]

SECTION 3: BASIC TRIGONOMETRY
THE STUDY AND MEASUSREMENT OF TRIANGLES

Trigonometry (triangle measurement) is the study, application and measurement of and with triangles, triangle-like structures, constructions and angles in general. A triangle is bounded (ie., defined) part or portion of a plane, and having three straight sides. A plane is like an infinitely "flat" surface extending in all directions, but without a thickness. A plane is a flat, 2 dimensional concept that can be described and measured in two ways: a length, and a width. A plane is formally defined as having no thickness measurement (other than being 1 infinitely small point thick). A line is an infinite amount or set of adjacent, infinitely small points on a plane, and all being in the same direction with respect to each other. For a triangle construction, this bounded or enclosed portion, shape or figure of a plane has three sides that are line segments or "sides", and of which each side will intersect the other two sides.

An angle is a separation created by the rotation of a line or point about another point (such as the center of a circle) or line that is used as a reference position, and the measurement of an angle is the amount of (circular-like) the rotation or separation. Each side of the triangle will intersect (ie. meet or join at) the two other sides, and this will create three interior angles of the triangle. The "tri" in the word "triangle" means triple or three, therefore, the word "triangle" literally means "three angles". The word "angle" as used here, is actually from an old word of "angle", which means a bend, turn, or a corner (such as the location where two walls joined, met or connected together). See [Fig 81 for an image of an angle, and Fig 83 for and image of a triangle].

Angles are usually measured with angle or rotation units called degrees which is the amount rotation about a point. The word "degree" means the intensity, quantity, amount or size of the rotation and-or angle. The word "degree" is rooted in an the old words of "step" as for stairs, steepness, and "grade" for the intensity, level or marking (as in the successive "graduations" or indicated steps of a measuring device). The word degree is also often used when stating a temperature value such as: "it is 72 degrees Fahrenheit" (= 72° F). The symbol of: (°) is often used to indicate that a value is an angle with degrees as it units measurement. For example, 35° is "thirty-five degrees" or "a thirty-five degree angle" = 35 degrees.

To give you an idea of what various sized angles and their corresponding degrees of measurement are, a complete rotation of a point around another point, regardless of the distance between those two points, is defined as a 360° ("360 degrees") angle or rotation from its initial, starting or reference (0°) position. This full rotation will create a circle when the distance (the radial, or radius distance) between those two points was always constant. This arbitrary and manageable (not too big and not too small) value of 360 degrees for 1 full rotation was chosen long ago when noting that it took planet Earth roughly, or about, 360 days to cycle through all the seasons and start again for a new year, This is roughly how long it takes Earth to orbit the Sun, and that is about 365 days, and technically it is 365.25 days. 360 is also number which can be easily divided. Any angle less than 360° is, and can be thought of as a fraction of 1 full rotation.

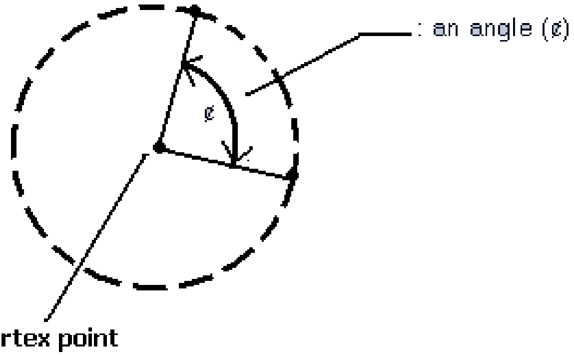
An angle can be described as the following:

Two lines (or line segments) that cross or are connected together at one ("pivot", rotation) point, such as an endpoint on each line, and can then be made to rotate about each other, creating an angle or separation between those two lines.

Given a circle, you can imagine or draw an initial (starting) line between a point rotating about or around a (fixed, or stationary) center point, and then draw another (ending) line between where the rotation of that initial line or point has stopped and the center point. The intersection (vertex point, which is similar to a pivot point) of these two lines, or any other two lines such as two sides of a triangle, will create an angle (a separation) between those two lines.

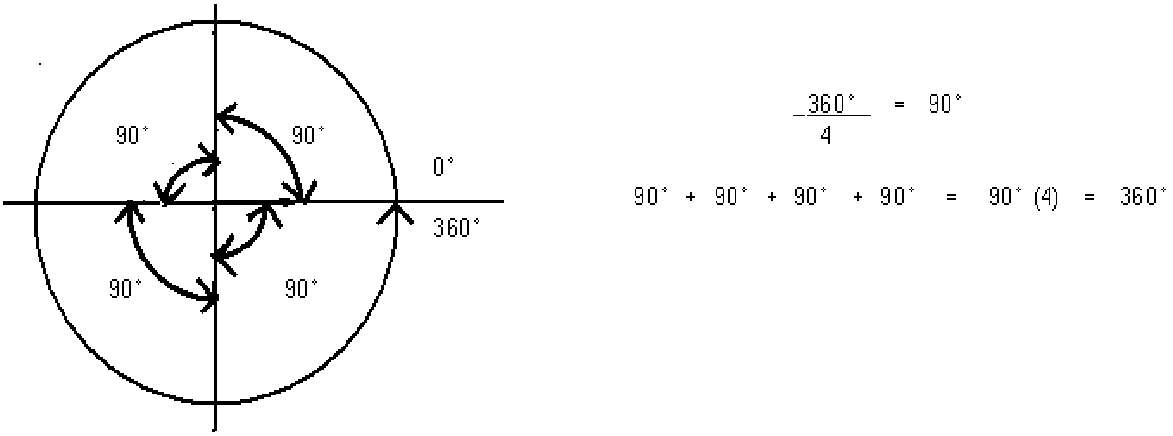
It could be said that the degrees or the measure of an angle is the amount of separation of or between two lines that intersect at a point (the vertex), and which have, or could even be considered to have rotated about that common point (the vertex, reference, or pivot point, as the "origin or center of rotation").

The amount of degree units of an angle is its (rotational, separation, or angular) measure, and this is not a linear, one-dimensional length or distance measurement. For example, circles can be very small or big, or a point or object can rotate near to, or very far from the center (of rotation), and yet each angle would still be the same value regardless of the distances or size from the (reference) center. Any circle has a 360 degree angle for a full rotation about it center, and a (360/2) = 180 degree angle for half of a full rotation, and a (360/4) = (180/2) = 90 degree angle for a quarter or one-fourth of a full rotation. A common symbol for an angle is: ¢ , and may be sometimes noted with the degree units symbol: ¢° [FIG 81]



The point where two sides (considered as lines) of a angle or triangle meet or intersect is formally called the vertex ("point", "location" , "meeting", "joining", or "intersection") of the angle. The word of "vertex" is rooted in the words such as "vertical peak", "apex" (vertex is a short and combined form for the words: "vertical apex"), or "summit" where the sides of a hill or mountain meet (intersect). The word "vertical" basically means in an upward or downward direction, as opposed to the word "horizontal" (ie. "horizon") direction which means "level" (no upward direction or angle) or in the left or right directions. The curved arrows are often used to indicate that some movement, separation or rotation has happened, hence an angle and-or its shape was created or is present.

A right angle is defined as one-quarter (1/4) of an angle that would give a full rotation of 360°, hence a right angle is (360°/4 =) 90° ("ninety degrees"). A triangle that has two sides that intersect at a right angle (perpendicularly, like two sides of a square or rectangle) is called a right triangle. The sum of any triangles interior angles is always 180°. [FIG 82]



$$\frac{360^\circ}{4} = 90^\circ$$

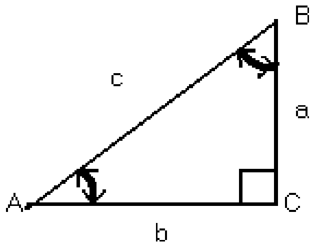
$$90^\circ + 90^\circ + 90^\circ + 90^\circ = 90^\circ(4) = 360^\circ$$

The above illustration also shows that when a line is completely rotated (a 0° to 360° angle) once (1) about the fixed center (point of rotation), that an angle of 360 degrees is created. Clearly a rectangular coordinate system or a circle can be divided up into 4 equal sections and each is called a quadrant (meaning one-fourth or a quarter of something). Each quadrant corresponds to, or has a maximum angle of (360 degrees / 4) = 90 degrees.

The amount of a rotation and its corresponding angle of measurement is often measured or can be considered to be in reference to the x-axis in the upper right quadrant. This would be considered the starting or 0 degree position, and the starting side of a rotation or angle. The x-axis is therefore often called the "reference axis" or "x-reference axis" for all "standard measured" angles. The angles measured this way will then have its second or ending side within one of these four quadrants and these angles are sometimes called as a specific (1 to 4) quadrant angle. A standard measured angle will have its "ending" side within one of these quadrants. The angle between that ending side and the x-axis (when considered as a side of an angle) is created and this angle will be less than or equal to 90 degrees and it therefore has an equivalent "mirror image" or corresponding angle of the same value in the first quadrant. [See Fig. 152] Therefore, the specific given quadrant angle can often be analyzed or considered as if it were a first quadrant angle that is less than or equal to 90 degrees. This practical property will be used later in this book when considering the very useful topic of trigonometric values. The word "trigonometric", which could actually mean any measurement pertaining to a triangles, is a usually associated with the ratio values of two sides of an angle or triangle. For basic discussions of triangles, the concepts of quadrant angles are generally not used since for a triangle, the maximum angle is 180°, and often the maximum angle encountered is just 90° such as for a common right-triangle.

The longest side of a right triangle is formally called the **hypotenuse** (side). Sometimes the longest side of any triangle is called this so as to also reverence it as the longest side of that triangle. In a right triangle, the hypotenuse side is directly opposite the right angle, and vice-versa. The somewhat (modernly) odd word of "hypotenuse" is a Latin-Greek word-form meaning "stretching [teinein] - a word similar to the modern English word of tension - a pull force, such as to straighten a cord] under [hypo], under, beneath or across from. This longest side of a triangle could probably be called the major side of a triangle.

Since the shortest distance between two points (such as the end points of the hypotenuse side) is the straight-line distance between those two points, the hypotenuse side is therefore always shorter than the other two sides summed together. Right triangles are perhaps the most studied triangles since their concepts have many practical applications. Right triangles are also used for models or theory of many concepts. Below is an example and description of a right triangle. [FIG 83]



: a right triangle

Here, capital lettered variables are used to represent the triangle's angles. As mentioned previously, angles can be explicitly (directly, surely) expressed or indicated between the two sides (lines) of an angle with a small arrow or the angle symbol: (¢) with a possible subscript indicating which specific angle it is. For conformity and understanding, the sides directly opposite of those angles in a triangle are usually indicated with a corresponding small letter variable. This is the method done so as to avoid a problem of knowing which one of the two actual sides forming, or of that angle should be indicated as corresponding to that angle(s), and then how to then possibly indicate the side opposite that angle(s). For example, side (a), is directly "opposite" or across from the corresponding angle and vertex labeled as A. The corresponding side that is directly across from an angle will also intersect the two sides of that defined angle, and so as to create or complete the triangle shape.

A small square box shape is frequently used to indicate the "right", "square", or perpendicular (at the side of), 90° angle (here, angle C) in triangles or in any other construction that has a perpendicular intersection of (perpendicular) sides or lines in drawings. This small box, square, or "turn symbol" indicates that the corresponding sides there are perpendicular (at a right angle = 90°) or "square" to each other. In the right triangle shown, the side opposite of this 90° angle is the hypotenuse side and side (here, side c).

Even though the hypotenuse side (here, side c) is the longest side of a triangle, and like any line, it is actually the shortest distance between its' two endpoints since the "straight-line" distance from one point to any other point is always the shortest distance, and any other path or directions taken between them will only result in a longer distance. The sum of any two sides is therefore always longer than the third side in a triangle. Consider a right triangle with side (c) being the hypotenuse side:

$c > a$ and $c > b$: c, the hypotenuse, is always the longest of the three sides of a right triangle

$(a + b) > c$: this can also be expressed as: $c < (a + b)$

To determine if an angle is indeed a right, 90° angle, you can first measure the same distance from the angles vertex and along on each of the sides or "legs". The distance from one point to the other will be about $\sqrt{2}$, (= about 1.414) times that of the same distance along each leg. This can be derived and checked from the Pythagorean Theorem.

SOLVING FOR AN ANGLE

If given any triangle, and one angle is unknown, this angle can be easily solved for by the fact that the interior angle sum of angles in a triangle is always 180°, and that a right angle is 90°. Placing this information into equation form:

$180° = A + B + C$ Letting angle C=90° for a right triangle:
$180° = A + B + 90°$ transposing 90°:
$180°-90° = A + B + 90°-90°$ combining:

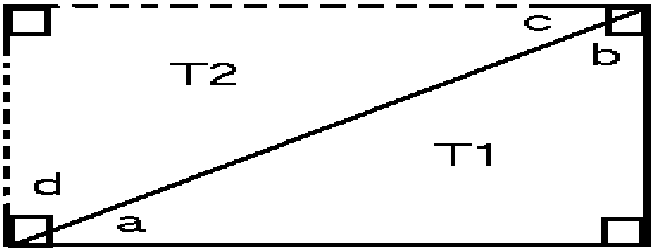
$90° = A + B$: In a right triangle, the sum of the other two angles that are less than 90°, such as A and B here, is always equal to 90°.

Ex. Given a right triangle, if A=30°, what is B ?

$90° = A + B$
$90° = 30° + B$ T., transposing 30°:
$90°-30° = 30° +B -30°$ C., combining terms:
$60° = B$: switching sides:
$B = 60°$

Given a triangle, since the sum of internal (or interior) angles is always 180°, if any one angle changes in value, one or both of the two other angles must change in value. If one angle is to remain fixed or constant in value such as when a triangle is to remain a right triangle with its 90° angle, then if one angle increases the other (the complementary angle) must decrease, and vice-versa. A and B, the non-right angles, are said to be complementary angles to each other and of the of a right triangle. Those angles complement each other by always completing a sum of 90°

Here is a quick verification that the interior angle sum of any right triangle is 180° [FIG 84]



Clearly, the interior of any rectangle has four 90° right angles, turns or corners: 4(90°)= 360° = interior angle sum of any rectangle. Since the rectangle is divided exactly in half, creating two identical right triangles, the interior angle sum of each triangle is half of 360° or 360°/2 = 180°. If you were to subtract the 90°, right angle of this triangle from the triangles interior sum of 180°, there will remain 90° left over. In the drawing or figure, clearly, (a+b) must then sum to this remaining 90°, and (c+d) will also. The two non-right angles in a right triangle will always sum to 90°.

$(a+b) = (c+d) = 90°$ since by construction, T1 and T2 are identical (the same, but mirror images), therefore (a) and (c) are identical: (a=c), and (d) and (b) are identical: (d=b).

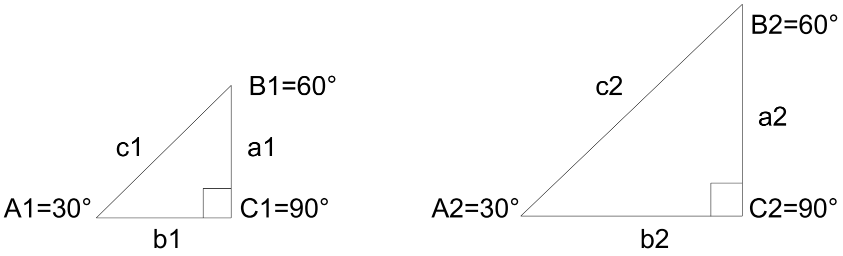
$(a+b) = (c+b) = 90°$: clearly also: (a+d)=90 , and (c+b) = 90° due to a right angle being 90°
$a+b = c+b$ after subtracting b from each side of this equation:
$a = c$: showing that the **alternate interior angles are equal**, and likewise:
$b = d$ In this instance of using a rectangle,,both the corners, and alternate interior angle sum to 90. This topic here is also a future reference in this book: Notice that the diagonal line goes from, transverses or crosses, the two parallel lines (here the upper and lower sides of the rectangle). All the angles created within the two bounding parallel lines are called interior angles. The angles created on opposite or alternate sides of that ("transversal") line are called alternate

angles, hence they are also called alternate interior angles since they are between the two lines. Here, c and a, and b and d are alternate interior angles of equal value.

Due to the construction of the rectangle having 90° internal (corner) angles, of which are called "right angles", angles (a) and (d) are complementary angles that sum up to 90°, and angles (b) and (c) are complementary angles that sum up to 90°.

SIMILAR TRIANGLES

Triangles that look very alike, but are either "bigger" or "smaller" in size, are called similar triangles. It could be said that one triangle is simply a magnified (bigger), or demagnified (smaller) view of the other. Besides from the visual point of view, certain (mathematical) conditions must also be met so that the triangles are indeed similar. They actually look alike, and are similar triangle constructions because the corresponding angles of the two are the same. The sides of similar triangle constructions usually differ in length, but they are not just any random lengths within that similar triangle. A similar triangle has sides that will have the same mathematical proportions (equivalent portions, ratios, fractions) among them as any other similar triangle. That is the result when each side of a similar triangle is a constant multiple (ie. a magnification factor) of the corresponding side of another similar triangle. Below are two right triangles that are similar, and in fact, there is an infinite number of similar triangles. [FIG 85]



TRIANGLE 1 TRIANGLE 2

The small numbers next to the variables are called subscripts. Subscripts were mentioned previously where they were used to represent a particular instance of the same variable or equation. They are also used to show that the variables are not actually the same, but are unique even though the same symbol or identifier (identifying name) for the variable is chosen for a specific set, class, group, or type of data. Here, identical variable names with the lower case letters represent corresponding sides of the similar triangles, and the subscripts represent which triangle it is in reference to. Also, capital or "upper case" letter variables represent the inner or interior angles (of the triangle) created due to its intersecting sides. Sometimes, a subscript is written or expressed in standard or normal notation, for example, A1 might be written as A_1., however this is technically a new variable name or identifier which may even be sub-scripted; ex. $A1_5$ For simplicity and for use with most text readers, this book often uses a common or standard typeset instead of standard subscripts which is a smaller print.

Though the sides of similar triangles usually differ in length, there is still a mathematical relationship among those similar triangles. The relationship, as stated previously, is that they are proportional. A part of any one triangle of all similar triangles is mathematically a certain portion or fraction value in reference to any other part in that triangle. Therefore, the ratio of any two sides of one triangle is equal to the ratio of the same two corresponding sides of another similar triangle. This is a proportions (equivalent, of or having the same portion of the whole or entirety) and-or an equivalent fractions concept when the ratio of corresponding sides are considered.

A similar triangle is essentially a magnified construction of another triangle. Each and every part of a construction must be magnified (increased, or possibly decreased) in value by the same (factor) value so that the result is truly a complete similar construction.

If the sides of a triangle1 are (a1) , (b1), and (c1), we can create a similar triangle, triangle2, by multiplying each side of triangle1 by the same factor or magnification value (n):

a1(n) = (a1)n = a2
b1(n) = (b1)n = b2
c(1n) = (c1)n = c2

Besides having all angle values the same value as another triangle, when a triangle or other construction is similar to that of another, the ratio of all corresponding parts of the two triangles must have the same (magnification) value:

$\frac{a2}{a1} = \frac{b2}{b1} = \frac{c2}{c1} = n$: the reciprocal of each ratio, or "inverse reciprocal", will also have the same value, and that is of the reciprocal of n or= (1/n).

Given that triangle 1 and triangle 2, as shown in the last figure, are similar triangles, here are some examples of all the possible equivalent fractions or proportions of their parts:

ratio of parts of a triangle = corresponding ratio of parts of any similar triangle

Ex. $\frac{a1}{c1} = \frac{a2}{c2} = r1$: the ratio of sides of similar triangle 1 = the ratio of corresponding sides of similar triangle 2. If the angles, and-or ratios are not the same, the triangles are not similar.

Ex. $\frac{a1}{b1} = \frac{a2}{b2} = r2$: these ratios (r1, r2, r3, etc.) of the sides of similar triangles are generally not the same value

Ex. $\frac{b1}{c1} = \frac{b2}{c2} = r3$

When dealing with similar triangles, there are two different types of ratios to consider. One type of side ratio is a ratio of the parts of just one triangle. For another type of side ratio, it is a ratio of corresponding parts of two similar triangles.

As indicated previously, for similar triangles, the relationship among the sides is that the ratio of any side of triangle1 to the corresponding side of triangle2, is equal to the ratio of another side of triangle1 to its corresponding side of triangle2:

Ex. $\frac{a1}{a2} = \frac{b1}{b2} = m$: the ratio of a corresponding sides of two similar constructions, such as similar triangles, is the common magnification ((m), ie., multiplication) factor for all corresponding sides of the similar triangle

For the verification of this, notice that for the previous examples, that these two different types of side ratios for similar triangles can be mathematically derived from each other:

Given: $\frac{a1}{a2} = \frac{b1}{b2} = m$: the ratios of corresponding sides of two similar triangles are equivalent after multiplying each side by (a2/b1), and canceling common factors in the num. and den.:

$\frac{a1}{b1} = \frac{a2}{b2} = r$: the corresponding ratio of sides within each similar triangle are equivalent. In general, (m) and (r) are not equal in value.

You might ask: "What is it that makes these ratio values equal to each other?" "Why is the ratio of a1 to a2 equal to the ratio that b1 is to b2?" There's nothing intuitive that the ratio values should be the same, other than the sides are now known to be mathematically proportional, a simple answer is that you are actually viewing the same triangle either closer (where its apparently bigger and measured as such) or farther away (where its apparently smaller and measured as such), hence the triangles are "visually proportional". For similar triangles, corresponding sides will be different, but the corresponding angles always remain the same. Hence in a fundamental sense, similar triangles are initially due to identical angles. These identical angles define the similar shape of all similar triangles. Although the concept of magnification and its value to create a similar triangle or construction were mentioned, a verification to this equivalent magnification ratio (m) value of all corresponding parts or sides of a similar triangles or other planar constructions is presented further ahead after the discussion about trigonometric ratios.

With the information presented above, when given two similar triangles, the length of a (unknown) side can now be solved for if there is enough information to place into a proportion (ie., equivalent fraction) problem as shown above:

Ex. Using the triangles shown previously in [FIG 85], solve for c2 given: a1=3, b1=4, c1=5, a2=5.25, and b2=7.

Since the triangles are similar, writing a known mathematical relationship of the sides of similar triangles:

$\frac{c1}{b1} = \frac{c2}{b2}$ substituting the known values:

$\frac{5}{4} = \frac{c2}{7}$ after solving for c2:

$c2 = 8.75$

Checking:

$\frac{5}{4} = \frac{8.75}{7} = 1.25$: the corresponding ratios or fractions of each similar triangle are equivalent in value

Extra: The trigonometric ratio and topics in the following not will be discussed throughout the rest of this book here and there. Some of this relates to what has just been discussed.

Given a right triangle, the ratio of the side opposite of an angle to the longest or hypotenuse side is called the sine of that angle. The ratio of the side adjacent to an angle to the longest or hypotenuse side is called the cosine of of that angle. The ratio of the side opposite to an angle to the side adjacent to an angle is called the tangent value of that angle. For this example we will use just the cos ¢ value, but sin and tan analysis also will be similar.

cos ¢ = adjacent the angle / hypotenuse = adj. / hyp. = b / c , mathematically:

b = (cos ¢) c

Though trigonometric values are not linear with respect to the angle, the above equation has the form of a linear (ie., graphs as a line) equation of: y = m x . Here, (m) is a constant value. For a constant angle, such as for a similar triangle, the (cos ¢) value is then also a constant value.

For creating a similar triangle, If say side (c) increases or changes by a factor of (n), being greater or less than 1, then all the other sides of that similar triangle, here (a) and (b) will likewise change by that same factor value. If the heights of a triangle are considered, then they will also change by that same factor of (n).

Mathematically, to keep both sides of this equation in balance, each side will need to be multiplied by that same factor of (n):

n b = n (cos ¢) c
n b = (cos ¢) n c mathematically:

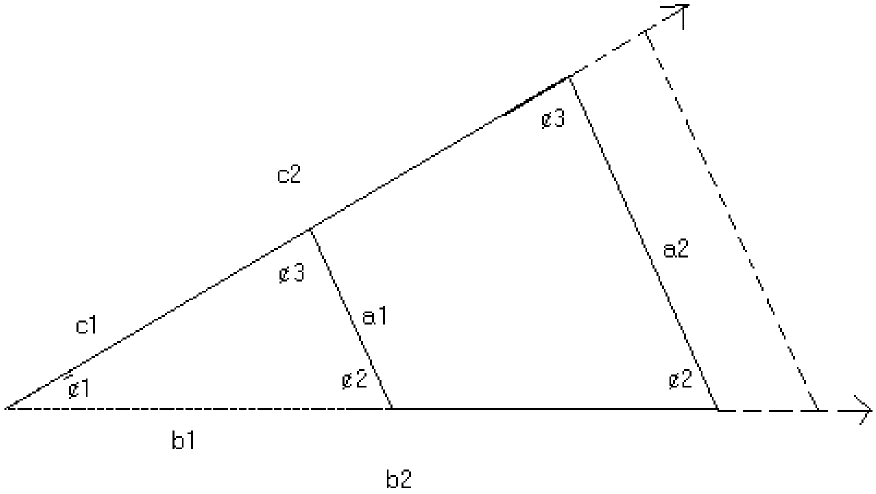
cos ¢ = $\frac{n\,b}{n\,c} = \frac{b}{c}$: showing the equivalent ratios, fractions or portions of similar triangles

CONSTRUCTING SIMILAR TRIANGLES

Constructing similar triangles, whether actual constructions, or drawings, is quite easy. Most of the facts and details to do this were previously indicated or mentioned, and a few others will be mentioned.

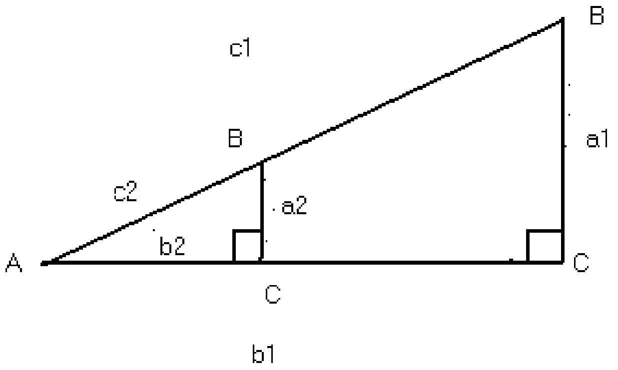
The simplest method to create a similar triangle is to use a line(s) that is parallel (and possibly even on the same line or an "extended line") to each corresponding side. Of course, to construct a similar triangle, the side lengths will be changed in value so that all its sides can intersect at some point, creating the triangle. In general, to make a parallel line to any side of a triangle, extend or reduce both (adjoining) nearby sides by the same factor or percentage value, and then connect these new end points with a (parallel) line(s). The length of each parallel lines will correspondingly be the same portion, factor or percent longer or shorter than the corresponding side of the original similar triangle.

Ex. Below, triangle1 with sides: a1, b1, and c1, is a general representation of any triangle. Sides b1 and c1 were then extended (here, partially indicated with the dotted lines, and arrow) to create a larger similar triangle called triangle2 with sides a2, b2, and c2. Sides b2 and c2 were then also extended (lengthened) by the same percentage or multiplier. Side a2 of triangle2 will be parallel to a1 and extended (ie., mathematically multiplied by) by the same factor used for b2 and c2.. After the construction below, triangle1 will becomes a smaller and internal similar triangle to triangle2. [FIG 86]



Obviously, ¢1 for each of the similar triangle's above is the same. The verification that ¢2, and ¢3 are the same for both triangles, as expected for similar triangles, is discussed ahead in the topic of: Corresponding Angles Created By A Transversal Line.

In the figure below, a line parallel to side a1 of a given triangle construction (a1, b1, c1) will be created and it will be called a2, and will be used to construct a small internal similar (right) triangle: [FIG 87]



It is quite easy to prove that they are similar triangles. For both triangles, angle A is the same value since it is bounded by the same sides or lines that intersect at a common vertex. Angle C is also the same, here it's 90° since they are right triangles. Angle B must also be the same value for both triangles due to the fact that the complementary angles (A and B), a concept that will be discussed further in this book, of a right triangle always total to 90° Hence if angle A is the same for both, angle B must be the same for both. Since all angles are the same, the triangles can only be similar, regardless of the side lengths. The result is that one triangle is simply a magnification of the other. Note that side a2 is parallel to side a1, and this "parallel side method" is actually a quick method to create a similar triangle.

By using the triangle above and the mathematical concepts of similar triangles and equivalent fractions, a very useful observation can be made. For example, at a point that is located at half of side b1, what is the (perpendicular to b1) height (to the other side) of the triangle at that specific point? The answer is the height is also halved, and this is verified below:

Since the angle (A in the above diagram) is constant, the tangent (TAN, a specific ratio of sides of a given (constant) angle which will be discussed ahead) value of that angle will also be constant:

$$\text{TAN } ¢ = \frac{a1}{b1} = \frac{a2}{b2}$$: the ratio of sides within a triangle are the same for any similar triangle

In more general terms, multiplying or dividing both the numerator and denominator by the same (factor, multiplier (m), or magnification) value will create an equivalent fraction whose ratio value is the same, and the ratio is constant, such as in similar triangles.

$$\text{TAN } ¢ = \frac{a1}{b1} = \frac{ma1}{mb1} = \frac{a2}{b2}$$: m is some multiplying factor

For the above example, half of b1 is (b1/2) = 0.5b1. Multiplying a1 by 0.5 to make an equivalent fraction (and similar triangle):

$$\text{TAN } ¢ = \frac{a1}{b1} = \frac{0.50a1}{0.50b1}$$: 0.50 = 1/2 = 50% = "half"

At half of b1, then a1, the (perpendicular) height at b1, must also be halved so as to be a similar triangle with the same portions.

Ex. At a tenth (or 10%) of b1, the height (a2) is also a tenth of a1.

$$\frac{b1}{10} = b1(0.10) = b2\,, \quad \text{and} \quad \frac{a1}{10} = a1(0.10) = a2$$

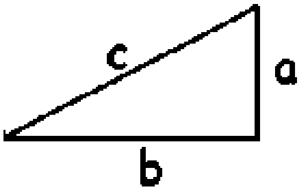
In short, to construct a similar triangle, you can reduce or increase each side by the same factor or percentage value.

If given just a single triangle, solving for the value of a side using proportions would not be possible since there is no other similar triangle to relate or be in reference to. There is however, a mathematical relationship among the sides of a single right triangle which will allow us to solve for a side if enough parts of that triangle are known. This method uses the Pythagorean Theorem, and it is discussed next. There are also some generalized methods that are discussed later that can solve for a part of any triangle if enough of its other parts are known.

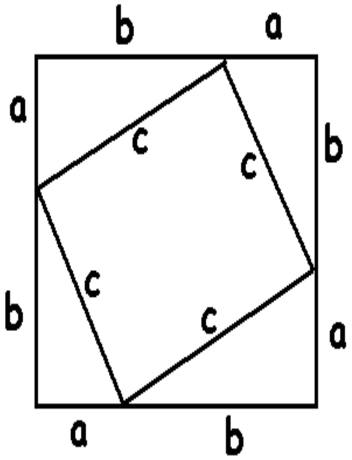
DERIVING THE PYTHAGOREAN THEOREM

Here is a derivation of the Pythagorean Theorem, and more specifically a simple mathematical **verification** of it among the several possible ways to do so. The mathematical relationship among the sides of a right triangle (ie., contains a 90° degree "right angle") is expressed by the very popular **Pythagorean Theorem** which is named after an ancient Greek mathematician named Pythagoras (570BC-495BC) who was the first to mathematically proved it in about 530BC, however the concepts of the theorem were known for perhaps a thousands years before him. A **theorem** (related to the word: "theory") is an idea or proposition of something that appears to be true by being verified by many supporting ideas and examples, and-or can be proven as true as a fact. Perhaps a more general name for the Pythagorean Theorem would be the Right Triangle Theorem. Expressing this mathematical relationship among the sides [FIG 88]:

$c^2 = a^2 + b^2$: here, c = hypotenuse or longest side of a right triangle
and (a) and (b) are the sides or "legs" of the right angle



There are many mathematical derivations of the Pythagorean Theorem. This formula for the longest or hypotenuse side of a right triangle construction should be memorized since it is one of the most useful formulas found in mathematics. Observe the drawing and derivation below for a verification of the Pythagorean Theorem: [FIG 89]



Like the area of a puzzle, the total area of the drawing above is the sum of all the areas of each piece: the inner square and the four identical (right) triangles. The total area is also equal to the area defined by the outer perimeter which is a square whose side length is (a + b), hence the total area is $(a + b)^2$

Total Area = Area of outer square = Area of inner square + Area of the 4 similar triangles
Total Area - Area of the inner square = Area of the 4 similar triangles

$$(a + b)^2 - c^2 = 4\left(\frac{ab}{2}\right) = \frac{4ab}{2} = 2ab$$

after some expanding and simplification:

$a^2 + 2ab + b^2 - c^2 = 2ab$ after solving for c^2, the hypotenuse of the triangles:

$c^2 = a^2 + b^2$: **PYTHAGOREAN THEOREM** (verified for right-angled triangles with (c) as the longest side)

$c = \sqrt{a^2 + b^2}$

Ex. A right triangle has sides: a=3 and b=4. What is side c, the hypotenuse side ?

$c^2 = \underline{a^2 + b^2}$ isolating c by taking square root of both sides:
$c = \sqrt{a^2 + b^2}$ substituting the given values for the variables:

$c = \sqrt{3^2 + 4^2}$ simplifying the radicand:
$c = \sqrt{9 + 16}$: ORD 1, order of operations step 1; powers and roots, here, in the radicand of the radical
$c = \sqrt{25}$: ORD 4, order of operations step 4; combine
$c = 5$: ORD 1, order of operations step 1; powers and roots

When the two sides or legs of a triangle are equal in value, the hypotenuse side is equal to the square root of 2 times that side length. This would also equal the diagonal length within a square shape:

$c = \sqrt{side^2 + side^2} = \sqrt{2\ side^2} = \sqrt{2}\ \sqrt{side^2} = \sqrt{2}\ side$: note, $side = c / \sqrt{2} = \sim (0.707)\ c$
$c = 1.414213562373096\ side = \sim$ about $1.414\ side$

Ex. If each side is 3, the hypotenuse side is equal to the 3rd multiple of the square root of 2, which is: 4.242640687

When one side or leg of a triangle is equal to twice (2 times) that of the other side or leg, the hypotenuse side is equal to the square root of 5 times that side length:

$c = \sqrt{side^2 + (2\ side)^2} = \sqrt{1\ side^2 + 4\ side^2} = \sqrt{5\ side^2} = \sqrt{5}\ \sqrt{side^2} = \sqrt{5}\ side$
$c = 2.23606797749979\ side$

When one side or leg of a triangle is x (a variable factor which can even be a fractional value less than 1) times longer than that of the other side or leg, the hypotenuse side is equal to:

$c = \sqrt{side^2 + (x\ side)^2} = \sqrt{1\ side^2 + x^2\ side^2} = \sqrt{(x^2 + 1)\ side^2} = \sqrt{(x^2 + 1)}\ \sqrt{side^2}$

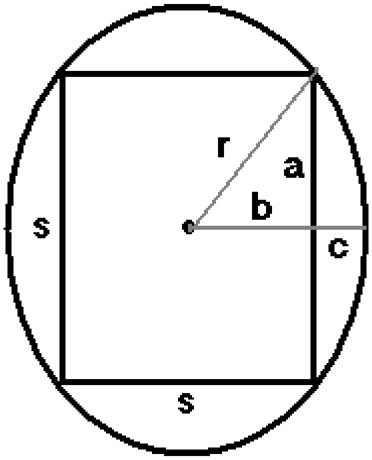
$c = \sqrt{(x^2+1)}\ side$

As the value of x gets larger and larger, the added 1 term has less of an effect to both x^2 and the result value, which is (c), and the expression approaches or becomes very close to the value of just:

$c = \sqrt{x^2}\ side$ which simplifies to:

$c = x\ side$

Ex. **THE LARGEST POSSIBLE SQUARE WITHIN A CIRCLE** [FIG 90]



In the above figure, s = the side of the internal or inscribed square, and $a = b = s/2$. The radius (r) of this circle is $r=(b+c)$. It could also be said the circle is circumscribing the square. The diagonal of the largest square in a circle is equal to the diameter (D) of that circle; $2r = 2R = D$

Due to the Pythagorean Theorem, and that $a=b$:

(radius of the circle)^2 = $r^2 = a^2 + b^2 = a^2 + a^2 = 2a^2$ therefore, by taking the square root of both sides:

$r = \sqrt{2}\ \sqrt{a^2} = 1.41421\underline{4}\ a$ solving for variable $a = b$ = half the side of the square:

$a = r / 1.41421\underline{4} = 0.70710\underline{7}\ r$

$2a = 2b = 2\,(0.70710\underline{7})\ r = 1.41421\underline{4}\ r = \mathbf{\sqrt{2}\ r = s}$: A formula for the side (s) of the largest square in a circle.
r = radius of the circle

$$\mathbf{r = \frac{s}{\sqrt{2}} = 0.7071\underline{1}\ s = \frac{d}{2}} \quad \text{and} \quad \mathbf{diameter = d = 2r = 2\,(0.7071\underline{1})\ s = 1.41421\underline{4}\ s}$$

Extra: From: $r = c + b = c + a$

$c = (r - b) = (r - a) = 1r - 0.70710\underline{7}\ r = r\,(1 - 0.707107) = 0.2928\underline{9}\ r$: = about or approximately $0.3\ r$

Note also that the diameter length of this circle is also equal to the diagonal line length of the square:

diameter $= 2r = 2\,(1.414214)\ a = 2.828427\ a$ or since $s = 2a = 2b$:

diameter$^2 = s^2 + s^2 = (2a)^2 + (2b)^2 = (2a)^2 + (2a)^2 = 2\,(2a)^2 = 2(4a^2) = 8a^2$

diameter $= \sqrt{8\,a^2} = \sqrt{8}\ \sqrt{a^2} = 2.828427\ a$

diameter$^2 = s^2 + s^2 = 2s^2$ after taking the square root of both sides:

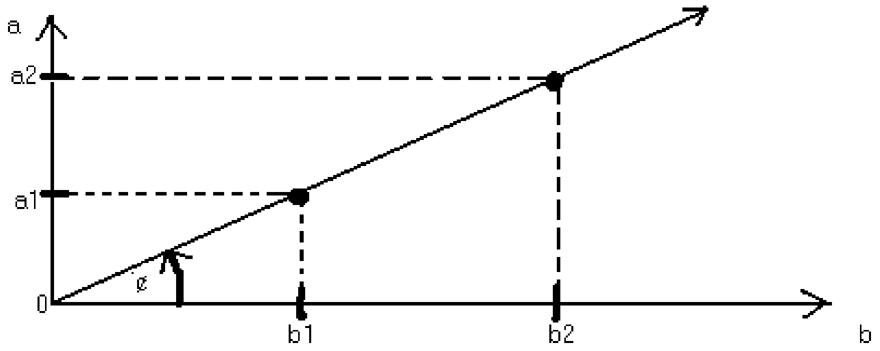
diameter = 1.414214 s = 2r

What about other triangles that are non-right triangles, does the Pythagorean Theorem hold true for them? Lets consider that if the right angle is changed to just slightly over or less than 90°. The triangle is then a non-right triangle but still appears to be as one. It is not to difficult to imagine that all the sides of this non-right triangle are nearly equivalent in length to that of a right triangle, and therefore, the Pythagorean Theorem is still practical for estimating and-or checking the results, however we will eventually need to use general (ie., for any) triangle analysis methods to find the sides and-or angles of a general triangle.

TRIGONOMETRIC RATIOS OF A TRIANGLE

Trigonometric basically means the study, measurements and mathematical relationships of the parts (sides and angles) of a triangle. Trigonometric ratios are (formal, defined, standardized) ratios among two specific sides of a right-triangle with respect, or in reference, to an angle of that triangle. The three most commonly used trigonometric ratios are given the names of: sine (SIN), cosine (COS) and tangent (TAN). They are of great use when a side or angle of the triangle cannot be found by other means. They are also used in more advanced mathematics. You may sometimes see the word "trigonomic" used for the word "trigonometric".

Below, "opposite" means the side directly opposite ("subtending") or across from the angle in question, and "adjacent" means the side directly near or adjacent to the angle in question, but it is not the hypotenuse side. ¢ is a symbol (or variable if you will) for any particular angle in question and which the ratio of sides corresponds or is in reference to. It is recommended that you memorize the three common trigonometric formulas below: [FIG 91]



$$\text{sine ¢} = \text{sin ¢} = \frac{\text{opposite}}{\text{hypotenuse}}$$

: This does not mean: (sin)(¢). It means: (sin ¢)=a ratio of the triangle's sides value.
: The word "sine" is rooted in the word "sinus" for bend, curve and cavity, and this type of shape is seen when it is graphed and it looks like a wave shaped curve.

$$\text{cosine ¢} = \text{cos ¢} = \frac{\text{adjacent}}{\text{hypotenuse}}$$

: the prefix "co" in cosine indicates the complement or complementary (of) sine

$$\text{tangent ¢} = \text{tan ¢} = \frac{\text{opposite}}{\text{adjacent}}$$

: the word "tangent" is rooted in the words for "touch" and "surface".
: A tangent value is often used to express the steepness or tilt of a line or object.

Notice that tan ¢ is mathematically equal to: (sin ¢ / cos ¢), and some of these equivalent fractions will be discussed and verified later:

$$\text{tan ¢} = \frac{\text{opp}}{\text{adj}} = \frac{\text{"vertical rise"}}{\text{"horizontal run"}} = \frac{y}{x} = \frac{\text{(opp/hyp)}}{\text{(adj/hyp)}} = \frac{\text{r sin ¢}}{\text{r cos ¢}} = \frac{\text{(hyp)(sin ¢)}}{\text{(hyp)(cos ¢)}} = \frac{\text{sin ¢}}{\text{cos ¢}}$$

: hyp = hypotenuse side
: r = radius of circle, or "radius vector" which is essentially the hypotenuse side.

Here is a quick verification:

$$\frac{\text{sin}}{\text{cos}} = \frac{\text{(opposite / hypotenuse)}}{\text{(adjacent / hypotenuse)}} = \frac{\text{opposite}}{\text{adjacent}} = \frac{y}{x} = \text{tan ¢}$$

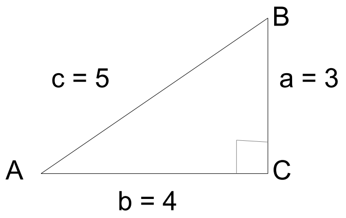
Three other, but less used trigonometric ratios are effectively the reciprocal of the three ratios just given:

cosecant ¢ = csc ¢ = $\frac{\text{hypotenuse}}{\text{opposite}} = \frac{1}{\sin \text{¢}}$

secant ¢ = sec ¢ = $\frac{\text{hypotenuse}}{\text{adjacent}} = \frac{1}{\cos \text{¢}}$

cotangent ¢ = cot ¢ = $\frac{\text{adjacent}}{\text{opposite}} = \frac{1}{\tan \text{¢}}$

Ex. For the triangle below, evaluate the sin, cos, and tan of angles A and B. [FIG 92]



SIN ¢A = SIN A = $\frac{\text{opposite A}}{\text{hypotenuse}} = \frac{a}{c} = \frac{3}{5} = 0.6$

COS ¢A = COS A = $\frac{\text{adjacent A}}{\text{hypotenuse}} = \frac{b}{c} = \frac{4}{5} = 0.8$

TAN ¢A = TAN A = $\frac{\text{opposite A}}{\text{adjacent A}} = \frac{a}{b} = \frac{3}{4} = 0.75$

SIN ¢B = SIN B = $\frac{\text{opposite B}}{\text{hypotenuse}} = \frac{b}{c} = \frac{4}{5} = 0.8$

COS ¢B = COS B = $\frac{\text{adjacent B}}{\text{hypotenuse}} = \frac{a}{c} = \frac{3}{5} = 0.6$

TAN ¢B = TAN B = $\frac{\text{opposite B}}{\text{adjacent B}} = \frac{b}{a} = \frac{4}{3} = 1.333333333...$

Usually, some of the intermediate steps would be eliminated:

Ex. SIN A = $\frac{a}{c} = \frac{3}{5} = 0.6$

Notice that the values of: sin A = cos B,
cos A = sin B,
tan A and tan B are reciprocals of each other: tan A = 1/tan B and tan B = 1/tan A

If given a trigonometric (ratio of two sides) value of an angle, you can mathematically solve for one of the corresponding sides of that trigonometric value if the other corresponding side is known:

Ex. If SIN ¢ = 0.6, and the hypotenuse is 5, what is the opposite side?

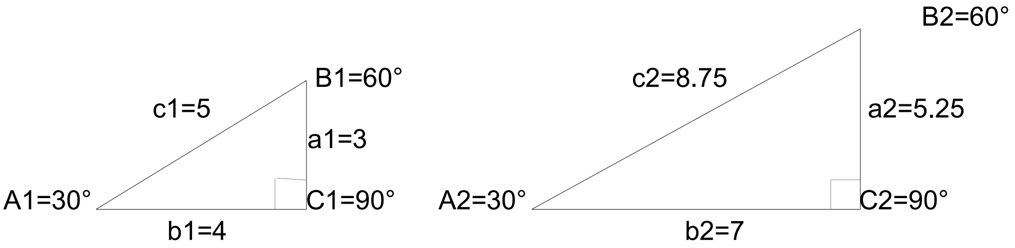
Letting ¢ = A, sin A = 0.6, a = side opposite angle A, c = hypotenuse,

From: $\text{SIN } A = \frac{\text{opposite}}{\text{hypotenuse}} = \frac{a}{c}$ we mathematically have:

$a = c \text{ SIN } A$
$a = 5\ (0.6)$
$a = 3$

Since the ratio of any two sides of a triangle is equal to the ratio of the two corresponding sides of a similar triangle, all the trigonometric ratio values of two similar triangles will also be the same. [FIG 93]

Ex.



TRIANGLE 1 TRIANGLE 2

$\text{SIN } A1 = \text{SIN } A2$

$\frac{a1}{c1} = \frac{a2}{c2}$

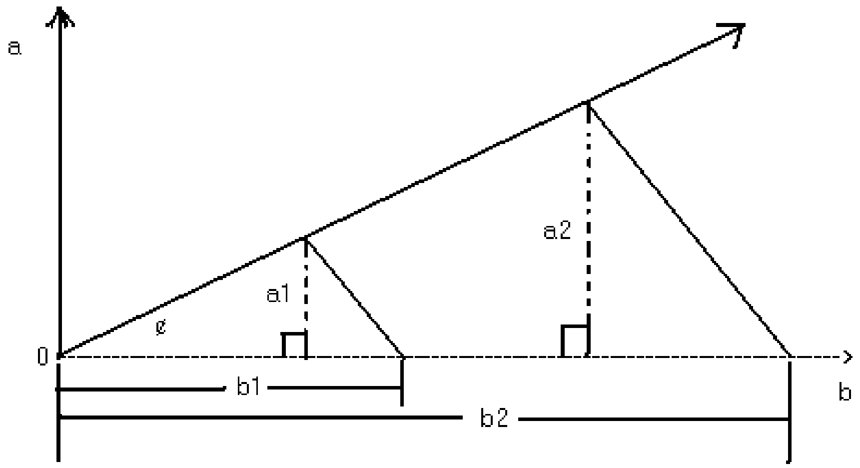
$\frac{3}{5} = \frac{5.25}{8.75}$

$0.6 = 0.6$: similar triangles have the same the trigonometric (ratio) values

Since the trigonometric ratios were in reference to an angle with the same value (here, A=30°), we could say that any other or all similar triangles would have the same ratio value. For this example, a sine value of 0.6. That is, every angle has its own particular and constant trigonometric ratio value associated with it. The sin of any 30° angle is always 0.6. The cosine of any 30° angle is always 0.866, and the tangent of any 30° angle is always 0.577. This fact that a particular angle value corresponds to a particular trigonometric ratio value, and vice-versa, allows us to solve for either.

VERIFICATION OF THE SIDE LENGTHS OF SIMILAR TRIANGLES

Here is a verification that the ratio of corresponding sides of similar triangles is equal. Observer the drawing below of a line that effectively creates a general angle (¢) -*for this analysis, and for simplicity, side (c) of each constructed (right) triangle is not indicated: [FIG 94]



If we divide the value of a1 by its' corresponding value of b1 on this line, we obtain a ratio (r) value:

$$r = \frac{a1}{b1}$$

This particular ratio value of the particular points (or sides of a triangle) is also equal to the slope (m=rise/run) of the line, and it is also equal to the tangent of the angle (TAN ¢) = opp./adj.

Since for similar triangles which have different side lengths, to retain their similar shape, the angle(s) is constant, therefore the trigonometric ratio (of sides) values (such as TAN ¢, and therefore the ratio=r) remain constant. In simple terms, the ratio of corresponding sides remains constant.

Taking another set of corresponding values of (a) and (b) on the line we get:

TAN ¢ = $r = \frac{a2}{b2}$ hence:

TAN ¢ = $\frac{a1}{b1} = \frac{a2}{b2}$ and algebraically:

$\frac{a1}{a2} = \frac{b1}{b2}$ or: $\frac{a2}{a1} = \frac{b2}{b1}$: verification

If you want to find other corresponding points (or sides of the similar triangle) on this line you can solve for a relationship between the (a) and (b) coordinates, and this relationship is the ratio value (r):

From: $r = \frac{an}{bn}$: n is some multiplying factor such as used when creating an equivalent fraction.

$an = r\,bn$: relationship between (a) and (b), and this is also the equation of the line which is composed of all the (corresponding) points on it. This has a basic line equation form of : $y = mx + b$

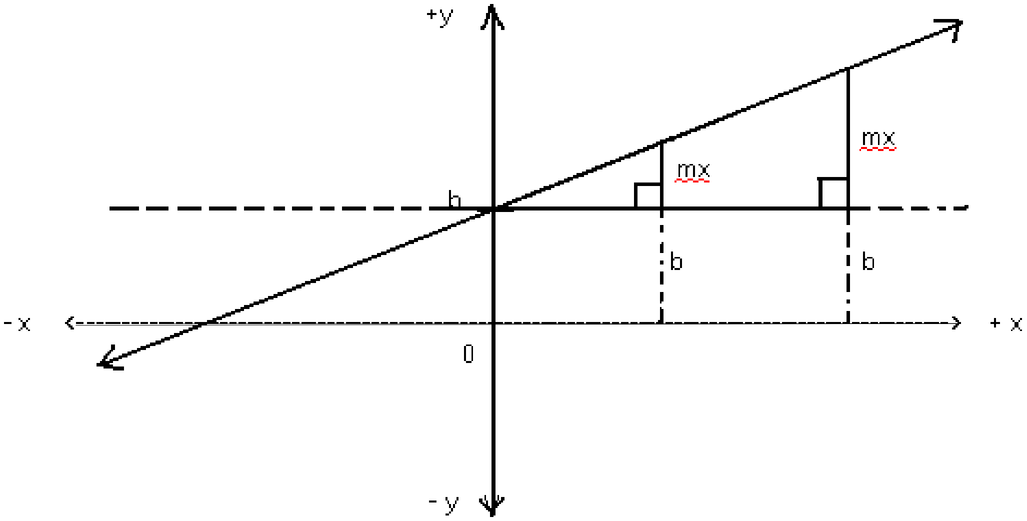
Dividing both sides by (n), this can also be expressed more simply as:

$a = r\,b$

Equating: (a) to (y), (r) to (m), and (b) to (x) , we arrive at:

$y = mx$: the basic linear (line) equation. (m) is a constant and the numerical coefficient of (x), and due to (m), (y) is a multiple (including <=1) of (x), and $(y / x) = (m)$.

Now, observe the two similar triangles below: [FIG 95]

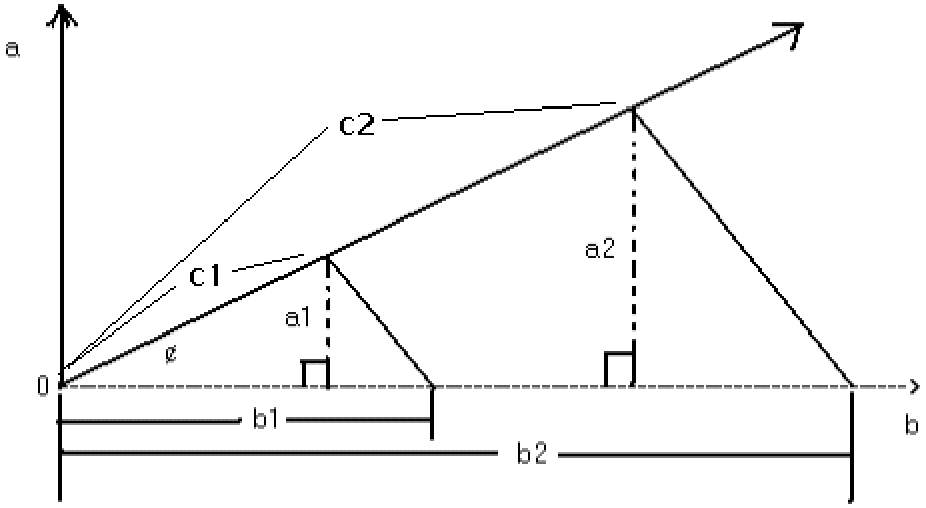


Notice that both of the right triangles have a side equal to (mx) for their height (which is related to the (y) value at those points; y=mx). This value of (mx) is not a constant, since (x) can vary, as expected for various sized similar triangles. The other (perpendicular to (y)) side, or base side of each right triangle is equal to (x). Considering just the graphing of the line, the corresponding (y) value for each (x) value is equal to the height (mx) of the similar triangle created at that point plus the value of the constant (b). Hence the (y) value on the line that corresponds to each (x) value is:

$y = mx + b$: basic linear equation for any line in a 2-dimensional, rectangular coordinate and measuring system.
: (b) essentially shifts each corresponding (y) value, and hence the entire line, vertically.
(m) can be thought of as the "steepness factor" (or slope) of the line.

Extra: Observing the above figure: $y1 = mx1$ and $y2 = mx2 = m(x1 + \text{ch. in } x1) = mx1 + m(\text{ch. in } x1) =$:ch.= change
$y2 = y1 + m(\text{ch. in } x1)$
$y2 = y1 + (\text{ch. in } y1)$
By equating the last two expressions and terms on the right sides:
$m (\text{ch. in } x1) = (\text{ch. in } y1)$, and mathematically:
$m = (\text{ch. in } y1) / (\text{ch. in } x1)$

Other useful facts can be derived here. Observe the drawing below of two general (non-right) similar triangles where the (a) value indicated within each triangle is equal to the (perpendicular) height (h, or "altitude") with respect to the base side (b) that it intersects with. These (a) values are also the (proportional) sides of similar right triangles. We can conclude from this that the ratio of (corresponding) height values of all similar triangles, and not just similar right-triangles, is equal to the ratio of any corresponding sides of the similar triangles. Remember that for a construction to be similar, each and every part, including the height or altitude sides, are magnified by the same value. For example: [FIG 96]



$\frac{h2}{h1} = \frac{a2}{a1} = \frac{b2}{b1} = \frac{c2}{c1} = r$: h is used to indicate height or altitude
: r is essentially the "magnification factor" of the similar construction that is a triangle.

The above graph shows that all sides, including the "height sides" of similar triangles are proportional (same portions or fractional values). The heights of similar right triangles are obviously proportional since any side, other than the hypotenuse, is actually the height with respect to the other side.

If corresponding sides of similar triangles are related by a ("magnification") ratio, is the perimeter (the outside edge length) of the corresponding similar triangle related by the same ratio? The answer is yes, and this is algebraically verified below where P1 and P2 are the perimeters of similar triangles:

$P1 = a1 + b1 + c1$ and $P2 = a2 + b2 + c2$

Since for example $a2 = r\,a1$, by algebraic substitution:

$P2 = r\,a1 + r\,b1 + r\,c1$ factoring (r) from each term:
$P2 = r\,(a1 + b1 + c1)$ dividing P2 by P1:

$\frac{P2}{P1} = \frac{r\,(a1 + b1 + c1)}{(a1 + b1 + c1)}$ canceling common factors of the numerator and denominator:

$\frac{P2}{P1} = r$

$\frac{P2}{P1} = \frac{h2}{h1} = \frac{a2}{a1} = \frac{b2}{b1} = \frac{c2}{c1} = r$

A logical question then arises: Is the ratio of the areas of similar triangles also equal to this ratio? The answer is: "close", but since area is a two dimensional or "square concept", the ratio (r) is the same, but squared (r^2).. This is verified below starting from the basic equations for the area of each triangle. A simple verification to this is when you double (ie., ratio=r=2) the sides of a square or rectangle, the area increases by 4 which is 2^2. If you tripled (r=3) the sides of a square or rectangle, the area increases by 9 = 3^2, hence we conclude that area increases by the square of the ratio (r) of similar (planar) constructions.

$$A1 = \frac{b1h1}{2} \qquad A2 = \frac{b2h2}{2}$$

From : $\frac{h2}{h1} = r$, we get: $h2 = r\,h1$

From : $\frac{b2}{b1} = r$, we get: $b2 = r\,b1$ by algebraic substitution:

$$\frac{A2}{A1} = \frac{\frac{r\,b1\ r\,h1}{2}}{\frac{b1\,h1}{2}} = \frac{2\,r\,b1\,r\,h1}{2\,b1\,h1} = r^2$$

: ratio of areas of similar constructions
such as triangles and rectangles.
r=the "magnification ratio" of the Area

While on this topic of similar constructions of which one is a magnification of the other and all its parts, here is a similar type of understanding for rectangles:

Given a rectangle with sides (a) and (b), its area is: A1 = (a)(b). If we want to make a similar and magnified (or demagnified, smaller) construction with respect or in reference to that first construction, we can multiply each and every part of it by the same value or magnification factor (n):

$$A1 = ab$$

$$A2 = (an)(bn) = an\ bn = (ab)n^2$$

$$\frac{A2}{A1} = \frac{(ab)n^2}{(ab)} = n^2$$

: this verifies that if all the sides of a construction are changed by the same factor value, that its area will increase by the square of that factor (here, n).

If you specifically wanted A2, rather than only the corresponding sides, to be a certain factor (n), a multiple bigger or smaller than A1:

A2 = A1 (number of times bigger) = A1 (n)

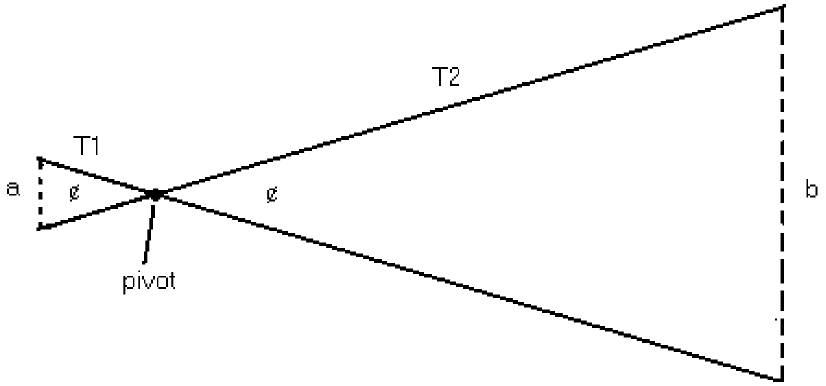
$A2 = (bh)\,n$ which can be expressed as:

$$A2 = b\sqrt{n}\ \ h\sqrt{n}$$

: to make a similar construction that is a certain factor or multiple bigger, change all of the parts by the square-root of that factor (here, n).

A SIMPLE DEVICE TO MEASURE SMALL DISTANCES

Using the concepts of similar triangles and vertical angles that are identical angles on both sides of the intersection of two lines, a device can be created to measure small distances and-or to obtain a distance measurement which will have greater precision (precise, the fineness, more least significant values, smallest capability) possible than without using it. The device presented below is only a very simplified form of such a device which can eventually be improved upon. Typically, a finely scaled ruler can only measure (precisely) to within as small as one sixty-fourth = 1/64 = 0.015625 of an inch. The device shown here is designed to measure to within about one thousandth = 1/1000 = 0.001 of an inch which is a more precise measurement. [FIG 97]



The device above is designed to measure a max. distance (or thickness) of 1 inch at side (a). That is, side (a), the "input location", of T1 (triangle 1) opens to 1 inch. Side (b) of T2, the "output or result (location or measurement)", is 20 inches when the distance being measured at side (a) is 1 inch. Hence, for any given distance measurement at side (a), side (b) will be 20 times longer or larger. Therefore, given this longer or magnified representative distance, to find out what it does actually represent (the true or actual measurement) we will divide (to reduce or demagnify) this output value by the known magnification factor or 20, hence essentially making the value of (1/magnification factor) = (1/20) as a demagnification factor.

What is the verification that side (b) is always 20 times longer? To begin with, both angles indicated are the same due to the concept of vertical angles. A vertical angle is the (equal) angle created on the opposite side of an angles vertex after extending the sides of the angle. You can recall the concepts of creating similar triangles to help verify this. The sides of T2 are extensions of the sides of T1, and side (b) is parallel to side (a), therefore, T2 is a similar triangle to T1. All the sides (and heights) of T2 are constructed to be 20 times longer than the corresponding sides of T1, hence the ("magnification") ratio (r) value is 20:

magnification ratio $= \frac{\text{output}}{\text{input}} = \frac{b}{a} = r$ mathematically:

output = input (r) and input $= \frac{\text{output}}{r}$ = output (1/r) : input = (output)(demagnification factor)

$b = a(r)$ if $(r) = 20$:
$b = a(20)$ or:

$b = 20a$: the "magnified value of (a)"
: this is of the form of a linear equation of: $y = mx$
$a = \frac{b}{20}$: the actual, true or "unmagnified" value of (a) . or:

$a = \frac{b}{20} = \frac{(1)b}{(20)} = 0.05\ b$: (1/20) = 0.05 = demagnification factor for, or applied to the value of (b)

Note that whenever the value of side (a), and therefore the angle, of T1 changes (such as when taking new measurements with this measuring instrument), the new triangle T1 will obviously not be similar to the old triangle T1, however, T1 and T2 will always similar triangles.

If side (b) is expressed or scaled in 1/64 of an inch unit increments, the decimal equivalent of this fraction is:

$\frac{1\text{in.}}{64} = 0.015625$ in. : slightly over 15 thousandths of an inch
: This is the precision of the (output or result) side, or (magnified) scale, of b.

, and if (b) indicated or was read to be (n) such increments during a measurement at side (a), the total length indicated at side (b) is a matter of repeated addition, or simply multiplication:

$b = 0.015625\text{ in. }(n) = n\ 0.015625\text{ in.}$ therefore:

$a = \frac{b}{20} = \frac{n\ 0.015625\ \text{in.}}{20}$

If only one (n=1) increment (1/64 of an inch) was indicated at side (b), we can find the measuring precision of this device:

$a = \frac{0.015625\text{ inch }(1)}{20} = 0.000{,}781{,}25$ inch :slightly less than 1/1000 of an inch. This is the (smallest) precision or measurement possible with this measuring instrument.

For the readout scale only, the smallest unit of measurement is (1/64) in. (ie. the precision = how precise, fine or minute a measurement on the this readout can be). The actual reading on this scale will be indicated, on average, as somewhere between one of these smallest units or graduations on the scale. Hence, if performed correctly, it is possible that a measurement may be inaccurate by as much as this precision of (1/64 in.) on this scale. Since the smallest unit of measurement is (1/64) in., we must either round up or round down the observed measurement to the next closest unit in order to express the measurement with this precision. The form of rounding used will depend upon the person reading the scale and-or the standard used. This (+,- 1/64) in. maximum possible "output" or reading error corresponds to an "input" error (e) of (1/64)in./20 = +,- 0.000,781,25 in. for the actual object being measured. A general formula which includes this possible error (e) can be expressed as:

$a = b/20 \quad +,- \quad e$

$a = \frac{n\ 0.015625\text{ in.}}{20} \quad +,- \quad 0.000{,}781{,}25$ in : actual measurement which includes the possible error

As mentioned above, the drawing of the device is only a basic one. Perhaps the "read-out" scale at the side (b) end would be of the form of an arc that is concentric (surrounding like a circle or part of a circle) about the pivot point. Perhaps one "arm" of the device would remain "fixed" (not movable) at the "0" or reference position end of the "read-out" scale. Note also that if the intersecting (non-parallel) line segments are equal in length, the center, halfway or mid-point of either line is located at their intersection point, and the distance between the endpoints is the same on both ends.

The device is also a very simple mechanical calculator. The operations capable with this device are multiplication and division. Here, due to its construction, the multiplier and divisor are 20. If you can adjust or set the length of the "arms" or "legs" of this device, and-or have some movable pointers or indicators, and you can then effectively make a variable (operand) multiplier and divisor calculator. The above construction of a distance multiplier is also the basis of a speed (= distance covered per time unit) or force multiplier (including demagnification) of a "simple machine", however, in the opposite direction, that is, the end at the smaller arm section will be where the (output) force is multiplied or increased, and likewise, the larger opening is where the (applied) force is less or decreased. The force gain or multiplier is determined by the ratio of the length of the sides or arms (or "lever arms") on opposite sides of the vertex or (rotational, "axis") pivot point of the construction. For premade mechanical devices that can measure small distances, such as the thickness of a piece of pipe (ex: inside diameter, thickness and outside diameter), metal or some material, research the measuring tools called (screw thread) "**micrometer**" and "**vernier calipers**". The initial concept and device of a micrometer was invented and used for astronomical measurements in about 1638 by **William Gascoigne** (1612-1644), from England. These devices have a reasonably high precision of about a tenth, hundredth or thousandth of a length unit, and for most practical measurements. Many of these devices are relatively inexpensive (perhaps under $20 USD and even less if made of plastic) as of the year 2022. Some of these devices have mechanical or printed scales, and some may have a rotating dial reading (ie., a disk with a indicator or pointer on it, much like a mechanical clock) or a digital-electronic display of the measurement taken. Vernier calipers were invented in about 1631 by **Pierre Vernier** (1580-1637), from France. This is a type of ruler with a common scale for the largest measurement, and another scale so as to calculate a fraction of the smallest unit on the common scale. This fractional length is then added to the measurement from the common scale. It is possible to make measuring device using gears, and with each next connected gear and allowing more precision and accuracy in a measurement, much like a mechanical counter. Before these fine devices there have been some other methods of obtaining more precision and accuracy such as the **Transversal Ruler** and-or concept which is thought to have been invented in the early 1300's.

With the device shown in the previous figure, it is even possible to plan and construct a similar device to find a fractional portion of any length positioned at the "output end". The input end would be scaled in fractions of its length, and it is even possible to use similar shaped and length (here, diameter) objects for this such as similar coins. For example, using 3 coins, each would then indicated (1/3) of the total input length. Using 5 coins, each would then indicate (1/5) of the input length. The output length needs to be perpendicular to the input length, and the (opposite) endpoints of each length need to be connected by an imaginary line, hence showing a complete magnification of the full input length. .Using a string(s) or rod(s) with a fine pointer at the center of its end, say (1/3) or (1/5) of the input length can then be effectively projected and-or magnified onto a corresponding (1/3) or (1/5) portion of the entire output length.

Extra: The above device can also be considered as like a lever, and with one side fixed in position or not, and various useful and similar concepts can be shown. The reader may skip over this section and consider it at another time.

When one end (a or b) of the device is brought together, the other end of the device will also be brought together at the same instant. Since (b = d2) is a greater distance than (a = d1), it endpoint(s) must be traveling faster to go that greater distance in the same amount of time. If v2 corresponds to the points at (b), and v1 corresponds to the points at (a) then:

$t2 = t1 = t$ From $d = vt$, we have: $t = \frac{d}{v}$, $\frac{d1}{v1} = t = \frac{d2}{v2}$, and mathematically: $\frac{d1}{d2} = \frac{v1}{v2}$,
$d2 > d1$
$v2 > v1$

or: $\frac{d2}{d1} = \frac{v2}{v1}$: equivalent fractions, and showing that distance and velocity are proportional in values

If d2 is (n) times greater than d1, then v2 will be (n) times greater than v1.

It can then be said that the velocity on one side is a magnification of the velocity of the other side.

$$\text{Energy} = E = \text{Work} = W = (\text{force})(\text{distance}) = Fd = (\text{mass})(\text{acceleration})(\text{distance}) = mad = mavt = m(v/2t)(v)t = mv^2/2 \text{ Joules}$$

Energy in = Energy out : for a system with no losses (ie., transfers) of energy
E in = E out A common example is plier(s) tools, and of which are essentially a lever.

From $E = Fd$, $F = \frac{E}{d}$, We see that force and distance are inversely related when given an amount of energy to apply as a force or vice-versa. If the distance decreases, the force will increase by the same factor, and this will happen at side (a) in the drawing since side (a) is the shorter and-or the side closer to the pivot, rotation or lever point. The velocity at side (a) is less than that at side (b) by the factor of n=(b/a), hence va = vb / n , and the resulting output force will be (n) times greater than the input force.

$E = \frac{n}{n} Fd = nF \frac{d}{n} = \frac{F}{n} nd$, $F = \frac{E}{d} = \frac{E}{v\,t}$, $nF = \frac{nE}{d}$, Also: If a given amount of energy is applied for a low or short distance, the force will be high. If the energy is high, the force will be high.

Levers, gear speed and torque have a similar analysis to what was shown above. When a small gear is used to transfer mechanical power (P **=** E / t **=** Fd / t **=** Fv) to a larger gear, the arc distance moved per time of the small gear is low, and the force applied to the larger gear is high. Again this maintains that: Pout = Pin and-or Eout = Ein less any friction losses, etc:

For an example of the above, a device called a **wench** that can apply a force to a cable and move (ie., pull) a heavy load attached to the end of it closer to that (anchored, set to not move) wench, and by essentially using a relatively low power motor and small gear connected to a larger gear(s). A wench mechanism often contains a ratchet mechanism so as to prevent it from becoming unwound, slipping and causing a dangerous situation such as when pulling a vehicle or tree out of a ditch. a wench can also be used as a type of electric pulley system so as to lift things vertically.

By using successive gears, say each ten times larger, it is possible to put numbers on each gear so as to create a decimal number system counter, and-or a measuring device to measure small distances to a high precision.

CONVERTING BETWEEN AN ANGLE AND ITS CORRESPONDING TRIGONOMETRIC RATIO VALUE

The easiest way to convert between an angle and one of its corresponding trigonometric ratio values, or vice-versa (in reversal), is to use a pre-written reference table or a ("scientific") calculator that has these ((automatic) calculating or conversion) functions or abilities. Section 4, the ADVANCED TOPICS section of this book, will show you some formulas for how to make these calculations, especially when a scientific calculator or reference table is not available. These calculations can be greatly assisted by using a simple ("5 function") calculator, and if that is not available, performing the calculations by with pen and paper can always be used.

Ex. What is the sin of 60° ?

Using a scientific calculator, first enter 60 and then press the SIN function key or button. The result displayed should be about 0.866 when the calculator is in standard degrees angle input and output (processing, conversion) mode.

SIN 60° = 0.866

Ex. If the sin value of an angle is 0.866, what is the angle ?

Using a scientific calculator, first enter 0.866 and then press the inverse sine key. Sometimes this key is labeled INV SIN (INVERSE SINE), SIN^-1 (this is just a certain notation or indication, so do not use the mathematical reciprocal since the notation here rather means the inverse function of, rather than an inverse or reciprocal value), ARC SIN or ARCSIN (ARCSINE, as in the arc or angle of a circle). This specific calculator key needed could be located on the calculator where some other common key (such as the SIN key itself) can be reused as another or second function, such as INV SIN if you first press the calculator's "2nd function key" first, so as to activate all the "2nd function keys". The specific "dual or second function key" here is often for the SIN key itself. The result displayed should be 60 which is to be interpreted as 60 degrees = 60°. Expressing this mathematically:

ARCSIN 0.866 = 60°

The formal or standard mathematical expression for the corresponding trigonometric function of a given angle,
and the formal or standard mathematical expression for the inverse trigonometric function to find the corresponding angle given its trigonometric value have this form:

To find the corresponding trigonometric value of a given angle:

trigonometric_value = trigonometric_function(¢) or: trigonometric_value = trigonometric_function ¢

And

To find the corresponding angle given its trigonometric value:

¢ = arc_trigonometric_function(trigonometric_value) or: ¢ = arc_trigonometric_function trigonometric_value

The specific arc_trigonometric_function to use must correspond to the given trigonometric_value:

Ex. ¢ = arcsin(sin ¢) : arc-sine , If x = sin ¢: ¢ = arcsin(x) or = arcsin^-1(sin ¢) or = arcsin^-1(x)
¢ = arccos(cos ¢) : arc-cosine
¢ = arctan(tan ¢) : arc-tangent

Trigonometric Function and Inverse Trigonometric Function

Ex. 0.866 = sin(60°) and 60° = arcsin(0.866)

0.5 = cos(60°) and 60° = arccos(0.5)
$1.732\underline{1}$ = tan(60°) and 60° = arctan($1.732\underline{1}$)

A SHORT TRIGONOMETRIC TABLE

In order for you to have some trigonometric values when a calculator is not available, a small table of perhaps the most common values is presented below. Further ahead, this book devotes much attention to showing you how to calculate such values yourself, with or without the aid of a calculator. The appendix section contains a larger table.

¢	**SIN ¢**	**COS ¢**	**TAN ¢**
0°	0.0	1.0	0.0
1°	0.01745240643728	0.9998476951564	0.01745506492822
2°	0.03489949670250	0.9993908270191	0.03492076949175
3°	0.05233595624294	0.9986295347546	0.05240777928304
4°	0.06975647374413	0.9975640502598	0.06992681194351
5°	0.08715574274766	0.9961946980917	0.08748866352592
10°	0.1736481776669	0.9848077530122	0.1763269807085
15°	0.2588190451025	0.9659258262891	0.2679491924311
20°	0.3420201433257	0.9396926207859	0.3639702342662
25°	0.4226182617407	0.9063077870367	0.466307658155
30°	0.5	0.8660254037844	0.5773502691896
35°	0.573576436351	0.819152044289	0.7002075382097
40°	0.6427876096865	0.766044443119	0.8390996311773
45°	0.7071067811865	0.7071067811865	1.0
50°	0.766044443119	0.6427876096865	1.191753592594
55°	0.819152044289	0.573576436351	1.428148006742
60°	0.8660254037844	0.5	1.732050807569
65°	0.9063077870367	0.4226182617407	2.14450692051
70°	0.9396926207859	0.3420201433257	2.747477419455
75°	0.9659258262891	0.2588190451025	3.732050807569
80°	0.9848077530122	0.1736481776669	5.671281819618
85°	0.9961946980917	0.08715574274766	11.43005230276
89°	0.9998476951564	0.01745240643728	57.28996163076
90°	1.0	0.0	(undefined, approaching infinity near 90°)

Actually, this table can be reduced to a single trigonometric value (such as SIN ¢) per angle since the other two values, COS and TAN, associated or corresponding with that specific angle, can actually be calculated from that just the SIN value as will be shown further in this book. Many formulas for the conversion of trigonometric values will be shown ahead. With the table above, you can find the SIN, COS, or TAN trigonometric value of an angle. On the other hand, if given the trigonometric value, you can work in a reverse manner so as to find the corresponding angle.

Notice that TAN 45° = 1, this happens when the side opposite the angle, and the side adjacent the angle are equal in value and their ratio is 1. Ex. TAN ¢ = (side opp ¢/side adj ¢) = 5/5 = 1 . Some other helpful values to consider memorizing are:

SIN 0° = COS 90° = 0
SIN 30° = COS 60° = 0.5
SIN 45° = COS 45° =~ 0.707
SIN 60° = COS 30° =~ 0.866
SIN 90° = COS 0° = 1 : the maximum SIN or COS trigonometric value

You can plot the above values to show the relationships graphically. For example, letting x = ¢, and y = sin x = sin ¢, so as to view the sin ¢ trigonometric curve or waveform.

SOLVING A RIGHT TRIANGLE

To "solve" a right triangle is to find the values of its 6 main parts or components, that is, its 3 interior angles and 3 sides. To solve a triangle, at least 3 of its parts need to be known, and at least one of them must be a side so as to make it a certain, specific or unique triangle among all the other similar triangles (which all have the same 3 identical angles).

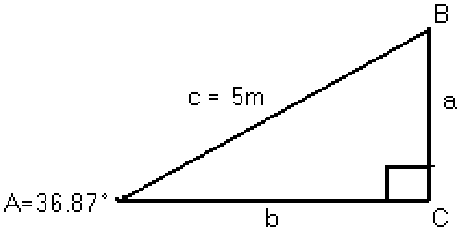
If given a trigonometric ratio value of an angle and one of the sides used to determine or calculate that trigonometric value, the other side which would be necessary to calculate that trigonometric value can be mathematically solved for. This is another method to solve for a side other than using equivalent fractions or portions of similar triangles, or the Pythagorean Theorem.

Ex. From SIN ¢ = $\frac{\text{opposite}}{\text{hypotenuse}}$: this assumes a right triangle construction or analysis, and we mathematically have:

opposite = (SIN ¢)(hypotenuse) : Since SIN ¢ is always less than or equal to 1, the opposite side length will always be less than or equal to the hypotenuse and is therefore only a fraction (ie., <= 1) of the length of the hypotenuse, and this fractional value is expressed as the SIN ¢. Mathematically, we also have:

hypotenuse = $\frac{\text{opposite}}{\text{SIN ¢}}$

Ex. Solve the given triangle: [FIG 98]



We are given: A=36.87°, c=5m, and C=90° since the triangle is indicated as a right triangle.

Note that here, 5m means: 5 units = 5 meters, and not (5)x(m) = (5)(m). Here, (m) is not a variable but it is the units of the measurement or reference.

Solving for angle B:

90° = A + B transposing A and switching sides:
B = 90° - 36.87° combining:
B = 53.13°

We can solve for side (a) since it is used in angle A's trigonometric sine ratio.

SIN A = $\frac{a}{c}$

Mathematically solving for (a) we get:

$a = (c)\ \mathrm{SIN}\ A = c\ \mathrm{SIN}\ A$ or= $(\mathrm{Sin}\ A)(c)$
$a = 5\mathrm{m}\ \mathrm{SIN}\ (36.87°)$
$a = 5\mathrm{m}(0.6)$
$a = 3\mathrm{m}$

We can solve for side (b) since it is used in angles A's trigonometric cosine ratio:

$\mathrm{COS}\ A = b/c$:

$b = c\ (\mathrm{COS}\ A)$
$b = 5\mathrm{m}\ \mathrm{COS}\ (36.87°)$
$b = 5\mathrm{m}(0.8)$
$b = 4\mathrm{m}$

Checking, using the Pythagorean Theorem:

$c^2 = a^2 + b^2$
$5^2 = 3^2 + 4^2$
$25 = 9 + 16$
$25 = 25$: checks

It is very helpful to remember that the side opposite an angle (formally) corresponds to that angle. For example, side a is opposite from angle A. Side b is opposite from angle B. Side c is opposite from angle C. It is also very helpful to remember that the two sides of an angle correspond to the other two sides. For example, angle A is composed of sides b and c. Considering the above example:

Side (a) can also be found and-or checked using angle B's trigonometric COS ratio:
$\mathrm{COS}\ B = \text{adjacent} / \text{hypotenuse} = a / c$
$a = (\mathrm{COS}\ B)\ c$

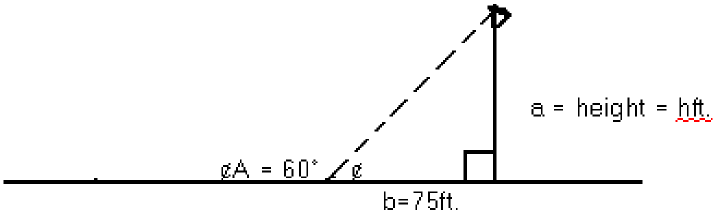
Side (b) can also be found and-or checked using angle B's trigonometric SIN ratio:
$\mathrm{SIN}\ B = \text{opposite} / \text{hypotenuse} = b / c$
$b = (\mathrm{SIN}\ B)\ c$

SOME PRACTICAL USE OF A RIGHT TRIANGLE

Many practical applications of the concepts of right triangles require only solving for a part of the right triangle construction. A helpful way to begin solving for a part is to make a drawing of the situation, information and values.

Ex. If a person is 75 feet from the base of a flagpole and measures an angle of 60° between the ground and the (imaginary) line of (eye) sight to the top of the flagpole, how high (h) is that flagpole above the horizon or eye level at the height of the observer?

Drawing a sketch of this situation, we note that we are to effectively find side (a) of a right triangle. [FIG 99]



a = h can be solved for by using the TAN A trigonometric ratio.

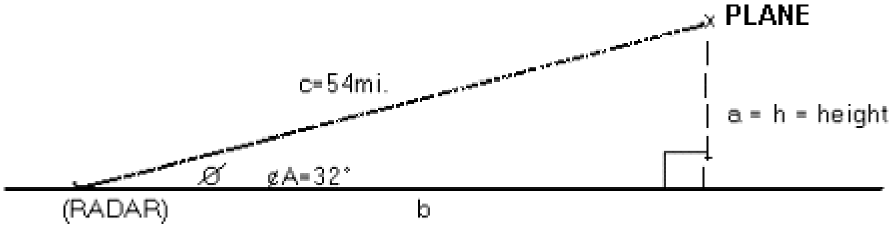
$$\text{TAN A} = \frac{\text{opposite}}{\text{adjacent}} = \frac{a}{b} = \frac{h}{b}$$

solving for h:

h = b (TAN A)
h = 75ft.(TAN 60°) = 75ft.(1.7321)
h = 129.9ft. , and if the height of the observer is to be considered in this calculation:
h = 129.9ft + height of the observer at eye level

Ex. An airplane (ie., a "plane") is detected by radar (radio waves used to sense metallic flying objects such as airplanes) to be 54 miles away (the distance of line of sight and-or radar) and at an angle of 32° above the horizon. How high is the object with respect to the ground (horizon, near horizontal level, surface of the earth), and how far away is it with respect to the radar or observer on the ground?

Drawing a sketch of the situation, we note we are to find the sides opposite and adjacent to angle A of a right triangle. [FIG 100]



h = a = c SIN A
h = 54mi. SIN 32° = 54mi. (0.53)
h = 28.62 mi. = height

b = c COS A
b = 54mi. COS 32°
b = 54mi. (0.848) = 45.8mi. = horizontal distance. : This is the distance to the location where the plane is located directly overhead.

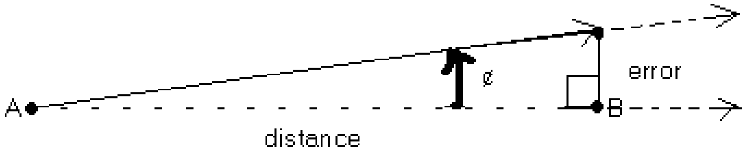
If the airplane is farther away, and yet at the same altitude or height, the angle it appears to be above or with respect to the horizon would be less and perhaps giving the appearance that it is at a lesser height.

A SMALL ANGLE ERROR CAN MEAN A LOT OF ERROR

The following describes the type of situation when a small, seeming insignificant angle error can grow and become a large and significant (meaningful, large) error. First, a common or practical example is when a rod or something like a tree branch moves (ie., rotates, like on a pivot) just a small angle and distance one end, and it will correspondingly move a much larger distance at its other, more distant end.

Observe the drawing below, the shortest distance between two fixed points is the straight-line distance between those points. [FIG 101]

If something is to go from point A to point B, whether it is to move from point A to point B, or be some type of construction that connects the (A and B) points, and is "off" ("the mark", exactness, an error) by only a small angle, say a 1° error with respect to the straight-line direct course from A to B, how much will it actually be or result in the amount of (distance) error from point B? This type of question can be analyzed without unnecessary complexity by using the concepts of a right-triangle: [FIG 102]



Considering the angle remains constant, the amount "off" or error depends upon the distance between those two points (A and B). The smaller the distance, the smaller the error, and vice-versa. In many non-critical applications, small errors are typically accepted without being a problem. Notice in the drawing above that the error value (the distance between the expected location and the error location (due to the angle error) can be considered as a side of a right triangle, and the distance between the (start and ending) points can be considered and analyzed as another side of that right triangle, particularly, the hypotenuse side.

From: $\text{TAN ¢} = \dfrac{\text{opposite}}{\text{adjacent}} = \dfrac{\text{error}}{\text{distance}}$: ¢ = "error angle", solving for error:

error = (TAN ¢)(distance) : the farther (greater) the distance from the vertex ("start or origin") of the angle, the greater the error. This is expressed in the equation as a direct relationship. Also, since TAN ¢ is directly related to the angle, the larger the amount of (error) angle from the (reference) angle, the larger the "error" distance.

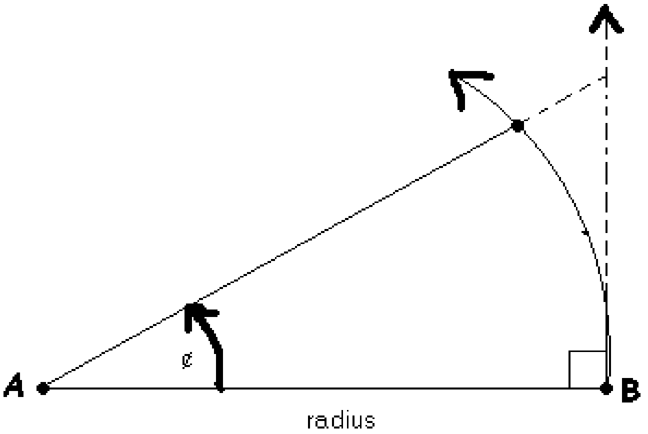
If the distance between the points is 1,000 feet, and the "error angle" is only 1°, the (perpendicular) distance error is:

error = (TAN 1°)(1,000 feet) = (0.017455064)(1,000 ft.) = 17.455 ft.

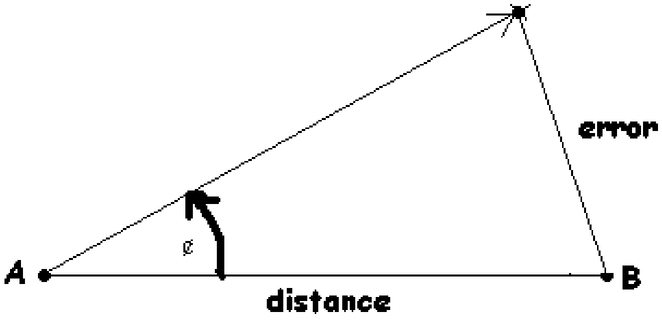
If the distance between the points was much larger, say 1,000 light-years (a light-year = light-year-distance = the distance light will travel in 1 year of time; light travels at about 186,000 miles/second), perhaps the distance to a particular star in the universe, the error distance would be an enormous value of 17.455 light-years due to a just a relatively small 1° error.

If you wish to consider a more accurate analysis:

If there was an error angle, and if the distance actually traveled was equal to the distance between points A and B, the hypotenuse side of the right triangle would now be reduced in distance. This is easily verified by rotating this distance line (from A to B) about point A, as if this distance was the radius of a circle:
[FIG 103]



The hypotenuse, being the longest side in that right-triangle, will always be smaller when it is set to a value equal to the smaller distance (here A to B) of that right-triangles other sides. When the error angle is small, the error side is practically a side of a right triangle and can be analyzed as initially shown above. As the error angle gets larger, the triangle becomes less of a right-triangle and the error distance must now be analyzed using non-right, or general triangle analysis:
[FIG 104]



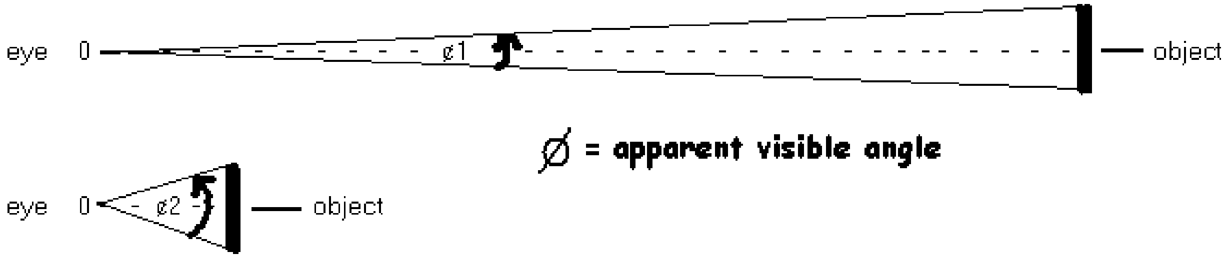
For the specific given situation, two sides of this triangle are equal. This type of triangle is called an isosceles triangle. Those two sides will intersect the third side and create two equivalent angles at that side.

THE APPARENT SIZE OF AN OBJECT

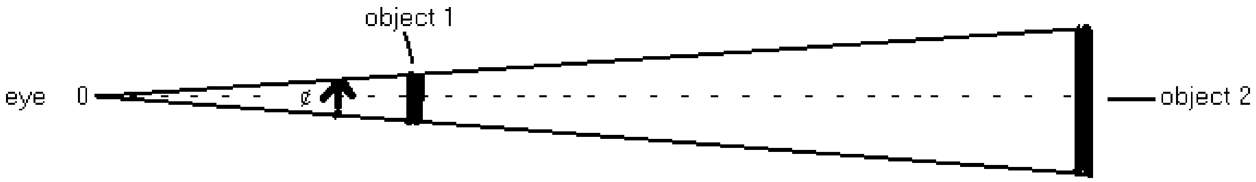
You or someone else might want to know the actual size of a distant object that you have seen. The discussion below initially assumes that there are no other nearby objects to it with their known (as a reference for measurement and comparison) size.

A object having a certain constant actual size will appear bigger when closer, and smaller when more distant. But why? The reason is that the apparent (visible with your eye) angle of the object is changing, and that the (observed, observation) angle size or value is related to the objects distance from you. The specific mathematical relationship between the observed angle and the objects distance from you is an inverse relationship. In more technical words or terms, it is said that when the distance between you and the object changes the angle that the object will subtend (be directly across from, and corresponding to) will change. When the object is closer to you, the apparent or observed angle of its size or width will be greater, yet the true or actual size of the object is still the same. As the object gets farther away from you, its apparent or observed angle and therefore, its apparent observed size will be less.

Consider these illustrations of the same object being farther, and then closer: [FIG 105]



Notice that when the same object is farther away from you, that the ("height" or "width") angle is smaller. Clearly, the distance to the object and the angle are inversely related. However, you still cannot determine the actual size of an object just by this angle alone. Two or more objects of various sizes may subtend the same observed angle and visually look the same size when the distance to each particular object is such that this same angle condition exists. For example: [FIG 106]



As seen above, even though the angle is the same for both objects, object 2 is clearly farther away and bigger. These object will appear as the same size even though they are not. This is an example of an "optical illusion". In this situation both the actual size of the objects and distances to them are not known and can only be estimated if there is not other data or a reference size known. For objects having a small viewing angle, at approximately half way to you, it will appear twice as large in width and-or viewing angle.

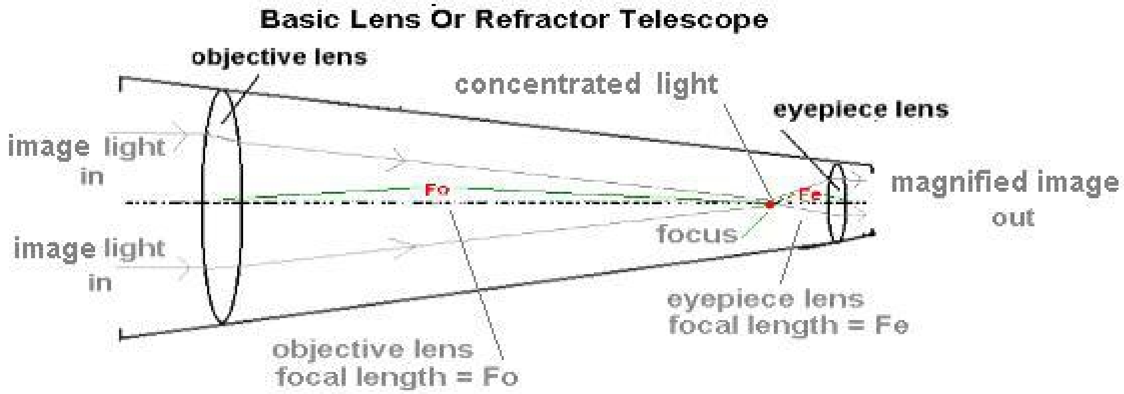
Along with the visual angle and the distance to the object, you can use right angle trigonometry (using ¢/2; "half angle") to find out the actual (length or width) size of the object, otherwise, you will need the reference of a known distance to a nearby object. If you know the size of a nearby object, you can use it as a reference (ie. for comparison, measurement and estimation) for the size of the object in question. One common example where reference sizes are used is in photographs or drawings of objects, and where it may be unclear or uncertain of the objects actual size, especially if it is a highly magnified image or view of a small object. Here, you will often see a ruler or a well known object that has a constant specific known size such as a coin being used as a reference size within the photograph itself. Most maps (which are a demagnified image of a true or actual sized image) showing vast areas and distances will also have a (greatly demagnified) distance or size reference line, rule or scale of measurement that corresponds to, or represents an actual distance between locations or points on the map or photograph. Basically, its a magnification, equivalent fractions or proportions concept. For example: Indicated on a certain map is that 1 inch is to 5 miles, and this means that 1 inch here on this demagnified image or map, corresponds to, or represents 5 miles of the true, real or actual image. If you measured a distance of 2 inches between two points on this map, how far in reality are those points apart or distant from each other?

1 inch is to 5 miles , as 2 inches is to what (x) miles?

$\frac{1\text{in}}{5\text{ miles}} = \frac{2\text{in}}{x\text{ miles}}$ after solving for x miles: x miles = (5 miles)(2) = 10 miles

A telescope and-or microscope increases the apparent viewing angle of an object or a part of it, therefore making the object or subject appear larger and-or closer, hence a magnified image of the object. The initial or objective lens gathers, refracts (ie., bends, redirects due to the slowing of the velocity of the light - much like for example: slowing the tires of the left side of a vehicle will cause it to turn leftward) and concentrates the incoming light available to the eyepiece, hence the objective lens will effectively increase the apparent visible brightness of the image (and not the actual object or subject) seen. The eyepiece lens is then used to focus (for the best clear and sharp image) and magnify the image (or part of it) received from the objective lens. As discussed in this book, if the light and-or image is magnified to a larger area, the available light energy and-or intensity is "spread out" and becomes dimmer, and that is why a large objective lens is used. A glass substance, usually silicon-dioxide, aka "quartz", can **refract** (ie., refraction,refactor, bend at an angle) the direction of incoming light, and it could be thought of as much like a surface and-or internal reflection caused by the new medium (here, glass) the light is passing through. A lens will have a certain light diffraction angle due to its material. **Diffraction** is generally associated with the scattering or spreading of light rays in various directions. When the light exits the lens there will be a second refraction due to the medium has changed from glass to the less dense air. A lens, usually one with a convex (ie., a bulging, thicker in the middle, semi-spherical) shape, can then effectively refract all the incoming light so as to eventually concentrate it all to be at one point called the **focus point** of that lens. The size (diameter) and-or curvature of a lens will determine how far the focus will be from the center of that lens, and therefore it will also help determine or set the total magnification in a particular designed telescope. A very common lens that many people have is called a **magnifier lens**, and it is a convex lens. The magnifier lens is most likely the first lens created in antiquity. They were rare and expensive, and a few have been found. From about the year 1700, the word "lens" was used since it is shaped like a lentil (a type of edible bean with a convex shape on both sides - double convex). Several magnifier lenses stacked together will increase the total magnification available. If each lens can magnify 2 times, the total magnification of this lens system is the product of each individual magnification, hence, here it would be (2) times (2) = 4. A magnifier lens can sometimes be used as a makeshift close-up and focusing adapter lens for some cameras that cannot focus on objects that are very close, say less than 1 foot or about 30cm away. An eyepiece lens from binoculars also makes an excellent high power magnifier or "jewelers loupe" to view small objects. Generally for a "hand magnifier (lens"), the object to be viewed is about 1 inch to 3 inches from the lens, and the lens curve shape is designed for this, but for a telescope, the object to be viewed is generally considered at a long to infinite distance, and the telescope lens shape is designed for this, and resulting that the parallel rays of light from the object will be at the focus point. For a microscope with its highly spherical or curved lens, the object to be viewed is very close to the lens and therefore the area of the object seen, and in focus, will also be very small. Due to the high magnification of microscopes, the light viewed from the object will be dim and will therefore need the aid of a light source (sun and mirror, or electric lamp) shined onto the object to brighten up its image. Some microscope systems use an oil drop between the subject and (sealed) lens so as have an increased magnification and-or clarity.

The basic design of a common telescope is shown below, and this one is called a refractor telescope because the glass lens will cause and-or direct the incoming light (or: light rays or lines) to refractor or bend so as to converge and be focused at one point. One of the largest (ie., objective lens) refracting telescopes is the Yerkes Observatory telescope open in 1897 near Chicago, USA, The "doublet" (2 lenses used together in series so as to help correct some image focus and chromatic and aberration distortion) objective lens of this telescope is 40 inches = 3.33 ft = 101.6 cm in diameter. Its focal length is about 63 feet. This main telescope of the Yerkes Observatory was also specifically designed to make many scientific and-or astronomical measurements and high quality photography. A "triplet" uses three lenses. [FIG 106A]



Today, the initial magnification of an image by using a telescope is still the most important factor, but with modern image sensors (ie., a digital camera) with many pixels (picture elements or parts) being able to produce a higher **resolution** (smallest discernible distance or portion of the object and-or its resulting image seen) than that possible with the human eye, it increases the effective telescope system magnification and resolution, perhaps by two or three times more than without it. Rather than state the optical magnification of a telescope, it is perhaps better to state the final image resolution of the entire telescope system including the image sensor and-or final resulting image and-or photograph. For example, 1 pixel of the image or photograph is equal to a certain value of degrees of arc (ie., viewing angle) in the sky, and-or some minimal (resolvable, resolution) distance on the subject itself. A smaller arc and-or image resolution of the entire telescope system is good for comparison the abilities of telescope systems.

Many modern telescopes, such as those having the "(Isaac) Newtonian" design, use a thin silver or aluminum surface coating for the thick glass mirror, and in such as way and combination so as to reduce the overall size of the telescope and yet still increase the focal length of the telescope to have a high amount of magnification. Again, it is rather better to state the minimal angle that a telescope can resolve (make clear, distinguish), because for example, if the (linear) resolution or minimal part of an object is say 1 meter of length of a distant object and-or in the (photographic, or screen) image of it, if the distance to that object changes then that value of linear resolution is not constant and will change, but still, the (minimal) resolution angle of the telescope system will remain the same, A (maximum) image or resolution angle is sometimes called the (total, focal, "viewing angle") **field of view** or ("viewing field" of the object width seen at its distance) of the telescope, binoculars or camera system, and may be stated as a ratio of distances such as 100 meters wide (across. horizontally or "left to right" distance seen through the telescope) at 1000 meters distance, or a specific total viewing angle extending outward from the observer. This angle can be found from: Tan ¢ = (side opposite to the angle) / (side adjacent to the angle) = 100m/1000m = 0.1 , and ¢ = arc-tan (tan ¢) = arc-tan 0.1 = 5.71° This field of view angle is usually not the (smallest) resolution angle, and for example, the resolution angle may be just a fraction of this value, say (1/100th) of 5.71° and that value is only: 5.71°/100 = 0.0571° Note that the resolution angle by a human eye vision may be not as fine or small as that of a image sensor, such as a digital camera with an enormous number of pixels in a small area, and where each is an image or light sensor.

Another concept with telescopes, microscopes, and other lens systems is called **depth of field**, and this is the range of distance to and behind the object that will still be in focus to a high degree of viewing and-or image clarity. Generally, reducing the opening to a center area of a lens will increase the depth of field, and the best example of this is with a pinhole camera which has a large to infinite depth of field with no curvature of the lens - like a tiny piece of flat glass. With only a smaller area of any lens being utilized, that lens area is flatter (ie., less of a curve) portion of that lens. Microscope lenses are for very high magnification, and are made to be more spherical in shape, and these small lens shapes, much like a small bead of clear glass with a relatively high curvature, have a very small depth of field or focus distance. The lens must be very close the subject or object being viewed, and a cover slip (glass cover) is often placed over some objects being viewed so as the lens does not get debris on it. These objects to be viewed are initially placed onto a larger clear glass slide or plate, and a light source to brighten up the image seen can be placed beneath the glass slide and object, and-or above the object to reflect its light. Often with lenses, such as a magnifying lens, there is a small and minimum distance the lens must be from the object being viewed so as it will be in focus. In general, higher lens curvature results in more image distortion along its edges and-or sides, and due to that the light must be refracted or bent more so as to be at the focus, and this extra distance makes it effectively out of focus with image from the central area of the lens, and it will now have a another focus point nearby. This image and-or focus problem can be overcome by using a corrective lens. In a telescope or lens system:

f-ratio, f-number or f/number or f-stop = $\dfrac{\text{focal length mm}}{\text{diameter of lens opening mm}}$: objective lens opening = aperture.
Note: f-ratio does not mean focal ratio

Ex. (A 50 in. focal length / 5 in. diameter mirror) = 10 = fr = focal ratio = f10 = f/10 = hence: (focal length) (1/10)

Many "35mm sized" cameras, film or digital, have an adjustable lens opening, and which can effectively make a smaller objective lens, however, the total amount of light from the object will be reduced. As mentioned previously, the depth of field will increase when only the center part or area of the lens is being utilized, and this corresponds to a low f-number.

Since **power or magnification = (focal length of objective lens / focal length of eyepiece lens) = focal ratio**, if the focal length of the objective lens is short, the magnification will be small, and the f-ratio will also be small.

When magnification increases, such as with a longer focal length and-or bigger f-ratio, the part or area of the subject seen is actually less, but it will also appear as more magnified to the observer. What is happening is that the effective field of view decreases when magnification increases.

Lenses that let more light in are said as being "fast lenses" since a photographic image will be developed faster (ie., quicker, in less time) by the larger amount of light received than that of a smaller lens. Since a circle that is twice as big in diameter has 4 times the area, a lens that is twice as big can gather and focus 4 times as much light:

A1 = (pi) r^2 , if r doubles, A2 = (pi) (2r)^2 = (pi)4r^2 = 4 (pi) r^2 = 4 A1.

Concave and-or parabolic lenses, which if made flatter will have a low amount of curvature (ie., being less spherical, "more flat"), but will then have a longer focal length and greater magnification, however this will reduce the light intensity seen, and then some dimmer or fainter stars may not be visible. That is the "trade-off" size versus quality. Nonetheless, there is a solution to this problem using long exposure photography so as to effectively "build up" a better resulting or processed image. There are some computer programs to also do this, and you may look up **Registax** and similar programs that do "image stacking". These programs will process many images of the same scene and subject, and so as to produce an image having an effective longer exposure and with more sharpness or clarity (ie., with less noise [light pollution, sensor pixel issues] and blurring).

For more magnification, say double or triple, a special lens that you can purchase is called a **Barlow lens** that can be placed between the telescope and the eyepiece of the telescope. As indicated above, increasing magnification also decreases the intensity (id., amount of photons or energy per unit area) or apparent visible brightness of the light and-or object being viewed. Adding a Barlow lens and-or a diagonal viewing lens will also require you to refocus the telescope so that the focal length of the objective lens is kept, hence the viewing path will need to be shortened.

If the object you are viewing is high up in the sky, a diagonal mirror or special lens can be used to aid your viewing by making it more comfortable. Here, instead of viewing an object that is in the same direction as the length of the telescope, you can rather look perpendicular to that direction. This device can also be used to invert (ie., flip horizontally and-or vertically) the image of the object so as to have its proper (vertical) orientation, and especially when viewing objects "terrestrially" (ie., terrain, on Earth's surface. Optics and lenses is a fascinating scientific field of study, manufacturing and research, and a great hobby. Using a thick glass "blank [bulk, plate]" some people have made (ground, polished, and mirrored its surface) a main objective mirror for a Newtonian parabolic reflector telescope, but just like with solar-panels, it is typically much cheaper and less of a burden to buy it already made and assembled. It is very possible to make an inexpensive, thick (ex. 1 in. to 2 in.) glass mirror blank out of used scrap plate glass, perhaps 1/4 inch thick each, cut to a circle shape, and then slumping the layers in an electric kiln furnace to fuse them together as one. You will also have to research this kiln and mirror grinding process so as to have good results after some experimentation and practice. The longer the focal length of the mirror, the greater its (effective, parabolic) radius of curvature, and less glass will have to be removed, and in short, the mirror is "flatter" having less curvature.

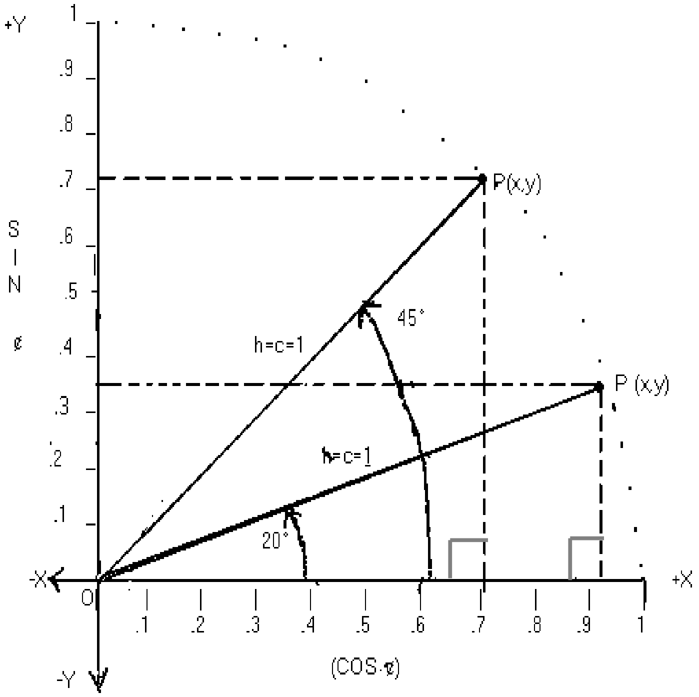
The diameter of the human pupil averages from about 2mm to 3mm in bright light conditions, and up to 6mm to 8mm in the dark. Since telescopes are generally used at night, an eyepiece with a diameter of 3mm to 5mm are commonly used, and this will help maximize the magnification of a telescope system, however the trade-off or loss when using high magnification is lower light intensity or brightness. This should not be problem when viewing the Moon which is relatively bright. Note that a common size for a telescope eyepiece is 1.25", and this also indicates the size of the mounting tube it is in, however the final light output, exit lens or pupil lens on it is much less that this value. To focus an object, usually the eyepiece is moved slightly in or out along the light path (the direction(s) of the light)) through the telescope. The higher the magnification used for an object, the lower the (angular) field of view at the observers end. To see (ie., discern, resolve) the rings of Saturn, you will need a telescope with at least 50 power minimum or greater. Binoculars are generally lower power than this, perhaps 20 power, and are very useful for terrestrial use such as "bird watching" and astronomical use such as "star watching" where many more stars can be seen. Galileo is said to be the first to see a large, thin and flat "ring" surrounding the space about Saturn, and while using a telescope.

A general rule to expect for telescope magnification is that there can be up to a maximum power of 60 power per each inch (25.4mm) of objective lens, and before image quality is degraded. The focal lengths of the objective and eyepiece lenses used will determine the actual magnification. If the focal length doubles, the magnification doubles, however the image brightness or intensity decreases by the square of that value hence s^2 = 4. Note ex.: Given a 400 power telescope, note the square root of 400 is 20, as in 20 times (linear) wider, but given a 600 power telescope with 200 more power, the square root of it is slightly less than 25, hence an image about 25 times wider which is only a value of 5 units more, and this may not justify the price and-or reduction in image brightness. Today, with photographic techniques of long exposure duration photography and-or high quality (ie., resolution) digital cameras, many negative issues with brightness, magnification and resolution of a given telescope can be reduced.

[This space for book edits.]

APPROXIMATING ANGLES AND TRIGONOMETRIC VALUES GRAPHICALLY

If a line segment, acting as a hypotenuse side of a right triangle, is given a length of one (1) unit (in "relative terms" or portions, this whole =1=100% value can represent any other whole or entire length value) and is rotated about the origin (O) of a rectangular coordinate measuring and location system, it will create an angle between that line and the X or horizontal axis. The Y coordinate of the endpoint (P) on the line will be equal to the sine of the angle, and the corresponding X coordinate of this endpoint will be equal to the cosine value of that angle. The point's location is therefore: P(x,y) = P(cos ¢, sin ¢). This is easily seen when lines are extended or "dropped" to both axis from that endpoint, and therefore creating a right-triangle construction that can be mathematically analyzed as a right- triangle. You may need a device that can measure (or create) angles such as a protractor. To "protract" is to extend outward as opposed to "retract" which means extend inward. In general, better or more accurate results are often easier to achieve by drawing a larger graph. [FIG 107]



Using the graph above, and the definition of SIN ¢:

$$\text{SIN } ¢ = \frac{\text{opposite}}{\text{hypotenuse}} = \frac{y}{\text{hypotenuse}}$$

Since the hypotenuse here is equal to 1, or is considered as a relative value of 100% = 1.0 portion of some other length:

SIN ¢ = y : If the hypotenuse was a relative or percentage value of some length, then (y) and (x) will also be a relative values.

Likewise, $\text{COS } ¢ = \frac{\text{adjacent}}{\text{hypotenuse}} = \frac{x}{\text{hypotenuse}}$ Since the hypotenuse here is equal to 1:

COS ¢ = x : clearly in the graph, as the angle increases, the cosine of that angle decreases, and its sine value increases, but **not** linearly, such as for example that sin¢ + cos ¢ = would always some constant value

Also, TAN ¢ = $\frac{\text{opposite}}{\text{adjacent}} = \frac{y}{x}$: also note that y = (TAN ¢) x , an equation which has the form of: y = mx. We see that the larger the angle drawn, the larger TAN ¢ is, and TAN ¢ is basically a numerical value indicating the slope or steepness of the line. For the equation on the left, note that TAN ¢ is inversely related to x (the side adjacent to the angle) and directly related to y (the side opposite the angle). From the equation y=(TAN ¢) x, you would initially think that (y) is directly related to (x) from general mathematical or algebraic reasoning and from the concepts of linear equations. However, this is not always the case, as it is here, when it comes to the "non-linear" or "non-algebraic" functions such as the trigonometric functions. For example, clearly in the graph, as (x) increases, (y) decreases, and this is an inverse type of relationship. Trigonometric functions are "circular" or "periodic" (values eventually repeat in a continuous cycle) as opposed to being "linear" with values without limited bounds.

By use of the graph, SIN 20° is about 0.34, and COS 20° is about 0.94. SIN 45° is about 0.7 and COS 45° is about 0.7. Only at 45° (half of 90°) are the sine and cosine values equal. The SIN and COS values are identical in a reverse type of manner. While one value is increasing to 1, the other value is decreasing from 1. For example: SIN 0° = 0 and COS 0° = 1, SIN 90° = 1 and COS 90° = 0, and only at 45° are the values the same (at about 0.7) since 45° is halfway between 0° and 90°.

Note that SIN 0° = 0 and SIN 90° = 1, and this is verified below:

SIN 0° = $\frac{\text{opposite}}{\text{hypotenuse}} = \frac{y}{1} = \frac{0}{1} = 0$

SIN 90° = $\frac{\text{opposite}}{\text{hypotenuse}} = \frac{y}{1} = \frac{1}{1} = 1$: at here: opposite side = hypotenuse

Only at 90° is the sine value equal to the maximum possible value of 1. All other sine values will be less than one (1).

Likewise, in an opposite or reverse manner: COS 0° = 1 and COS 90° = 0:

COS 0° = $\frac{\text{adjacent}}{\text{hypotenuse}} = \frac{x}{1} = \frac{1}{1} = 1$: at here, adjacent side = hypotenuse side

COS 90° = $\frac{\text{adjacent}}{\text{hypotenuse}} = \frac{x}{1} = \frac{0}{1} = 0$

Like the SIN values, all COS values of an angle will be equal to or less than one (1). TAN values will rapidly get larger as the angle increases since the ratio of the opposite side (with respect or in reference) to the adjacent side, or (y) to (x), increases rapidly as (x) decreases when the angle increases. This increase in TAN values as the angle increases is practically an exponential relationship, and in fact, the value of TAN 90° approaches infinity and therefore it is considered unspecific or undefinable in value. A good TAN value to memorize is the tangent of 45° which is equal to one (1). Here, the values of the sides opposite and adjacent to the angle are exactly the same length, and therefore, their ratio is 1.

If the above graph is drawn in a similar manner with all four quadrants of a rectangular co-ordinate system, then all angles from 0° to 360° and their corresponding (signed) trigonometric values can be observed and approximated. Each angle can then be shown to have the same (unsigned, signless or absolute) trigonometric values as that of a trigonometrically corresponding angle that is less than or equal to 90° in the upper-right or "first quadrant" of the rectangular coordinate system. To understand this, consider that angles from 0° to 90° will have a specific trigonometric value, for example, such as SIN ¢ having the values of 0 at 0°, and up to 1 at 90°. Due to the cyclic (repetitive) or periodic nature of the trigonometric functions, then in a reverse type of manner as the angles get larger than 90°, the corresponding SIN ¢

values are decreasing from 1 to a value 0 at the angle of 180°. Therefore, an angle in the "second quadrant" having a value between 90° and 180° will have a corresponding angle and trigonometric value of an angle less than or equal to a 90° angle in the first quadrant.

By applying the Pythagorean Theorem to the triangle constructions that can be created in the graph, alternate expressions for SIN ¢, COS ¢, and TAN ¢ can now be derived:

h^2 = x^2 + y^2 or r^2 = x^2 + y^2, when h, the hypotenuse, is considered as the radius (r) of a circle.

Since x = COS ¢ and y = SIN ¢, h = 1, and substituting this into the above expression :

1 = (COS ¢)^2 + (SIN ¢)^2 : You can remember this as the trigonometric "Pythagorean identity".
An alternate syntax or notation form often used is:

1 = COS^2 ¢ + SIN^2 ¢ : For this indicated notation, only the trigonometric value is squared. Also in this special expression, (COS^2) and (SIN^2) are not being multiplied to the angle (¢).

Solving for SIN ¢ and COS ¢ from this expression:

$\text{SIN ¢} = \sqrt{1 - \text{COS^2 ¢}}$ and $\text{COS ¢} = \sqrt{1 - \text{SIN^2 ¢}}$: some TRIGONOMETRIC CONVERSIONS (Pythagorean-like equations)

The TAN ¢ in relation to the corresponding SIN ¢ and COS ¢ values can be found using:

from: $\text{TAN ¢} = \frac{\text{opposite}}{\text{adjacent}} = \frac{y}{x}$, and SIN ¢ = y , and COS ¢ = x

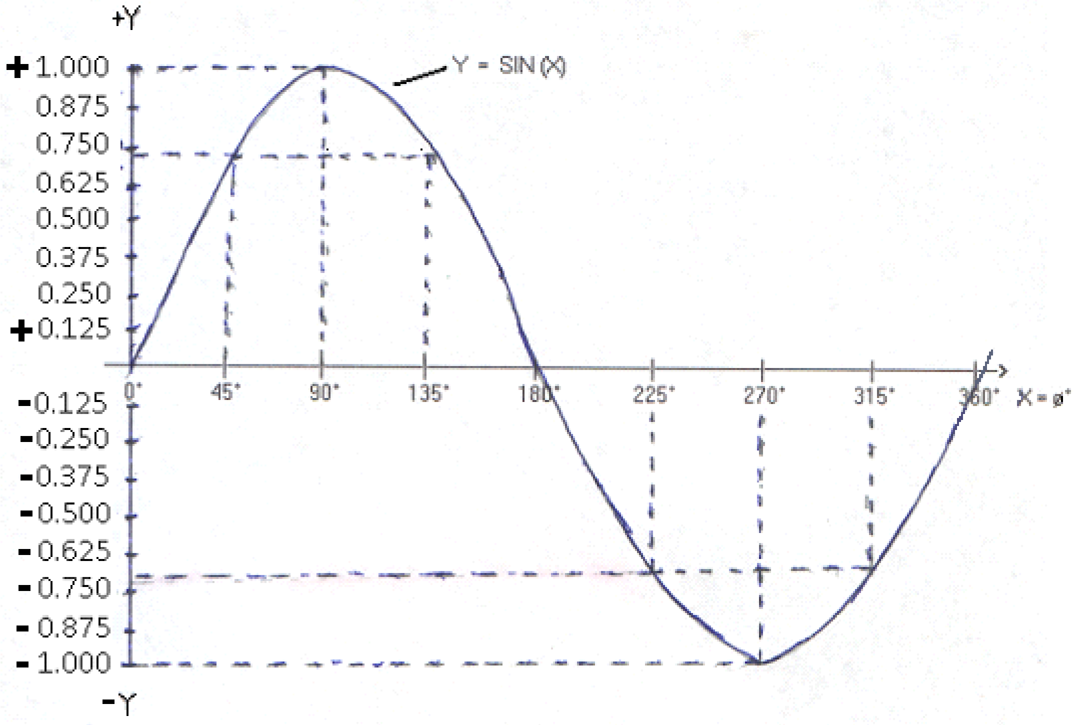
$$\text{TAN ¢} = \frac{\text{SIN ¢}}{\text{COS ¢}}$$

Another method for approximating trigonometric values is by drawing a graph of all the angles from 0° to 360° on the x-axis, and their corresponding trigonometric function values on the y-axis. This can be easily accomplished by selecting several of the angles between and including 0° and 360° and their corresponding trigonometric values, and then connecting the points with a smooth curve to represent and approximate all the other possible point values. The resulting curve is often called a periodic (repeating, repetitive, "oscillating" or cyclic) waveform. Below, the **sine waveform** is shown. Besides trigonometry where its' concepts originated, it is used to (graphically, visually) represent and analyze many other periodic events such as alternating (increasing in value, and direction) current (ie., ac electricity) and sound waves. Since a triangles trigonometric values are usually for angles less than or equal to 90°, and the values are cyclical or repeating for the larger angles, you may wish to only draw a graph with great detail or precision for only the angles between and including 0° and 90°.

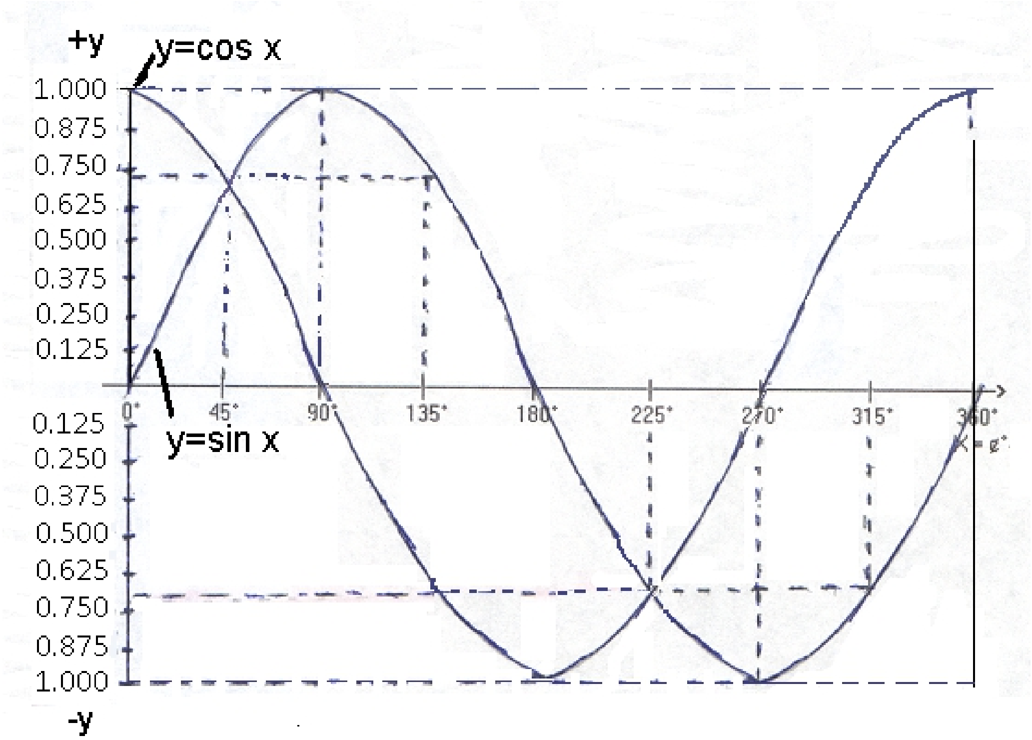
Selecting and plotting a few guiding, significant or "key" points (basically at the 45 degree increment for this specific curve) of this curve and drawing smooth line segments and-or curve segments so as to connect all the points of it, we have:

X = ¢	Y = SIN ¢	
0°	0	
45°	0.707	
90°	1	: the previous values in this set start repeating here. Trigonometric values of an angle (¢°) between 90° and up to 180° are equal to those of an angle from 90° down to 0°, and specifically: (¢° - 90°). For example, the trigonometric values of a 135° angle are similar to an angle of: (135° - 90°) = 45°
135°	0.707	
180°	0	
225°	-0.707	
270°	-1	

315° , -0.707
360° , 0 : The entire set of trigonometric values starts repeating here for angles >= 360°.
For any angle (¢) >= 360, the trigonometric equivalent angle is essentially: (¢-360°)
For example: sin 370° = sin (370° - 360°) = sin 10°.
In more technical terms it is: ¢ MOD 360. Though not needed in most circumstances in trigonometry, MOD is the modulus or "remainder" operator and it is discussed further ahead in this book. The result is that as the angle increases, the output of the MOD operation, the resulting, or "converted" (trigonometric equivalent) angle value will cycle from 0° up to 360° and then "restart" at 0°. In short, the "output" or "result" of a MOD mathematical operation are also cyclical. Most of the angles we will encounter will be less than or equal to 360°. An option to use if the angle is between 360° and 720° is that an ¢° in this range is trigonometrically equivalent to an angle of: (¢° - 360°). [FIG 108]



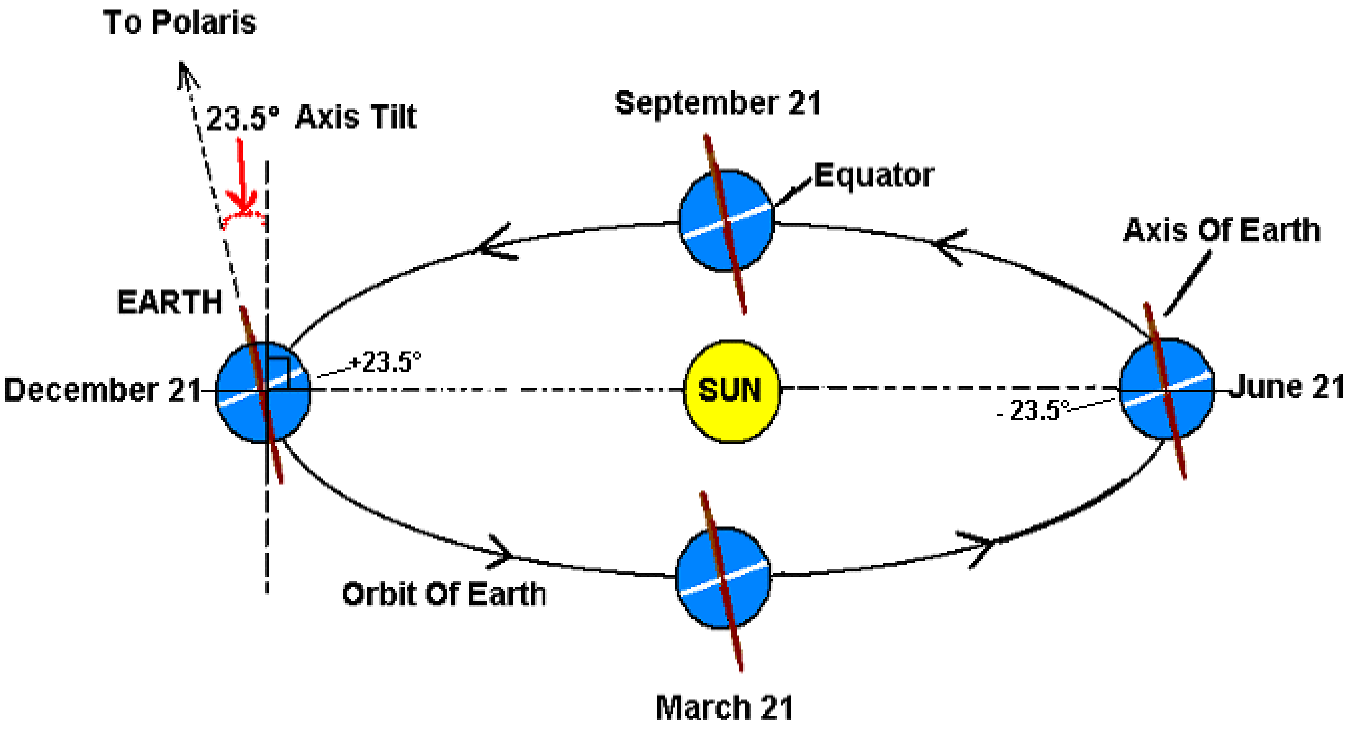
Notice how rapidly the SIN values change during the first 45° (half of 90°), where at 45°, it will have a value of about 0.707, and then the SIN values change much more slowly and only increase about 0.293 over the next 45° leading up to 90° where the SIN value is 1. As a graphical indication to how rapidly the initial SIN values change, notice how steep (steepness, or high slope values of) the SIN curve is near 0° and 180°. Also note at 30° (and 150°) , that the SIN value is already 0.50 which is already at half of the maximum SIN value of 90° which is 1.0, and that 30° is only at one-third of the way to 90°. In short, the relationship between the angles and their corresponding trigonometric values is non-linear (ie., non-proportional, or some other direct mathematical relationship), and non-algebraic (non-exact, no simple algebraic formula, irrational in value). Many algebraic-like methods have been developed that simulate or express their relationship so as to come as close as desired (usually in terms of practicality) to the true value or solution. Some of these will be presented further ahead in this book. Also notice that throughout the full 360° angle range, that the angles trigonometric (absolute) values (except at 0°, 90°, 180° and 360°) are repeated a total of four times during one cycle from 0° to 360°. Starting from the first quadrant (0° to 90°), each same trigonometric value instance corresponds to another quadrant of the rectangular coordinate system. The cosine curve is very similar to the sine curve above except that it effectively begins at the 90° mark of the sine curve and has a starting value of 1 instead of 0. This can also be thought of as like a sine curve being ("phase") shifted (in time and-or values) by 90°, and is often spoken as that the cosine curve (physically, in time) "leads" (ie., begins first) those of the sine curve. The sine curve is then often spoken as "lagging" the cosine curve by 90° in time and-or values. [FIG 109]



The SIN and-or the COS curves are known as periodic curves since the values will essentially keep repeating periodically as the angles grow larger over time. If the angle is greater than 360°, you can keep subtracting 360° from it to find its equivalent angle that is less than or equal to 360°. Since simple harmonic motion (ie., periodic motion or vibrations, that repeat after a certain amount of time, and are therefore said to have a frequency (ie. how often, or "hertz") or amount of cycles per amount of time, such as a second of time) such as the swing of a pendulum, sound and electro-mechanical generated electricity, and radio waves are periodic in nature, the SIN and-or COS curves are used to represent and mathematically analyze the physical creation, nature and motion or movements of this type. Here, the (x) axis becomes time, and the (y) axis becomes the voltage, current, or the height of a pendulum swinging which is its distance from an imaginary horizontal line directly equal to the height of the pendulum when it is not in motion.

As our planet Earth revolves around the Sun during a full year of time (indicated on the x-axis), the (apparent or effective) tilt of Earth (with respect to the solar (Sun) plane or "ecliptic", the direct line or orbital plane between the Earth and Sun) is (nearly) sinusoidal in nature. On about March 21 and September 21, the tilt (noted on the y-axis) of the Earth with respect to the Sun or solar plane is 0°. On about June 21 (toward the Sun) and December 21 (back or away from the Sun), the apparent or effective tilt is at it's maximum value of +,- 23.5°. If this was to be graphed, the x-axis would be the time (day, week or, month, etc.) of the year, and the y-axis would be the degrees of (apparent) tilt with respect to the Sun. Note that the rate of the tilt of the Earth is not consistent (a constant value) as indicated by the changing steepness or slope of the SIN curve or graph, and for the Earth to (apparently) tilt back in the other direction, it must first come to a brief stop after increasingly slowing down. This tilt was noted here as being apparent because Earth's axis, that the Earth rotates about in 1 day, always "points" (a direct line) to about (ie., very close to) the "North Star" (Polaris), and therefore the tilt of the Earth, or its axis, is only an apparent tilt, but still an "effective tilt" in terms of seasons due to Earths orbit (path of travel) around the Sun. More can be found about the tilt of the Earth in the topic of: An Equation For The Current Apparent Tilt Of The Earth. Since Polaris is many light-years away distant, then as Earths orbits about the Sun, and at opposite sides of this orbit which is equivalent to diameter of Earths orbit = 2 (radius of orbit) = 2 (93M miles) = 186M miles, the angular difference to Polaris is negligible, and approximately 0°.

[FIG 110]



Earth's equatorial (equator, shown as a white line in the above image) plane is constantly tilted about 23.5 degrees with respect to the (ecliptic or solar) plane of Earth's orbit about the Sun. On about Dec. 21, the Sun is directly overhead at noon at the tropic of Capricorn latitude (23.44°S) , and directly overhead at noon at the Tropic Of Cancer (23.44°N) latitude on about Jun 21 of the year. This can bee seen in the above image. It will take 6 months = 180 days of time to be overhead at these two maximum or extreme latitude locations mentioned, and overhead at noon at a slightly different latitude location for each different day that is between those two dates of time. The Earth's does not actually tilt, but it only appears (ie., the Sun and star angles) and feels (weather wise) as so, and this is due to the orbit of the (tilted) Earth. This effect also give the Earth its (real) seasons in the Northern and Southern hemispheres (half-sphere) of the Earth. When it is winter in the northern hemisphere, it is summer in the southern hemisphere, and vice-versa.

The above figure is an approximation showing linear, (24 hour) clock and-or calendar time imposed on an elliptical orbit with the Sun at the center - much like a circular orbit conceived by the yearly calendar time. Even though the orbit of the Earth is nearly circular about the Sun, it is infect an elliptical orbit with the Sun not in the exact center of the orbit, and which the velocity of the Earth increases as it gets closer to the Sun in the winter season of the northern hemisphere. It could be said that for half a year, the orbit is faster, and for the other half, it is slower, and the tilt angle of the Earth is not linear in nature and is constantly changing at a different rate. Nonetheless, it can be averaged like that of a circular orbit approximation as shown in this book further ahead, and so as to express the basic concept of Earths tilt angle with respect to the Sun. As mentioned, the Earth does not tilt with respect to the star Polaris, and is rather an apparent tilt due to the orbit of (tilted) Earth about the Sun.

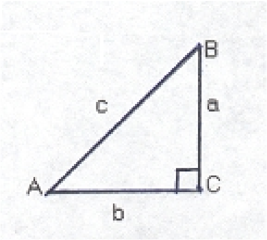
Etra: A Latin word for "Sun" that is still usd is "Sol". Greeks use "Helios" for "Sun". It is also used as part of the words "Solar" and "Solstice". Greeks use "Helios" for "Sun". A Latin word for "Earth" is "Terra". It is also used as part of the words "Terrain" and "Terrestrial". A Latin word for the "Moon" is "Luna". It is also usd as part of the word "Lunar".

COMPLEMENTARY ANGLES OF A RIGHT TRIANGLE

Since the right angle (C) of a right triangle is 90°, the other two angles of a right-triangle will always total to 90° since a triangles interior sum of angles is always a total of 180°. These other two angles that sum to 90° are called complementary angles, because they essentially complement each other so as their combined sum is equal to a (complete) 90° angle. Given two complementary angles, if one increases by N degrees, the other will decrease by N degrees so as to maintain their 90 degree sum.

$A + B + C = 180°$ Here, C=90° and is the right angle of a right triangle:
$A + B + 90° = 180°$ after transposing 90°:
$A + B = 90°$ **A and B, each less than 90°, are called the complementary angles of a right triangle and-or a right angle which is a 90° angle.**

[FIG 111]



For the figure above, Angles A and B, the non-right angles of a right triangle, are said to be complementary angles since the value of either angle always complements the other angle in order to create the required sum of 90° so as the internal angle sum of a triangle is 180°.

The trigonometric co-functions of complementary angles are equal. This is described below in mathematical terms:

SIN A = COS B and SIN B = COS A

$\frac{a}{c} = \frac{a}{c}$ $\frac{b}{c} = \frac{b}{c}$

If you had only a sine table, you would then also know the cosine of its complementary angle and vice-versa.

Ex. In a right triangle, if A = 50° , then the complementary angle, angle B = (90°- A) = (90°- 50°) = 40°

SIN A = COS B
SIN 50° = COS 40°
0.766 = 0.766

SIN B = COS A
SIN 40° = COS (90° - 40°) = COS 50°
$0.64\underline{3} = 0.64\underline{3}$

TAN A = COTAN B and TAN B = COTAN A

$\frac{a}{b} = \frac{a}{b}$ $\frac{b}{a} = \frac{b}{a}$

This equation above can also be expressed as:

$\frac{a}{b} = \frac{1}{\frac{b}{a}}$ and this can be expressed as:

$\text{TAN A} = \frac{1}{\text{TAN B}}$: Since the reciprocal of an angles TAN value is its COTAN value. Here, TAN B = 1/COTAN B, therefore mathematically, 1/TAN B = COTAN B

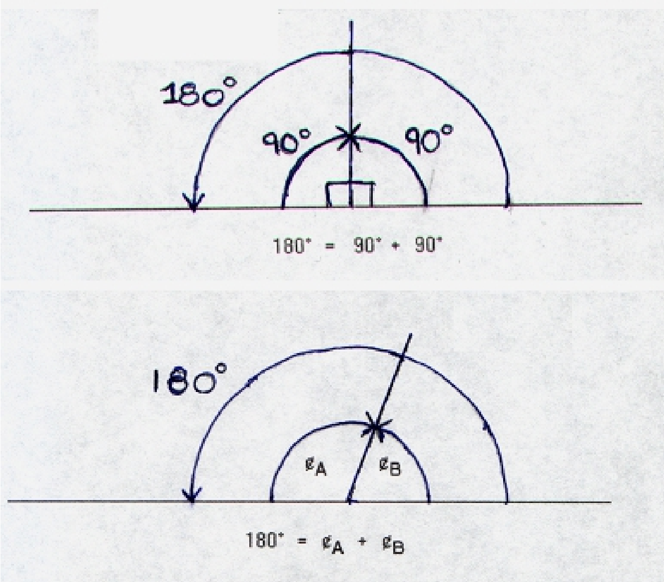
, and this can be used for solving for a part of a right triangle, or two angles that are complementary (that sum to 90°).

From the above equation, we mathematically have:

$(\text{TAN A})(\text{TAN B}) = 1$: the product of the TAN values of two complementary angles is always 1, and this is due to that they are reciprocals of each other

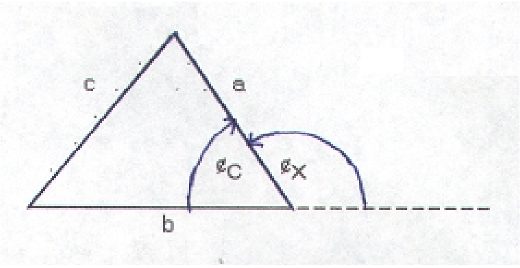
SUPPLEMENTARY ANGLES

Another important sum of angles not necessarily associated with triangles, but still within the practical realm of trigonometry, is the concept of supplementary angles. Any two angles that sum to 180° are said to supplement, or be supplementary to each other. An angle of 180° is very obvious since it forms a straight line segment. [FIG 112]



By knowing the concept of supplementary angles, it is easy to calculate angles such as the exterior angles to any triangle.

Ex. Below is a triangle with side (b) extended. Find angle X if angle C is 60° [FIG 113]



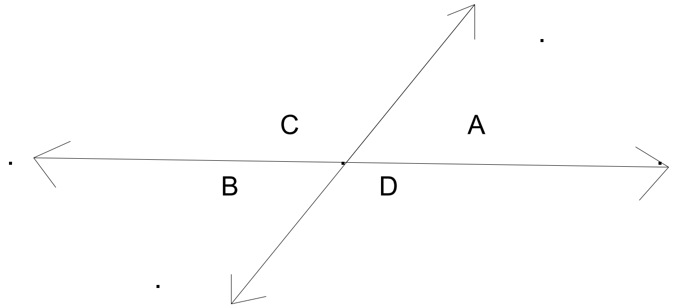
180° = ¢C + ¢X : by observation, ¢C and ¢X are supplementary angles that sum to 180°.
180° = 60° + ¢X Solving for ¢X by subtracting (or transposing) ¢C = 60° (the supplementary angle of ¢X) from each side of the equation, and then combining like terms:

¢X = 120° : also of note is that this value is also equal to the sum of the other two interior angles, here ¢A and ¢B, since all three interior angles of a triangle always sum to 180°.

The sum of all the exterior angles of a triangle is always 900° which is 5 times more than 180°.

VERTICAL ANGLES

Though not specifically related to triangles, the concept of vertical angles can play an important role in the further study of trigonometry, constructions and other fields of study. Vertical angles were previously briefly mentioned in this section. Whenever two lines cross each other, 4 angles are produced, all of which will have their vertex at the point of intersection of those two lines. 2 pairs of vertical angles are produced, and the angle for each corresponding pair will be equivalent. The equivalent pairs are directly "opposite", "across" or on the other side of the vertex point. In the drawing below, A and B are corresponding vertical angles, and C and D are corresponding vertical angles. [FIG 114]



What is the proof that vertical angles are the same (besides the somewhat obvious visual graphical proof)? In a worded form, for example, any and all supplementary angles to an angle in question are equivalent. If angle C is the supplementary angle of angle A, and angle D is also a supplementary angle (though along a different line that effectively creates another 180° straight-angle) to angle A, it is only logical to equate angles C and D. Here's an algebraic proof:

Due to supplementary angles:

$A + C = 180°$ and:
$A + D = 180°$ therefore, equating the two equations since they are both equal to 180° :

$A + C = A + D$ solving for C, transposing A:
$A + C - A = A + D - A$ combining:
$C = D$: C and D are vertical angles having the same value

Likewise:

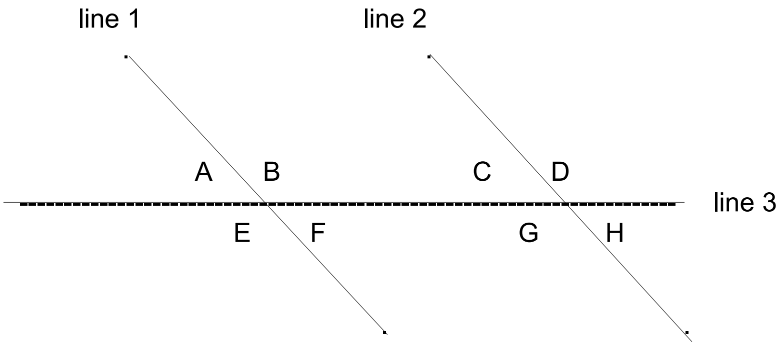
$A + D = 180° = D + B$

$A + D = D + B$
$A + D - D = D + B - D$

A = B : A and B are vertical angles having the same value

CORRESPONDING ANGLES CREATED BY A TRANSVERSAL LINE

A line that crosses two parallel lines is called a transversal line since it transverses (ie. crosses) between those two parallel lines. Below, line 1 and line 2 are parallel, and line 3 is the transversal line. [FIG 115]



At the intersection of each line it is obvious that pairs of vertical angles and supplementary angles are created. The corresponding angles at each intersection of the transversal line are also equivalent. That is:

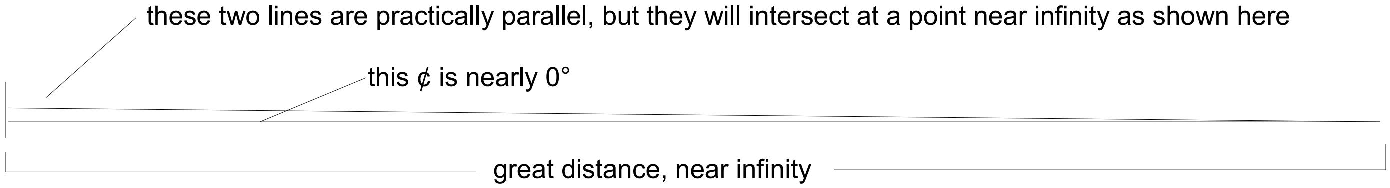
A = C and due to vertical angles:
A = F = C = H

B = D and due to vertical angles:
B = E = D = G

Perhaps it is not intuitive that corresponding angles created by a transversal line are equal. For example, what is a verification that angle A equals angle C?

One visual or graphical approach to answering this is to imagine the parallel lines as being so close that they practically overlap and yet are still distinct. Clearly, the angles A and C would clearly appear and be the same size. Consider that since the lines are parallel, they are exact images of each other, and all the angles created at each due to a transversal line will correspond and be equal.

Line 1 and line 2 extend to infinity without ever intersecting since they are parallel. Let's suppose that they meet at a point very far away or as "close to infinity" as can be. This can be accomplished when the lines are not quite parallel by only the very smallest amount possible, practically 0 degrees, a very minute value, but not equal to 0 degrees: [FIG 116]



The theoretical angle (¢) measured at this (imaginary) point of intersection is very close to a value to 0°. If we consider this (almost imperceptible) angle as the smallest of all angles possible, and angles B and C as the other two angles within this triangle construction, we get:

$180° = B + C + ¢$:180° = interior sum of angles of a triangle

Since the angle (¢), as mentioned above is nearly 0°, for all practical purposes, it can then be considered as 0°. Hence we get:

$180° = B + C + 0°$
$180° = B + C$ equating this to the supplementary angles of A and B, and C and D:

$180° = A + B = B + C = C + D$ therefore:

$A + B = B + C$ solving for A:
$A + B - B = B + C - B$
$A = C$

$B + C = C + D$ solving for B:
$B + C - C = C + D - C$
$B = D$

Also, though not quite obvious, angles B and C are supplementary angles due to that their sum is 180° as indicated above, and here is another verification that B and C sum to 180°:

Since: $(A + B) = 180°$ and $(C + D) = 180°$ adding both equations, or all the angles:
$(A + B) + (C + D) = 180° + 180°$
$A + B + C + D = 360°$

Since lines 1 and 2 are parallel, no matter how close (even if "on top" [coinciding] of each other) or far apart they are, the angles created by a transversal line at the intersection of any one parallel line will always be the same as those created at the intersection of another parallel line by that transversal line or another transversal line parallel to it. Since lines 1 and 2 are parallel or correspond to each other, the angles at each intersection of the transversal line will correspond and be the same value.

Since C corresponds to A: $C = A$
Since B corresponds to D: $B = D$

$A + B + C + D = 360°$ using algebraic substitution:
$C + B + C + B = 360°$ combining like terms:
$2B + 2C = 360°$ factoring 2 from each term on the left side:
$2(B + C) = 360°$ after dividing each side by 2:
$B + C = 180°$: verification

Perhaps a simpler way of expressing the above method and result is:

$A + B = 180°$ and since C corresponds to A, and as the same value:
$C + B = 180°$: sum of interior (between the parallel lines) angles on the same side of a transversal line is 180°, and this is equivalent to a "straight (line)", 180° angle.

Here is another derivation that the interior (between the parallel lines) angles on the same side of a transversal line will sum to 180°. Please refer to Fig 118.

Due to the concepts of vertical and corresponding angles created by a transversal line across two or more parallel lines we have:

A = C = F = H Since each is equal to angle C, and summing these angles, we have a sum of:
4C Likewise:

B = D = E = G Since each is equal to B, their sum is: 1B + 1B + 1B + 1B or:
4B

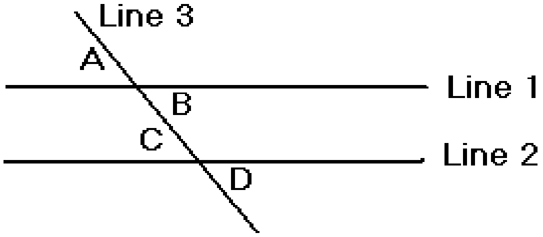
The total sum of angles around a point is 360°: A+B+E+F = 360° and C+D+G+H = 360°

sum of angles around a point+sum of angles around a point = sum of angles around a point+sum of angles around a point
sum of all angles around two points = sum of all angles around two points
A+B+E+F + C+D+G+H = A+C+F+H + B+D+E+H
A+B+E+F + C+D+G+H = 4C + 4B
360° + 360° = 720° hence:

4C + 4B = 720° factoring out 4 from each term:
4(C + B) = 720° after dividing both sides by 4:

B + C = 180° : verification that interior angles created on one side of a transversal line sum to 180°

Here is a verification that alternate (on opposite sides of the transversal line) interior (between the parallel lines) angles are equal. [FIG 117]

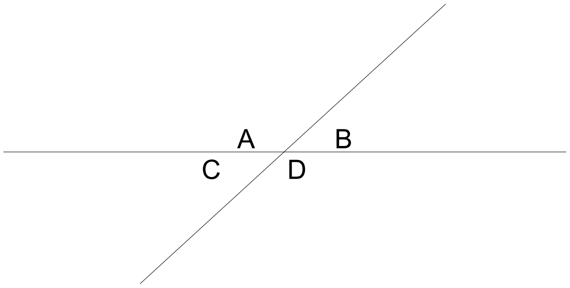


Line 1 and Line 2 are parallel lines. Line 3 is a transversal line that crosses both of the parallel lines. B and C are **alternate interior angles**. Due to vertical angles being equal:

A=B and C=D, Since A and C, and B and D are corresponding and equivalent angles, we have:
A = B = C = D hence:
B=C : a verification of alternate interior angles being equivalent
A=D : a verification of alternate exterior angles being equivalent

Angles A and D are examples of equivalent alternate exterior angles. A = D. Since vertical angles are equal:
A = B = D = C : all the angles shown in the figure above have the same value.

Now that transversal lines and the corresponding angles created have been discussed, a verification that the sum of all three interior angles of any triangle is always 180° can be described. First, observe the angles created by the intersection of two lines: [FIG 118]

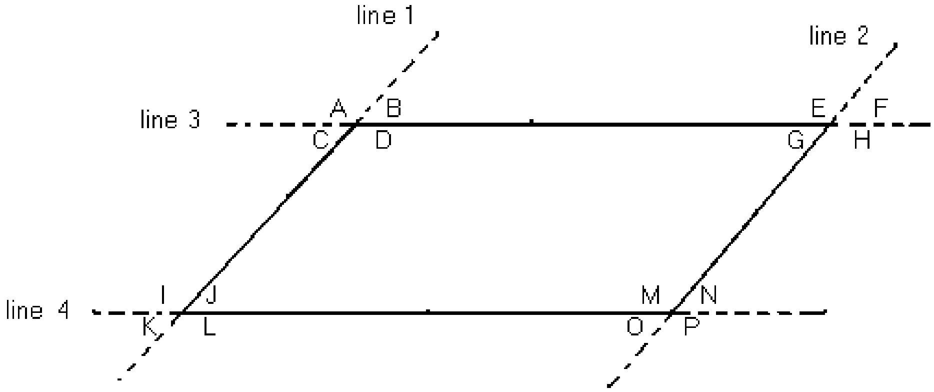


Since A and B are supplementary angles, and C and D are supplementary angles, the sum of angles around any point (as with the center of a circle) is:

$$180° + 180° = 360°$$

Verification Of The Sum Of A Triangles Inner Angles

It will now be shown that the sum of the interior angles of four sided (of any lengths) figures called quadrilaterals (any four sided portion of a plane; quad meaning four, and lateral meaning side) is always 360°. Squares and rectangles are common examples of quadrilaterals. A drawing of an quadrilateral called a parallelogram is shown below with its sides extended for the analysis. Note that a rectangle is a special instance of all possible parallelograms, and a square is a special instance of all possible rectangles. [FIG 119]



We see that a parallelogram can be drawn by intercepting two parallel lines by two parallel transversal lines.

Since there are 4 vertices or "corners" of the quadrilateral, and we know that the sum of the angles surrounding each corner or point is 360°, the total sum of all the angles indicated is:

$(360°)(4) = 1,440°$: internal and external sum of angles of a quadrilateral

We are to verify that the sum of interior angles of D, G, J, and M is (always) equal to 360°. By construction, line 1 and line 2 are parallel. Line 3 and line 4 are both parallel transversal lines to line 1 and line 2. From the concepts of vertical angles and corresponding angles, we can show some relationships of all the angles above (that total to 1,440°):

$A = D = E = H$: vertical angles, and since they all equal the same value of D, they sum to: 4D
$B = C = F = G$: vertical angles, and since they all equal the same value of G, they sum to: 4G
$N = O = J = K$: vertical angles, and since they all equal the same value of J, they sum to: 4J
$I = L = M = P$: vertical angles, and since they all equal the same value of M, they sum to: 4M

hence: $4D + 4G + 4J + 4M = 360°(4) = 1,440°$ factoring 4 from each term on the left side:

$4(D + G + J + M) = 360°(4) = 1{,}440°$ after dividing each side by 4:
$D + G + J + M = 360°$: verification of the inner sum of angles of a parallelogram

As mentioned previously, the internal or interior angles created at intersection of two parallel lines by a transversal line sum to 180° on one side of that transversal line:

Since: $D + G = 180°$: note that G = C, and D + C = 180°, and:
$J + M = 180°$ summing both sides of the equations:

$(D + G) + (J + M) = 180° + 180° = 360°$
$D + G + J + M = 360°$: verification

Continuing with the concepts of supplementary angles, it can be shown that the diagonal angles of a parallelogram are equivalent:

In the drawing above, if G is a supplementary (sum to 180°) angle to angle D, and if J is also a supplementary angle to angle D, then G=J. These angles are diagonal to each other. Likewise D=M. Considering any pair of the parallel lines, the internal angles created at their intersection of a line will sum to 180°. For two pair, the total is then 180° + 180° = 360°

$D + G = 180°$
$D + J = 180°$

$G = 180° - D$
$J = 180° - D$ Since both G and J are equal to the same value, they are equivalent to each other:

$G = J$: diagonal angles in a parallelogram are equal
$D = M$

If you were to divide the parallelogram in half, either vertically or horizontally, each half will contain half of the 360° internal sum or 360°/2 = 180°. This also shows that the internal angles created on one side of a (transversal) line that intersects two parallel lines have a sum of 180°.

As another simple verification::

Since A=D and B=C:

And $360° = A + B + C + D$ by substitution of equivalent angles:
$360° = D + B + B + D$ combining like terms:
$360° = 2D + 2B$ factoring 2 from each term:
$360° = 2(D + B)$ dividing each side by 2 and switching sides:
$(D + B) = 180°$ Since B=C=F=G:
$(D + G) = 180°$

Likewise:

$360° = 2J + 2L$:J=K, and I=L due to vertical angles
$360° = 2(J+L)$
$(J + L) = 180°$ Since I=L=M=P
$(J + M) = 180°$

$(D + G) + (J + M)$ removing grouping symbols:
$D + G + J + M$:sum of the interior angles of the parallelogram

180° + 180°
360° : checks

Here's another simple verification that uses all the angles on the "outside" (external) of the parallelogram to find those that are "inside" (internal) the parallelogram:

(A+B) = 180° , (E+F)=180, (K+L)=180° , (O+P)=180°, (I+C)=180° , (N+H)=180°

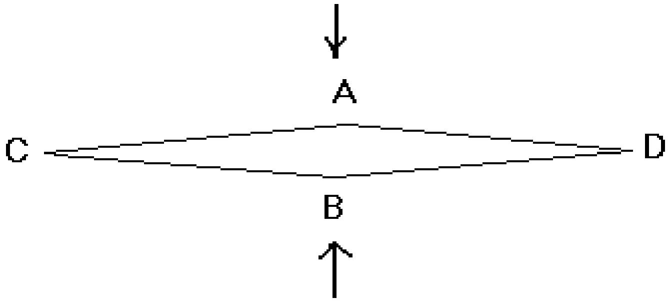
The sum of the above pairs is: 6(180°) = 1080°

Subtracting this specific external angle sum from the total possible vertice or "corner" angle sum of (360° x 4) = 1440° we have the sum of just the parallelograms internal angles:

1440° - 1080° = 360° : checks

Perhaps the simplest verification that the interior angles of a parallelogram sum to 360°:

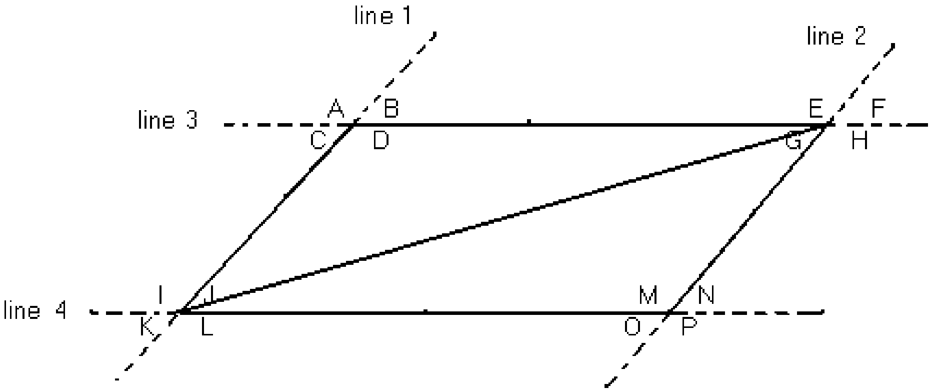
Here is a simple verification that the sum of the interior angles of a parallelogram is 360°. [FIG 120]



Consider A and B being pushed closer together as illustrated by the directional arrows. Those angles, A and B, will get larger and each will approach a value of a 180° "straight (line)" angle. At the same time, this will cause both angles of C and D to approach a value of 0 °. The net sum of internal angles of this parallelogram will be practically:

A + B + C + D
180° + 180° + 0° + 0° = 360° , or something as: 359.99999.... hence, approaching ----> 360°

When a (diagonal) line is drawn from two diagonal (ie. not on the same line) or "opposite" corners of a parallelogram, it will divide it into two congruent (identical) triangles. If the diagonal is extended for the analysis, and with the concept of supplementary angles, it is easy to see that the total vertice (ie. peak, corner, where two sides meet) sum of 1440° will be divided into two 720° (half of 1440°) sums. It is also easy to see that this line divides the interior sum of 360° into two 180° sums. Each 180° sum corresponds to the interior angles of a general or representative triangle.
[FIG 121]



Since the triangles are identical, their angles are identical, and therefore the sum of their angles must be the same:

(sum of angles of triangle 1) + (sum of angles of triangle 2) = 360°

Since the sum of angles of triangle 2 is the same as the sum of angles of triangle 1, using substitution:

(sum of angles of triangle 1) + (sum of angles of triangle 1) = 360°
2 (sum of angles of triangle 1) = 360° after dividing each side by 2:
sum of angles of triangle 1 = 180° : verification, and:
sum of angles of triangle 2 = 360° - sum of angles of triangle 1 = 360° - 180° = 180°

Since any quadrilateral can be divided into two (and not necessarily identical) triangles, the interior angle sum of any quadrilateral is twice that of a triangle or 2(180°) = 360°.

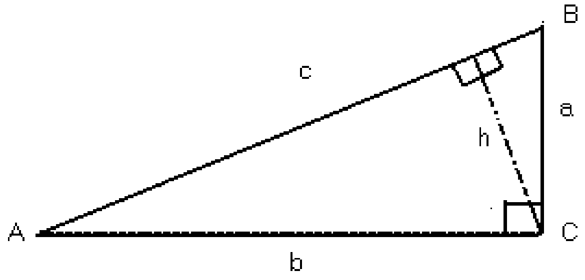
An interesting fact: Given the 3 vertex points of any triangle, the sum of angles around them is (3 x 360°) = 1080°. If you subtract the triangles 180° internal angular sum, we will have a triangles external angular sum of: (1080° - 180°) = 900°.

Given a corner (intersection of two straight line sides) of any construction such as a square or triangle, the external angle is 360° less the give angle of that corner: (360° - ¢°) = external or "opposite side" angle.

THE HEIGHT WITHIN A RIGHT TRIANGLE

Given any side of a triangle and considering it a base side, the perpendicular distance to the corresponding internal angle which is directly opposite from it is called the height or "altitude" at that base side or vertex. Sometimes the base side of a triangle needs to be considered as extended so as to create the perpendicular height line.

The two sides, other than the hypotenuse side, of a right triangle are equal to the height (or "altitude") from a vertex to the corresponding base side it intercepts perpendicularly (at 90° to that side). The third height (shown as (h) in the figure below) within a right triangle is the distance from the vertex of the 90° angle to the hypotenuse side it intercepts perpendicularly. [FIG 122]



As seen in the drawing of a right-triangle above, the height at (base) side (b) to the vertex B is equal to side (a). The height at side (a) is equal to side (b). A height line always intersects its corresponding base (of the height) line perpendicularly = (90°) . In the right triangle above: height at base side b = hb = a , and height at base side a = ha = b.

This height line to the hypotenuse (as a base) side will divide the right triangle into two smaller and similar triangles to the original outer triangle. This can easily be verified from the fact that each contains a right angle and that the complementary sum of the other two angles within each similar triangle is always 90°. In the drawing above, the pair of right triangles (the larger "outer" triangle, and the smallest interior triangle) have the same angle B. The other pair (the larger "outer" triangle, and the larger interior triangle) have the same angle A. Still, each of these similar triangles will and must have (so as to be similar) angles equivalent to A, B and C. Since we know that we have similar triangles, the simplest method to solve for the length of this height line (at base side c) is by using the concept of proportions (equivalent portions) of the sides of similar triangles sides, for example:

$$\frac{\text{hypotenuse}}{\text{adjacent}} = \frac{c}{b} = \frac{a}{h}$$ solving for h:

$$h = \frac{ab}{c}$$: INTERIOR HEIGHT FORMULA FOR A RIGHT TRIANGLE
: c = hypotenuse side

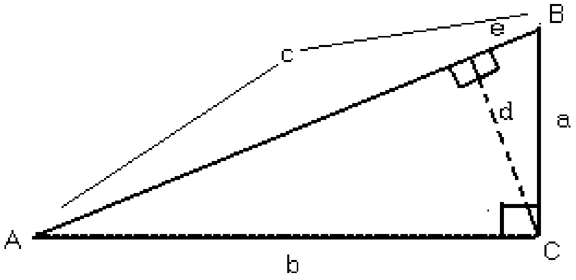
Ex. In a right triangle, a=3, b=4, c=5, find the altitude (height) from the right angle to the hypotenuse side.

$$h = \frac{(3)(4)}{5} = \frac{12}{5} = 2.4$$:height or altitude at side c

From the equation, also notice the possible methods to solve for a side if it is not known. For example, here is a simple formula for the hypotenuse (side c) if the height at side (c) is known:

$$c = \frac{ab}{h}$$: side (c) is the "base side" to altitude (line) of (h)

Using the concepts we now know, another derivation of the Pythagorean Theorem can be shown. Observe the following drawing of the right triangle with sides a, b, and c: [FIG 123]



Since the ratio of two sides of a triangle will equal the corresponding ratio of a similar triangle:

$\frac{a}{c} = \frac{e}{a}$ and $\frac{b}{c} = \frac{(c - e)}{b}$ simplifying:

$a^2 = ce$ and $b^2 = c(c - e) = c^2 - ce$

Using the two equations above, by adding both left-hand sides together, and adding both right-hand sides together, we have:

$a^2 + b^2 = ce + c^2 - ce$ combining like terms and switching sides:

$c^2 = a^2 + b^2$: PYTHAGOREAN THEOREM

Here is another way to solve for a part of a right triangle without needing to take a square root:

Considering $c = r =$ radius $= 1$, $\sin ¢ = \text{opp} / \text{hyp} = y / 1 = y$ and $\cos ¢ = \text{adj} / \text{hyp} = x / 1 = x$

$c^2 = 1 = x^2 + y^2 = \sin^2 ¢ + \cos^2 ¢$

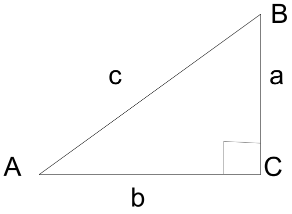
$\sin ¢ + \cos ¢ = x + y$

$\frac{c}{x + y} = \frac{1}{\sin ¢ + \cos ¢}$

$c = \frac{x + y}{\sin ¢ + \cos ¢}$ or $= \frac{a + b}{\sin ¢ + \cos ¢}$: ¢ = A or B in a right triangle.
Extra: $\sin A + \cos A = \cos B + \sin B = \sin B + \cos B$

LAW OF SINES

By using algebraic manipulation on the trigonometric ratio formulas for the angles, we can derive some other useful formulas. [FIG 124]



From: $\text{SIN A} = \frac{a}{c}$ and $\text{SIN B} = \frac{b}{c}$ therefore, mathematically:

$$c = \frac{a}{\text{SIN A}} \quad \text{and} \quad c = \frac{b}{\text{SIN B}}$$

, therefore, this is another method of calculating the hypotenuse without using the Pythagorean Theorem. The hypotenuse of a right triangle is equal to the ratio of any other side divided by the sine of its corresponding angle. For further practical use, the hypotenuse is also the diagonal line within a rectangle since a rectangle can be divided into two right triangles. In fact, the word hypotenuse seems to have originated first with rectangles since the root meaning of the word "hypotenuse" is to stretch or extend as we see with a diagonal line going (stretching or extending) from corner to opposite corner within a rectangle. Also notice that:

$$c = c$$ substituting the equivalent values for c:

$$\frac{a}{\text{SIN A}} = \frac{b}{\text{SIN B}}$$: alternate Hypotenuse Formulas

Since each fraction represents c, and SIN C = SIN 90° = 1, we can include side (c) into the equivalence above. This equivalence is known as the "law of sines".

$$\frac{a}{\text{SIN A}} = \frac{b}{\text{SIN B}} = \frac{c}{\text{SIN C}}$$: LAW OF SINES (here, verified for right triangles only)

From this we also have these equivalent fractions:

$$\frac{a}{b} = \frac{\text{SIN A}}{\text{SIN B}} = \text{TAN A}$$: Ratio Of Sines (derived for right triangles)

$$\frac{b}{a} = \frac{\text{SIN B}}{\text{SIN A}} = \text{TAN B}$$

Using the law of sines, if you have enough information to place into any two of the three equivalences shown, you can algebraically solve for a side or a trigonometric ratio value.

Ex. $a = \frac{b\ \text{SIN A}}{\text{SIN B}}$ also, $= a = \frac{b\ (\text{SIN A})}{(\text{COS A})} = b\ \text{TAN A}$:as expected since TAN A = a/b

This can also be expressed from what has been mentioned:

$\text{SIN A} = (\text{COS A})(\text{TAN A})$ likewise:

$\text{SIN B} = (\text{COS B})(\text{TAN B})$

Ex. $\text{SIN A} = \frac{a \text{ SIN B}}{b} = (\text{TAN A})(\text{SIN B})$: hence TAN A = SIN A / SIN B, and SIN B = SIN A / TAN A also:

Extra: Given a right triangle with C=90°:

$\text{TAN A} = \frac{a}{b}$ and $\text{TAN B} = \frac{b}{a}$ after dividing these two equations:

$$\frac{\text{TAN A}}{\text{TAN B}} = \frac{a^2}{b^2} = \frac{\text{SIN}^2 \text{ A}}{\text{SIN}^2 \text{ B}}$$: for right triangles only, where C=90°

Given a right triangle with C=90°:

$\text{COS A} = \frac{b}{c}$ and $\text{COS B} = \frac{a}{c}$ after dividing these two equations:

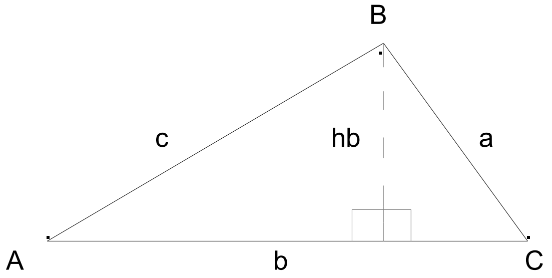
$$\frac{\text{COS A}}{\text{COS B}} = \frac{b}{a}$$: for right triangles only, where C=90° , note also: a COS A = b COS B

Inverting the above fraction, and squaring it:

$$\frac{\text{COS}^2 \text{ B}}{\text{COS}^2 \text{ A}} = \frac{a^2}{b^2} = \frac{\text{SIN}^2 \text{ A}}{\text{SIN}^2 \text{ B}} = \frac{\text{TAN A}}{\text{TAN B}}$$: for right triangles only, where C=90° taking the square root of each fraction:

$$\frac{a}{b} = \frac{\text{SIN A}}{\text{SIN B}} = \frac{\text{COS B}}{\text{COS A}} = \frac{\sqrt{\text{TAN A}}}{\sqrt{\text{TAN B}}} = \sqrt{\frac{\text{TAN A}}{\text{TAN B}}}$$: for right triangles only, where C=90°

All triangles can't be right-triangles and where two of the sides or "legs" are actually heights with respect to each other, so a more general verification of the law of sines is needed, and this is presented next. Observe the following drawing of a general (representative, and non-right) triangle: [FIG 125]



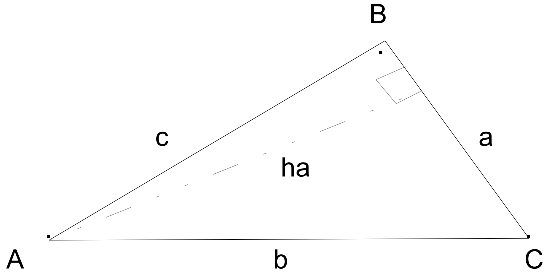
From: $\text{SIN A} = \frac{hb}{c}$, we get: $hb = c \text{ SIN A}$: hb = height at side b
For a right-triangle, hb is actually side a

From: $\text{SIN C} = \frac{hb}{a}$, we get: $hb = a \text{ SIN C}$ Equating the two expressions for hb:

$c\ SIN\ A = a\ SIN\ C$ algebraically:

$\frac{a}{SIN\ A} = \frac{c}{SIN\ C}$: for all triangles

Now observe the following drawing of the same triangle: [FIG 126]



From: $SIN\ B = \frac{ha}{c}$, we get: $ha = c\ SIN\ B$

From: $SIN\ C = \frac{ha}{b}$, we get: $ha = b\ SIN\ C$

Equating the two expressions for ha:

$c\ SIN\ B = b\ SIN\ C$ algebraically:

$\frac{c}{SIN\ C} = \frac{b}{SIN\ B}$: for all triangles

Equating this to the results of the previous drawing and equations (a use of what is known as the Transitive Law where if a=b, and b=c, then a=c. In short, a = b = c):

$\frac{a}{SIN\ A} = \frac{b}{SIN\ B} = \frac{c}{SIN\ C}$ **: LAW OF SINES (for all triangles)**

Some extra derivations from the above:

$\frac{side1}{side2} = \frac{SIN\ (corresponding\ angle\ to\ side1)}{SIN\ (corresponding\ angle\ to\ side2)}$, for example: $\frac{a}{b} = \frac{SIN\ A}{SIN\ B}$

Since SIN 90° = 1, for a right triangle:

$\frac{a}{SIN\ A} = \frac{c}{SIN\ 90°} = \frac{c}{1} = c$: where C is 90°, essentially, this is equivalent to SIN A = a/c
: for a right triangle only

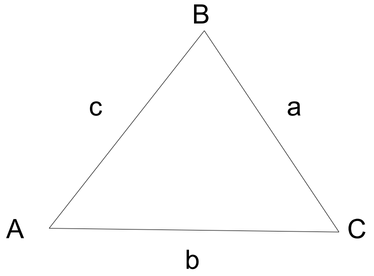
Likewise:

$\frac{b}{SIN\ B} = c$: where C is 90° , for a right triangle only

COMMON TYPES OF TRIANGLES

The most common type of triangle is the one that we have been studying so far, and that triangle is the **right-triangle**, however, there are other basic types or categories of triangles.

An equilateral (equal sided) triangle has all three of its sides equal in length, and all three interior angles have the same value of: (180°/3) = 60°: [FIG 127]



: EQUILATERAL TRIANGLE

In the above drawing of an equilateral triangle: $a = b = c$ and $A = B = C = 60°$

An **equilateral triangle** is always an acute (has no angle greater than 90°) triangle. If you were to divide an equilateral triangle along its' height (at exactly half of the base side) you can easily create two "30°, 60°, 90°" triangles.

You can divide an equilateral triangle into two right triangles to find a formula for the area of any equilateral triangle given just any one of its sides. In the drawing above, draw a perpendicular line from vertex B to half of side b. We will call this the height = h at side b. If we let s = side length, then from the Pythagorean theorem we have:

$s^2 = h^2 + (s/2)^2$: s = the lateral or side length, here, $s = a = b = c$, and $(s/2)$ is half that side length
$h^2 = s^2 - (s/2)^2$
$h^2 = s^2 - (s^2)/4$ combining fractions (LCD = 4), we have:

$$h^2 = \frac{4s^2 - 1s^2}{4}$$ combining like terms in the numerator:

$$h^2 = \frac{3s^2}{4}$$ taking the square root of both sides to isolate $h^1 = h$:

$$h = \sqrt{\frac{3s^2}{4}} = \sqrt{\frac{3}{4}}\ \sqrt{s^2} = \frac{\sqrt{3}}{2}\ s = 0.866025403\ s$$

: HEIGHT OF AN EQUILATERAL TRIANGLE.
The coefficient of (s) is also equal to SIN 60°
$\sin A = h/s$, $h = (\sin A)\ s$

$$A = \frac{b\,h}{2} = \frac{s\ \frac{\sqrt{3}\ s}{2}}{\frac{2}{1}} = \frac{s^2\ \sqrt{3}}{4}$$

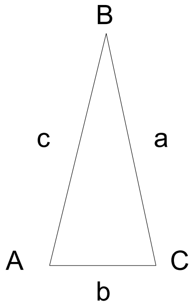
: algebraic formula for AREA OF AN EQUILATERAL TRIANGLE
It is based on, or directly related to, only one variable: s = side
Since $\sqrt{3}\ /4$ is a constant value:

$$A = 0.433012702\ s^2$$

: AREA OF AN EQUILATERAL TRIANGLE, (practical form)
The coefficient of (s) is equal to (sin 60°)/2

By observing the equation of the area of an isosceles triangle, it then becomes clear that its area is only a certain fraction of that of a square having the same side length. The area of a square is s^2. Also note that the height of the isosceles triangle does not equal its side length (s) or that of a square with side (s). Looking at the above equation for the height of an isosceles triangle, we see that it is less than (s). Also, by the Pythagorean Theorem, if (s) is considered a hypotenuse and the longest side of a triangle, the height must be less.

An **isosceles triangle** has only two of its sides equal in length. The third side of different length is often called the "base" (side), and the two equivalent angles created at the intersection of sides that base are called the base-angles of the isosceles triangle: [FIG 128]

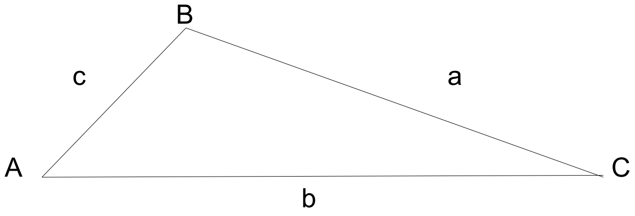


: ISOSCELES TRIANGLE

In the above drawing: $a = c$
$A = C$: "base angles" at b = "base side"

You can verify that A=C by drawing the height at side b and observing the two equivalent right triangles created. The height (h) of an isosceles triangle can be found using the Pythagorean theorem with: $c^2 = h^2 + (b/2)^2 = h^2 + b^2/4$
$h = \text{square-root}\,(c^2 - (b^2 / 4))$, For the isosceles triangle: Area = $bh / 2$ or= 2 (area of each inner right-triangle)

A **scalene triangle** has all three of its sides different in length: "Scalene" is a Latin-Greek word having a basic meaning of "odd scale or size", hence for a triangle it means that all sides of it are odd or different in size to each other. Note that a right triangle can be a scalene triangle. [FIG 129]



: SCALENE TRIANGLE

Congruent triangles are identical triangles. If all of the 6 parts (3 angles, and 3 sides) of two or more triangles have the same value, then those triangles are congruent or identical triangles. Even with a minimum of three specific corresponding parts having the same value is enough to determine that the triangles are congruent or identical, and all of the other corresponding parts will also be equivalent in value. Here is the minimum (3) number, and specific parts needed to determine if two triangles are congruent or identical:

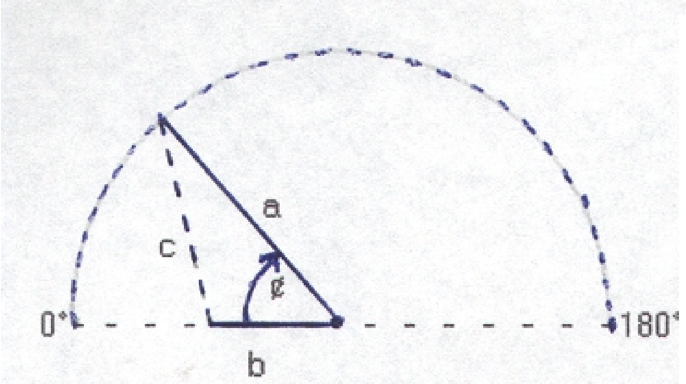
Three Sides : commonly known as the "SSS" test , S = side

An Angle And Its Two Adjacent Sides : commonly known as the "SAS" test, A = angle
(or "two sides and the included angle")

Two Angles And The Common Side Between Them : commonly known as the "ASA" test
(or "two angles and the included side")

AN OBSERVATION ON THE LENGTH OF A SIDE OF A TRIANGLE

Here is a general observation about the length of a side of a triangle in relation to the other two sides of that triangle. Observe the drawing below which shows a triangle being constructed: [FIG 130]



Sides (a) and (b) are shown and are representative of two sides of any angle of a triangle being constructed. When sides (a) and (b) are fixed in length, the length of side (c) then depends upon the angle (shown here at the intersection of sides (a) and (b)) created (usually called angle C since its opposite side c) when one of these sides is rotated about the other. Here, side (a) is being rotated about the intersection of sides (a) and (b). Since this angle can vary between 0° and 180° for the triangle, (c) can then vary in length, and it is therefore not possible to solve for side (c) given just the other two sides of the triangle alone (unless we know that it's a right triangle where C=90° and then the Pythagorean Theorem can be used to solve that triangle). Side (c) is then said to be ambiguous (undetermined, or can't be specifically determined) with just the limited amount of information given. For this not to be the case, more information about the triangle is needed such as an angle, a trigonometric ratio, a height, the perimeter of the triangle, or the area of the triangle. Even though the third side (side c) can vary in length, it does have a minimum and a maximum possible value. The minimum value for side (c) is when the corresponding angle (here, C) of it is small, practically or almost at 0° (there still needs to be an angle > 0° so as to have an actual angle and triangle construction). Here, the value of side (c) can be as low as (practically) 0 when the other sides (a and b) are near equal in length and the angle is near 0°. The size of (c) is always the distance between the endpoints of the two other sides (a and b) which intersect at and define its corresponding angle (C). The maximum possible value for side (c) is when the (corresponding) angle (here, angle C) is practically 180° (but not actually 180°, since a triangle must have 3 angles which sum to total value of 180°).

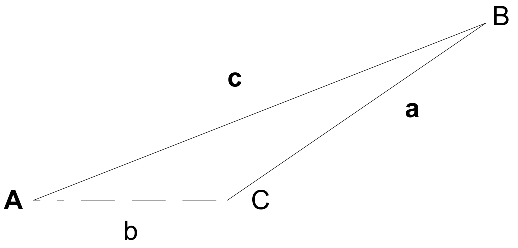
When the angle indicated in the above drawing is 180°, it is sometimes called a "straight angle". This is because the two sides (a and b) will form a (straight) line segment. For a triangle to exist, it must have three internal angles, and their sum is always 180°, and if one angle has that full value, the other two angles are 0° and non-existent, and therefore, the triangle is non-existent.

When the angle is fixed, the length of the side opposite that angle (side c above) depends upon the length of the two sides of that angle.

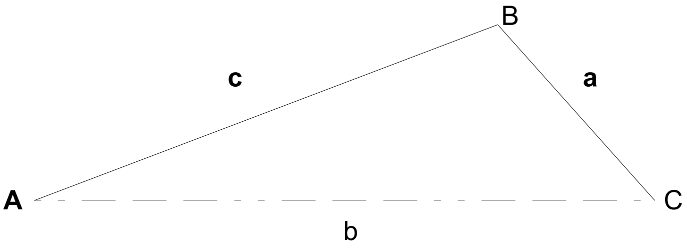
As hinted in the above discussions, even if you know the length of two sides of a triangle and an angle, a total of 3 parts of a triangle, it is possible that the triangle can't be completely solved for if the angle is not the angle between (ie., the "included" or vertical angle) those two given sides, and if no other information about the parts of the triangle are known. Such a condition is called the "ambiguous (undetermined) case". In the above drawing, side (a) and (b) are fixed in value, and side (c) then depends on the size of its corresponding angle, and if that angle is not known, then side (c) can't be determined if no further information about the triangle is known. Below is an example of this type of ambiguous situation.

For either or both triangles below, we are given these three parts: side (a)=3, side (c)=7, and ¢A=10° [FIG 131]

T1



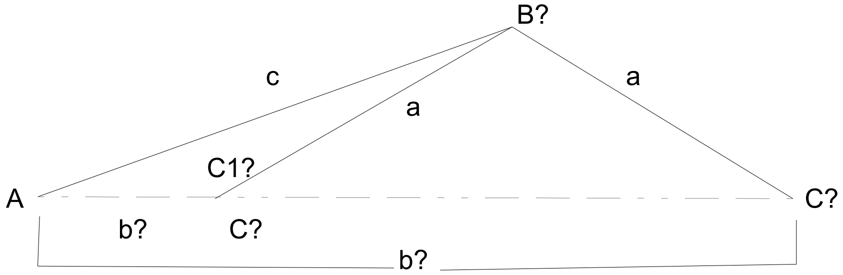
T2



Given the triangle information, first consider if it contains a minimum of 3 and specific parts needed, such as one part being a side, so as to solve that triangle, and then consider:

When given just two sides of a triangle and one angle, if the angle is not at the intersection of those two given sides, then a condition of an ambiguity exists, and even though the law of sines could be used (on each different ambiguous triangle), as it does with the limited information given in this example. We are given sides (a) and (c), and the angle that we need is at the intersection of these two sides, and that angle is B which was not given. If B, and not A, was given, we would of had enough information to use the law of cosines formulas to solve for some other parts of this triangle, such as:
sideb^2 = sidea^2 + sidec^2 - 2(sidea)(sidec)(cos ¢B) : a form of the law of cosines
Using the law of sines using: (a/Sin A) = (b/Sin B) = (c/Sin C), we can find C as about 23.90° OR (180° - 23.90°) = 156.01° due to the ambiguous condition being met. For both angles, their sine value is the same, here about: 0.405

Even though side (a) has the same length for both triangles, clearly, side (b) in T2 is longer than side (b) in T1. As mentioned previously, to continue solving either triangle, more information about the triangle must be known. This information can be found by measurement and-or by calculation using further known information about the triangle. Using the triangles above, here is a combined view of the two possible (ambiguous triangles): [FIG 132]



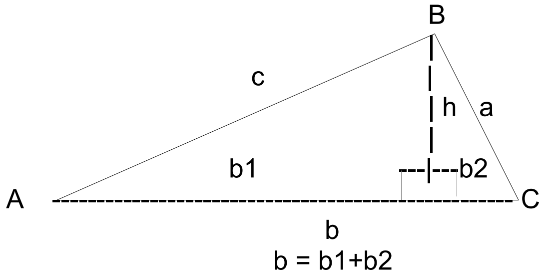
Given: a , A , c
Ambiguous: b , B , C
C + C1 = 180°
C1 = 180° - C

Notice the isosceles triangle indicated and having two sides equal to (a), and both base angles of it are equal to C. This fact will be of aid when solving for one of the two possible ambiguous triangle solutions. For one solution when ambiguity exists, C (which is the corresponding angle to the other given side, here side (c)) is greater than 90°, but if the given angle, here ¢A, is greater than or equal to 90°, there is no ambiguity since the other two angles will complete the 180° internal angle sum, and their sum will be equal to or less than 90°, and it is not then possible for another angle to be greater than 90°. If side (a), and which corresponds to the given angle A, was longer than side (c), then the two equal sides of the isosceles triangle indicated cannot exist, and therefore, the isosceles construction will not exist, and there will be one unique solution only since the ambiguous condition does not then exist.

When given 4 or more correct parts of a triangle, the triangle can be completely solved, that is, there is no chance for an ambiguous part(s). When given 3 parts, the minimum number of parts to solve a triangle, one part must be a side (to distinguish it from all other possible similar triangles that have the same angles), however, the triangle can still be ambiguous (have 2 possible solutions). A triangle is ambiguous when given only two sides and an angle (<90°) that corresponds to one of those sides (ie., the given angle was not the angle between and at the intersection of those two given sides). We were not given angle (B) at the intersection of sides (a) and (c). All other (the three remaining) parts of that ambiguous triangle will have two possible solutions. For the above example, the ambiguous parts are C, B and b. There are two possible solutions for these parts. Side (b) is an ambiguous side. Angles B and C are ambiguous angles.

METHODS FOR SOLVING ANY TRIANGLE

The discussion that follows is for solving triangles that are not necessarily right triangles, however, the formulas to be presented will also work for right triangles since a right triangle is also an instance of the infinite number of all possible triangles. Triangles that are not right triangles are also known as oblique (ie., tilted [from 90°]) triangles. The reason that these formulas to be presented are needed is that the Pythagorean Theorem mathematical relationship no longer applies to the 3 main sides of these triangles, and this should be somewhat obvious for equilateral triangles where all of its sides are equivalent in length, and all of its angles are equivalent but none are 90° which is required for a right triangle. Also, for an equilateral triangle, here is no hypotenuse, or longest side if all the sides are equivalent in length. Below is a representative triangle used for the derivation of THE LAW OF COSINES formula. [FIG 133]

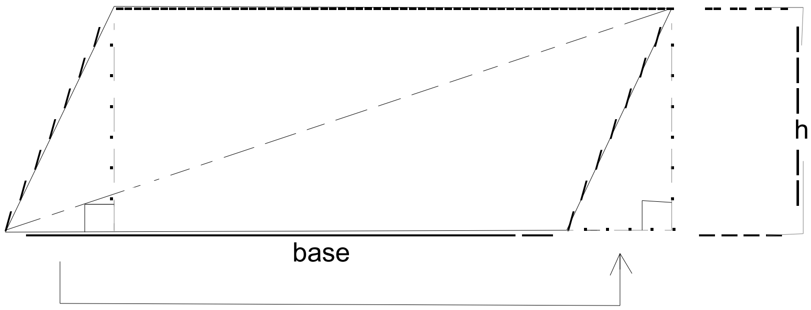


h = height is also known as the altitude of the vertice ("corner", peak, or vertex of a triangle, vertices is the plural of vertex) point where two lines, such as the sides of an angle or triangle meet or intersect. In a way, a vertex is like a "corner" of a triangle or construction. A triangle has three altitudes (either internal and-or external as when a (base) side needs to be extended so as to show the actual height of a vertex) since it has three vertices. The length of the altitude is the perpendicular distance from a vertice to the angles corresponding side or base. This base side is physically directly "opposite" or across from the angle and is sometimes said to "subtend" (meaning beneath) the angle. The three heights of a triangle will intersect or meet at a special point called the orthocenter. Note, for non-right-triangles that are obtuse ("large" or "wide", hence have an ¢>90°), the base line of two sides must be extended so as to show the altitude as perpendicular to the base. All the heights of an acute triangle (all ¢<=90°), such as an equilateral triangle, are within the triangle. The area of these triangles being discussed is also calculated from the same formula as that used for right-triangles.

$$\text{Area} = \frac{(\text{base})(\text{height})}{2}$$

: Area of any triangle
Height is the distance or altitude from the (perpendicular) base side to the corresponding vertice or angle.
For clarity: (base)(height) = (side of triangle)(height at that side)

This formula for area is so, since any triangles is equivalent to one-half of a parallelogram. A parallelogram, as discussed previously in this book, has 4 sides like a rectangle, but each pair of opposite sides need only be parallel, and adjacent (connecting) sides need not be perpendicular as required for rectangles. Actually, a rectangle is only one special case of an infinite number of possible parallelograms. If you imagine the corners of a square or rectangle as having hinges to let it tilt left or right, it is easy to conceive that a parallelogram and its associated area can be created. Given a parallelogram, it is easy to show the equivalent rectangular area when the indicated (as shown in the next figure) left triangular area of the parallelogram is moved over to the indicated equivalent triangular area adjoining the right side of the parallelogram and therefore creating a rectangle structure: [FIG 134]



Using the Pythagorean Theorem on the two internal right triangles that compose the general triangle indicated in Fig 133:

$a^2 = b2^2 + h^2$ and $c^2 = b1^2 + h^2$ solving for h^2 in both equations:

$h^2 = a^2 - b2^2 = c^2 - b1^2$

$\text{COS } C = \frac{b2}{a} = \frac{b - b1}{a}$, hence $b1 = (b - a \text{ COS } C)$, and $b2 = a \text{ COS } C$
therefore, $b2^2 = (a \text{ COS } C)^2 = a^2 \text{ COS}^2 C$

$a^2 - b^2 = c^2 - b1^2 = c^2 - (b - a \text{ COS } C)^2$ expanding the binomial:

$a^2 - b^2 = c^2 - (b^2 - 2ab \text{ COS } C + a^2 \text{ COS}^2 C)$ using substitution, and distribution:

$a^2 - b^2 = c^2 - (b^2 - 2ab \text{ COS } C + b^2) = c^2 - b^2 + 2ab \text{ COS } C - b^2$ combining terms:

$a^2 - b^2 = c^2 - 2b^2 + 2ab \text{ COS } C$ after solving for c^2 :

$\mathbf{c^2 = a^2 + b^2 - 2ab \text{ COS } C}$ **: LAW OF COSINES (for all triangles, side c)**
The formula is very similar to the Pythagorean Theorem, but has another term added to it. Below is an example.

$c = \sqrt{a^2 + b^2 - 2ab \text{ COS } C}$: side c, also:

$\mathbf{\text{COS } C = \frac{a^2 + b^2 - c^2}{2ab}}$ **: useful when only three sides are given and you need to find some angles**

¢C = ARCCOS (COS C) : ARC COS essentially means to find the corresponding angle given its corresponding COSine value. As cosine ¢ is a trigonometric function (can be thought of as an equation or process) that depends on the sides of that angle. arccos ¢ is a function that is essentially the inverse of the cos ¢ function.

Similar formulas for sides (a) and (b) can be derived as:

$a^2 = b^2 + c^2 - 2bc \text{ COS } A$: LAW OF COSINES (side a)

$b^2 = a^2 + c^2 - 2ac \text{ COS } B$: LAW OF COSINES (side b)

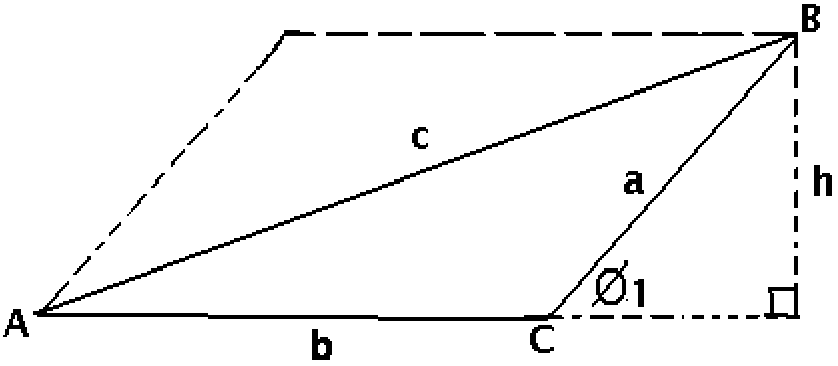
The basic format (which has a Pythagorean Theorem-like form) of each of the above equations for the law of cosines is therefore:

side^2 = (SUM of other two sides that are squared) - 2(PRODUCT of the other two sides)(COS corresponding angle)

Due to the fact that the LAW OF COSINES formula is so "cumbersome" or lengthy, if you like, you can always finish solving a triangle using the LAW OF SINES formula and the fact that the sum of a triangles interior angles is a constant of 180°. If the altitude that is completely within the triangle is known, it is also possible to solve for some of the triangles parts using the Pythagorean Theorem or trigonometric ratios. If the triangle is a right-triangle, the law of cosines formula reduces to the Pythagorean Theorem since COS 90° = 0. c^2 = a^2 + b^2 - 2ab COS 90° = a^2 + b^2 - 0 = a^2 + b^2. The fundamental basics of the law of cosines were known to early Greek mathematicians such as Euclid of Alexandria.

As an extra note, since c^2 = b1^2 + h^2 and a^2 = b2^2 + h^2 , we can get: h^2 = a^2 - b2^2
c^2 = a^2 + b1^2 - b2^2
b1^2 = c^2 + b2^2 - a^2 and b2^2 = a^2 + b1^2 - c^2
a^2 = c^2 + b2^2 - b1^2

Ex. Below is a triangle. Find side (c) given just two sides and (almost) the included angle between those sides. Side (a) = 5 , side (b) = 7 and ¢1 = 45°. Also indicated is that this triangle could be considered as half of a parallelogram and that (c) is equal to the diagonal within that parallelogram. [FIG. 135]



From the fact that supplementary angles sum to 180° :

C + ¢1 = 180° solving for C:
C = 180° - ¢1 substituting the known value for ¢1:
C = 180° - 45°
C = 135°

Now that we have two sides and the angle included between those two sides. We can use the law of cosines with this limited amount of information so as to find the third side which is side (c) which is also the length of the diagonal line in the parallelogram indicated.

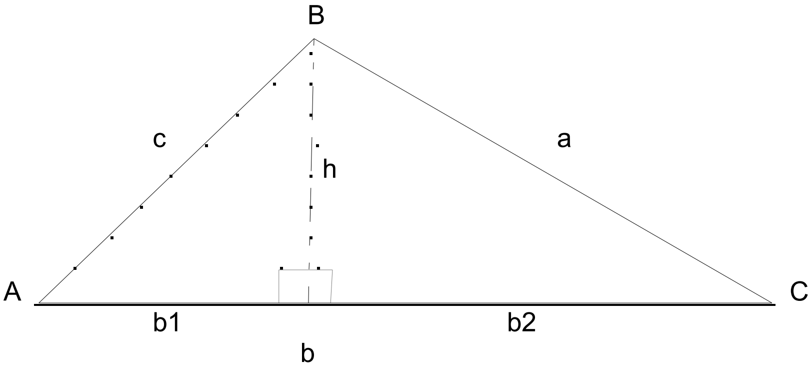
c^2 = a^2 + b^2 - 2ab COS C taking the square root of both sides and substituting the known values:

$$c = \sqrt{5^2 + 7^2 - 2(5)(7)(0.7071\underline{1})}$$

$$c = 11.11\underline{3}$$

CALCULATING ANY HEIGHT WITHIN A TRIANGLE

Here is a formula to calculate the (perpendicular) height (ie., "altitude") from any vertex of a triangle to its corresponding base side. The height between a side and the corresponding angle is also the shortest distance from that vertex to the opposite side. Though there are other methods, such as the law of cosines to solve for the height if enough information (triangle parts) about the triangle is known, the formula presented below can be helpful when a triangle construction is based upon a base side value and the (base) angles adjoining to that base side. [FIG 136]



$\text{TAN } A = \frac{h}{b1}$ $\text{TAN } C = \frac{h}{b2}$ therefore:

$b1 = \frac{h}{\text{TAN } A}$ $b2 = \frac{h}{\text{TAN } C}$

$b = b1 + b2$

$b = \frac{h}{\text{TAN } A} + \frac{h}{\text{TAN } C}$: An example of solving for a base side using the base angles and the height at that base side. After combining fractions:

$b = \frac{h\ (\text{TAN } A + \text{TAN } C)}{\text{TAN } A\ \text{TAN } C}$: an optional formula. Solving for h = hb:

$hb = \frac{b\ \text{TAN } A\ \text{TAN } C}{\text{TAN } A + \text{TAN } C}$: height at base side b given the adjacent angles. Likewise:

$ha = \frac{a\ \text{TAN } B\ \text{TAN } C}{\text{TAN } B + \text{TAN } C}$

$hc = \frac{c\ \text{TAN } A\ \text{TAN } B}{\text{TAN } A + \text{TAN } B}$

Observing the above formulas, here is a generalized or non specific HEIGHT FORMULA given a base side and the two adjoining angles to that base side:

$$\text{height} = \frac{\text{(base perpendicular to height) (product of the TAN values of both base angles)}}{\text{(sum of the TAN values of both base angles)}}$$

Here is a derivation of a helpful ratio, especially when the height is not known:

Given: $\tan A = \frac{h}{b1}$ and $\tan C = \frac{h}{b2}$ therefore:

$h = b1 \tan A = b2 \tan C$:

$\frac{b1}{b2} = \frac{\tan C}{\tan A}$: since b1 is closer to or adjacent to A, and b2 is closer to C, this is like a reverse ratio. A and C are the "base angles" adjacent or adjoining base side (b). b1 and b2 are segments of side (b) where the altitude or height intercepts that side.

A generalized formula for all sides is:

$\frac{\text{segment1 of base}}{\text{segment2 of base}} = \frac{\text{TAN of base angle at segment2}}{\text{TAN of base angle at segment1}}$: a base segments ratio, of how the height intercepts it and divides it into two segments

For example:

Between angle A and B is side (c). A=36.87°, B=53.13°, and (c)=5. The height at side (c) will divide that base side (c) into two segments (c1 and c2). What is the length of each segment?

$\frac{\tan A}{\tan B} = \frac{\tan 36.87°}{\tan 53.13°} = \frac{0.75}{1.3333} = 0.5625 = \frac{c2}{c1}$, hence: $c2 = 0.5625\, c1$, and: $c = c1 + c2 = 5$
also: $c1 = c2 / 0.5625$

Now we have two (simultaneous) equations. We can use substitution to create one solvable equation that contains only one variable:

$c1 + c2 = 5$ using substitution:
$1c1 + 0.5625c1 = 5$ combining like terms:
$1.5625\, c1 = 5$ after dividing both sides by 1.5625

$c1 = 3.2$: this segment is connected to, or nearer to (the vertice of) angle A

$c = c1 + c2$
$c2 = c - c1$
$c2 = 5 - 3.2 = 1.8$: this segment is connected to, or nearer to (the vertice of) angle B

Likewise:

Given: $\cos A = \frac{b1}{c}$ and $\cos C = \frac{b2}{a}$

$b1 = c \cos A$, $b2 = a \cos C$ dividing the left equation, by the right equation:
(dividing both sides by an equivalent (same) value)

$\frac{b1}{b2} = \frac{c \cos A}{a \cos C}$: another base segment ratio, of how the height intercepts it and divides it into two segments

$\frac{b1}{b2} = \frac{c \cos A}{a \cos C} = \frac{\tan C}{\tan A}$ hence: $c = \frac{a (\cos C)(\tan C)}{(\cos A)(\tan A)} = \frac{a \sin C}{\sin A}$, and: $\frac{c}{a} = \frac{\sin C}{\sin A}$
(law of sines)

There is a way to calculate the height of any triangle without using any trigonometric functions. This method utilizes a unique formula for the area of any triangle which was derived long ago in about the year 60AD by the Greek mathematician and inventor named **Heron** (aka Hero of Alexandria, Egypt). An easy to understand, modern version of the derivation of this formula is given in a book such as: **A Journey Through Genius, The Great Theorems Of Mathematics, by William Dunham**, and which could be described as an interesting, helpful, "good read", and which gives many mathematical topics a practical analysis for an easier understanding.

Given: $S = \frac{a + b + c}{2}$: half the triangles perimeter (variable S = Semi-perimeter distance), which is half the length of the sum of a triangle's' sides

TRIANGLE AREA = $At = \sqrt{S (S - a) (S - b) (S - c)}$: **HERON'S FORMULA** , for the area of a triangle. S = half the perimeter = semi-perimeter

As an interesting note for this unique formula and its structure, consider that half a square area with side (s) is equal to a triangle with half the area of that square, and if you square both sides of Heron's Formula , you will have this similarity:

(At^)2 = S (S-a) (S-b) (S-c) , and for a square: As = s^2 and therefore: (As)^2 = (s^2)^2 = s^4 = (s)(s)(s)(s)

Since: $At = \frac{(base)(height)}{2}$: base and height are perpendicular to each other. For example, if c is the base side, the corresponding height (h) is hc and its length is the perpendicular line from side c to the vertex of the two other sides (a and b) that define and are adjacent to angle C. (base)(height at that base) or= (side)(height at that side). Mathematically:

$h = \frac{2At}{base}$: another Height Formula (no TAN values needed)
: the height and base correspond and are perpendicular (right angle) to each other

$h = \frac{2 \sqrt{S (S - a)(S - b)(S - c)}}{base}$: a height formula based on Heron's formula for triangle area

From: $SIN\ A = \frac{hb}{c}$ and side b is perpendicular to hb = the height at side b, we can get:

$hb = \frac{2At}{b}$ using substitution:

$$SIN\ A = \frac{hb}{c} = \frac{\frac{2At}{b}}{c} = \frac{2At}{bc} = \frac{2 \sqrt{S (S - a) (S - b) (S - c)}}{bc}$$

¢A = ARCSIN (SIN A) : formal mathematical notation for finding the corresponding angle of the corresponding sine value of that angle

$SIN\ A = \frac{2\ At}{bc}$ $SIN\ B = \frac{2\ At}{ac}$ $SIN\ C = \frac{2\ At}{ab}$ and the general format is:

$SIN\ \text{¢} = \frac{2\ Area}{\text{product of both sides adjoining that angle}}$: adjoining=composing=creating=defining
From this, we can also derive another formula for the area of the triangle (At):

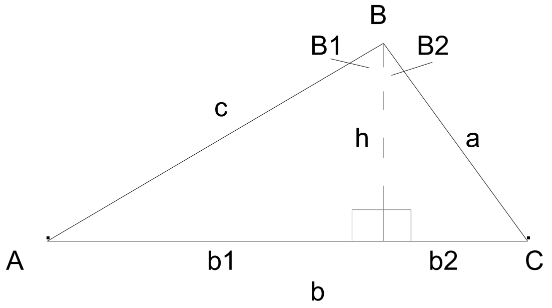
$At = \frac{(\text{product of both sides adjoining the angle})\ Sin\ \text{¢}}{2}$

Ex. $At = \frac{b\ c\ \sin A}{2}$: This can also be derived from A = (base)(height) / 2, where base = b, and Sin A = h/c, then h = c Sin A, From this we can also derive:

$\sin A = \frac{2\ At}{bc}$: this equation was also shown above

EXTRA EQUATIONS FOR THE SIDES OF NON RIGHT TRIANGLES

Observe this drawing below of a non-right triangle. To help solve for parts of it, the triangle is shown with two indicated internal right triangles which can be analyzed using the Pythagorean Theorem. The result is some helpful equations for your understanding, solving and utilization for non-right triangles: [FIG 137]



: h = hb (height at side b)
B = B1 + B2
b = b1 + b2

Using the Pythagorean Theorem:

c^2 = h^2 + b1^2 and a^2 = h^2 + b2^2

h^2 = c^2 - b1^2 h^2 = a^2 - b2^2

b1^2 = c^2 - h^2 b2^2 = a^2 - h^2 using substitution for h^2:

b2^2 = a^2 - (c^2 - b1^2) distributing (-1) to clear grouping symbols:

b2^2 = a^2 + b1^2 - c^2 solving for c^2 :

c^2 = a^2 + b1^2 - b2^2 : A Pythagorean-Like equation, where here, b2 is subtracted from the sum.

a^2 = c^2 + b2^2 - b1^2

Since: b = b1 + b2 ,

b2 = b - b1 and

b1 = b - b2

Here is a derivation of a helpful equivalence to remember so as to easily solve for a triangle height or side:

$At = \frac{(base)(height\ at\ that\ base)}{2} = \frac{(a)(ha)}{2} = \frac{(b)(hb)}{2} = \frac{(c)(hc)}{2} = 0.5\ a\ ha = 0.5\ b\ hb = 0.5\ c\ hc$:

Taking just the last three right side equivalences and "dividing through (all)" by (0.5) so as to "clear", "rid" or set all the numerical coefficients to 1, we have this equality or mathematical relationship among the sides and heights:

$a\ ha = b\ hb = c\ hc$: **EQUAL PRODUCTS OF BASE SIDES AND CORRESPONDING HEIGHTS**
All products of a side and the corresponding height at that side are equal.
Note also that twice the area = **(base) (height at base) = 2 At** = $a\ ha = b\ hb = c\ hc$
In general, (base) (height at base) is the area of a rectangle, hence this equals twice as much as the triangle area using the same (base) and (height at base).
Note the "reverse ratios" of, and for ex.: $(a / b) = (hb / ha)$

Many of the above values can also be derived and solved for if the other parts of the triangle are known. For example:

$a = \frac{b\ hb}{ha} = \frac{c\ hc}{ha} = At / ha$ These have the basic or general format of:

$$\textbf{side1} = \frac{\textbf{(side2) (height of side2)}}{\textbf{(height of side1)}} = \textbf{At / (height of side1)}$$

$ha = \frac{b\ hb}{a} = \frac{c\ hc}{a} = At / a$: in a right triangle, $(ha) = b$, and $(hb) = a$. * Basic format:

$$\textbf{(height side1)} = \frac{\textbf{(side2)(height of side2)}}{\textbf{(side1)}}$$ **: this can also be derived from the previous derivation above = At / (side1)**

Considering the above, and the law of sines, for example: $(a / b) = (\sin A / \sin B)$:

$a = \frac{b\ hb}{ha} = \frac{b \sin A}{\sin B}$ dividing each fraction by b:

$\frac{a}{b} = \frac{hb}{ha} = \frac{\sin A}{\sin B}$ The basic format here is:

$$\frac{\textbf{side1}}{\textbf{side2}} = \frac{\textbf{sin angle1}}{\textbf{sin angle2}} = \frac{\textbf{height of side2}}{\textbf{height of side1}}$$ **:** note that the ratio of the heights is in reverse ratio to both the sides and sines of the corresponding angles

* From the previously given, we also can derive: $hc = hb\ (b/c)$, and

If the triangle is a right triangle: $hc = hb \cos A$, therefore: $\cos A = hc / hb = b / c$: a and b are the "leg" sides of the hypotenuse side c

$hb = hc / \cos A = hc\ c / b$

$hc = ha\ a / c = ha \sin A$, therefore: $\sin A = hc / ha = a / c$

$ha = hc / \sin A = hc\ c / a$

$\tan A = a / b = \sin A / \cos A = (hc / ha) / (hc / hb) = hb / ha$

Extra: Since the products of any side and its corresponding height are all equal, their ratio is equal to 1, for example:

$1 = \frac{a\ ha}{b\ hb}$,

BASIC STEPS FOR SOLVING A TRIANGLE

1. In order to completely solve (find all 6 parts: 3 angles and 3 sides) a triangle, a minimum of 3 parts must initially be known and 1 part must be a side. Hence, we need, at a minimum, either 3 sides, or 2 sides and 1 angle, or 1 side and 2 angles to begin with. One side must be given so as to distinguish it from all other similar (ie. bigger or smaller) triangles which have the same angles, but different side lengths so as to be unique and-or non-congruent (same) triangle.

2. If an angle is 90°, the triangle is a right triangle, and the simplest method is to use the Pythagorean Theorem and the fact that angles $A + B + C = 180°$. If a triangle has an obtuse (>90°) angle, the triangle is an obtuse triangle, and the sum of its other two angles will be <90°.

3. If given just 3 sides, use Heron's formula to solve for the area of the triangle first, then use the formula shown previously to solve for the SIN of an angle. The law of cosines can also be used to solve for the cosine of an angle, and then the angle can be found using: angle = arccos (cos angle)

4. If given just 2 sides and 1 angle:

   A. Use the law of cosines if the two sides are the adjacent sides of the angle, that is, the angle is the included or vertical (at the vertex) angle. For example, given a, b, and C, use the law of cosines for side c. Angle C is at the intersection of sides (a) and (b).

   B. If the angle corresponds to one of the two sides given, that is, it is not the included angle between those two given sides, then the ambiguous triangle case exists when the angle is less than 90°. There are two possible triangles as the solution and you may have to choose either one depending upon the situation, measurements and calculations.

   For example, given (a), (c), and A that is less than 90°. Angle A is not the included angle, so the ambiguous case exists. The three remaining parts of the triangle, side b, angle B and angle C have two possible trigonometric solutions, resulting in two distinct triangles. By using the law of sines, you can find the sine of angle C, and therefore angle C. The law of sines, and the sine of the angle function, will return a sine value for an angle less than or equal to 90°, hence the corresponding angle to that sine value will be less than or equal to 90°. The other angle of this triangle, angle B, can be found from the fact that $A + B + C = 180°$. For the other value of angle C of the second ambiguous triangle, notice the isosceles construction shown previously in the discussion about the ambiguous case. Angle C of the second ambiguous triangle is the supplementary angle to both equivalent base angles of the isosceles triangle, hence this value of angle C being found for the second ambiguous triangle is 180° - angle C of the first ambiguous triangle. Angle B in this second ambiguous triangle can then be found from the fact that $A + B + C = 180°$.

   If the side given that corresponds to the given angle is greater than the other given side, then no ambiguity exists, and the triangle has only one solution. The internal isosceles construction, as shown previously and which shows the two possible solutions, does not exist. If this side equals the height (or altitude) at the ungiven third side, then the triangle is a right triangle.

5. If given just 2 angles and 1 side:

   The third angle can be found from $180° = A + B + C$. Use the law of sines to find a second side. For the third side, you can use either the simpler law of sines, or use the law of cosines.

6. If more than 3 parts of the triangle are known, the other parts can be found using either the law of sines, the law of cosines, the Pythagorean theorem, or the fact of: $A + B + C = 180°$.

7. If given just 3 angles, the triangle cannot be solved since it is indistinguishable from all the other similar triangles with the same exact angles, except that the triangle(s) may be magnified in size by magnifying all its sides by the same factor.

8. Sometimes you may be given some of the heights of a triangle and can solve for some of the 6 fundamental triangle parts from that. Here is a basic method for solving for a side or its corresponding height (ie., "altitude"), and this equation shows all the equal products of each base sides and its corresponding height:

   $a\,h_a = b\,h_b = c\,h_c$, from this, we can find some other mathematical relationships:
   : h_a = height at side (a)

   $\frac{a}{c} = \frac{h_c}{h_a} = \frac{\text{Sin } A}{\text{Sin } C}$, law of sines using the heights. Again, note the inverse ratios. From this we also have:

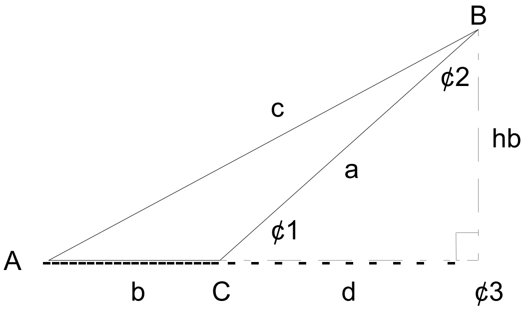
   $h_a \text{ Sin } A = h_c \text{ Sin } C$: $= h_b \text{ Sin } B$

9. You can make a check on all the given and-or found 6 parts by using the law of sines, and all the ratio values should be near in value to each other. If they are not near in value, then check the values used and the results. It always helps to draw the triangle during and for the analysis, and this may also prevent an ambiguous triangle:

$\frac{a}{\text{Sin } A} = \frac{b}{\text{Sin } B} = \frac{c}{\text{Sin } C}$: law of sines

FINDING THE HEIGHT USING SUPPLEMENTARY ANGLES

In the drawing below, there is a non-right triangle with side (b) extended to show the height from base (b) to the vertex of the other two sides (a and c) which defines the corresponding angle (here, angle B) to side (b). [FIG 138]



You are to find the value of the height (h) indicated (without actually measuring it), perhaps its' value needs to be known for some type of construction, or to simply calculate the triangle's area using the typical formula of: At=(base x height)/2. Note that the length of the base is always an actual (unextended) side of the triangle in question, that is, it never includes any extension added to that side so as to analyze and find the corresponding height. For example, in the triangle being analyzed above, the area is: ((side b) x height at (side (b))) / 2, and the area of the triangle is not: (side (b+d) x height at side (b)) / 2 , since that would be the area of a different triangle than the actual one shown.

From the concept of supplementary angles:

180° = ¢1 + C therefore:
¢1 = 180° - C

From SIN ¢1 = $\frac{h}{a}$: where h = hb

h = a SIN ¢1

Since ¢3 is a right angle, and from the concepts of complementary angles:

¢2 = 90° - ¢1

Angles A and (B+¢2) become complementary angles of a right triangle construction when the right angle (¢3) is considered, therefore:

90° = A + (B + ¢2)
(B + ¢2) = 90° - A which can be expressed as:
B + ¢2 = 90° - A after transposing ¢2:
B = 90° - A - ¢2
A = 90° - B - ¢2

Notice that side (c), and other parts of the triangle, can be found using the Pythagorean Theorem:

c^2 = (b+d)^2 + h^2 also:

From: SIN A = h/c, we can get:

$c = \frac{h}{\text{SIN A}}$ since $h = a \text{ SIN ¢}1$:

$c = \frac{a \text{ SIN ¢}1}{\text{SIN A}}$ algebraically:

$a = \frac{c \text{ SIN A}}{\text{SIN ¢}1}$

$\text{SIN ¢}1 = \frac{c \text{ SIN A}}{a}$ and $\text{SIN A} = \frac{a \text{ SIN ¢}1}{c}$

$\text{¢}1 = \text{ARC (SIN ¢}1) = \text{ARCSIN}\left(\frac{c \text{ SIN A}}{a}\right)$, and $C = 180° - \text{¢}1$, $B = 180° - (A + C)$

From the above equation for SIN ¢1, we can derive a "sort of" law of sines which can easily be memorized:

$\frac{a}{\text{SIN A}} = \frac{c}{\text{SIN ¢}1}$ from this we can also get: $\frac{a}{c} = \frac{\text{SIN A}}{\text{SIN ¢}1}$

Since ¢1 is the supplementary angle of: (180° - ¢1) = C, their trigonometric functions are equal: SIN ¢1 = SIN C, and the law of sines similarity above can now be expressed as the more familiar looking:

$\frac{a}{\text{SIN A}} = \frac{c}{\text{SIN C}}$ and: $\frac{a}{c} = \frac{\text{SIN A}}{\text{SIN C}} = \frac{hc}{ha}$: hc = height at side (c)
ha = height at side (a)

Can the relationship of side (b) and SIN B also be included into this law of sines for oblique triangles, therefore resulting into the same law of sines as shown for right triangles? Yes, and this will be shown ahead.

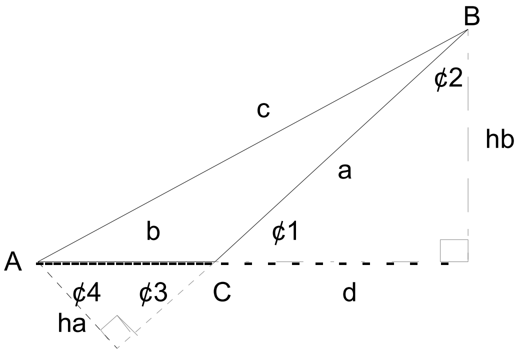
If your also looking for a Pythagorean-like relationship among this triangles sides, here is one which includes a "fourth" or extended side:

From: $c^2 = (b+d)^2 + h^2$, and $a^2 = d^2 + h^2$
$(b+d)^2 = c^2 - h^2$, and $d^2 = a^2 - h^2$ extending the left hand side:
$b^2 + 2bd + d^2 = c^2 - h^2$ after algebraic substitution for d^2:
$b^2 + 2bd + a^2 - h^2 = c^2 - h^2$ T. (-h^2), and switching sides:

$c^2 = a^2 + b^2 + 2bd$: PYTHAGOREAN-LIKE RELATIONSHIP
FOR AN OBTUSE TRIANGLE
(For when C > 90°, or B < the complementary
angle of A, or when b < c COS A since
COS A = adj./hyp., or when a > c SIN A since
SIN A = opp./hyp.)

$d = \frac{c^2 - a^2 - b^2}{2b}$

When side (a) is extended to show the height at side (a) (or base (a)), this will effectively create another right triangle construction: [FIG 139]



This right triangle construction is a similar right triangle (to the other newly created right triangle construction that is "attached" to the original triangle in question that is being analyzed) which can be verified by the concept of vertical angles:

¢3 = ¢1 : since they are vertical angles

Due to the concept of complementary angles that sum to a 90° right angle :

¢4 = ¢2 : (¢3 and ¢4) are complementary angles , and (¢1=¢3 and ¢2) are complementary angles

Since the angles are equivalent, their trigonometric values are therefore equivalent:

SIN ¢1 = $\frac{hb}{a}$ = SIN ¢3 = $\frac{ha}{b}$ therefore:

$\frac{hb}{a} = \frac{ha}{b}$: as should be expected for (magnified) similar triangles, the parts of each specific triangle have the same numeric portion or fractional value of that triangle

$\frac{a}{b} = \frac{hb}{ha}$: notice that the height and side ratios are expressed as an inverse ratio with respect to each other.

These can also verify, or can be likewise verified, by the fact of that the products of each base side and its corresponding height are equal in value: a ha = b hb = c hc

The above equation might not seem correct at first since each side appears to be a reverse or inverse type of ratio. One simple way to verify that this is correct is to consider a right triangle where the height at side (b), or hb, is equal to the other side (side a), and the height at side (a), or ha, is equivalent to the other side (side b), and all this is expressed above as the equivalent ratios.

Since ¢3 = ¢1 are supplementary angles to angle C, their trigonometric (absolute) values are identical.

SIN C = SIN ¢3 = $\frac{ha}{b}$ = SIN ¢1 = $\frac{hb}{a}$, therefore ha = b SIN C

By observing the new right triangle construction shown:

SIN B = $\frac{ha}{c}$, therefore ha = c SIN B

Equating the two expressions for ha:

$b\ \text{SIN C} = c\ \text{SIN B}$ algebraically:

$$\frac{b}{\text{SIN B}} = \frac{c}{\text{SIN C}}$$

expressing this equivalence to what was derived previously:

$$\boldsymbol{\frac{a}{\textbf{SIN A}} = \frac{b}{\textbf{SIN B}} = \frac{c}{\textbf{SIN C}}}$$

: LAW OF SINES (general, for all triangle)
Note also, mathematically, for ex.:

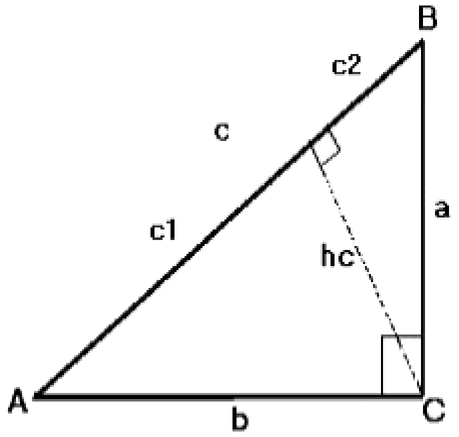
a / b = SIN A / SIN B = hb / ha

a = b (SIN A / SIN B) = b (hb / ha) = c (SIN A / SIN C) = c (hc / ha)

SIN A = (a/b) SIN B = (a/c) SIN C

EXAMPLES OF SOLVING FOR PARTS OF A TRIANGLE

[FIG 140]



The right angle, square, "turn" or "corner", in the above triangle indicates that this triangle is a right triangle. Here, C=90° = the right angle. By using the Pythagorean Theorem, the relationship among all the sides of a right triangle is:

$c^2 = a^2 + b^2$: note also that: $c = c1 + c2$

If a=3, and b =4: $c = \sqrt{a^2 + b^2} = \sqrt{3^2 + 4^2} = \sqrt{9 + 16} = \sqrt{25} = 5$

Note that $a = hb$ and $b = ha$. Due to equal products of the bases and their corresponding heights of any triangle:

$a\,ha = b\,hb = c\,hc$

$hc = \frac{a\,ha}{c} = \frac{b\,hb}{c}$: hc for a right triangle is therefore: $\frac{a\,b}{c}$

The height at side c of this right triangle will create 2 similar triangles to the original triangle, hence there is three similar triangles, and each will have the same three angles equivalent to: 90°, A, and B.

The height at side c will divide side c into two line segments (c1 and c2) that have a ratio that is equivalent to the ratio of the areas (A1 which corresponds to c1, and A2 which corresponds to c2) of each internal similar triangle:

$A1 = \frac{c1\,hc}{2}$ and $A2 = \frac{c2\,hc}{2}$ If you divide A1 by A2, you can find:

$\frac{A1}{A2} = \frac{c1}{c2}$

$\text{Tan } A = \frac{\text{opposite } A}{\text{adjacent } A} = \frac{a}{b} = \frac{3}{4} = 0.75$

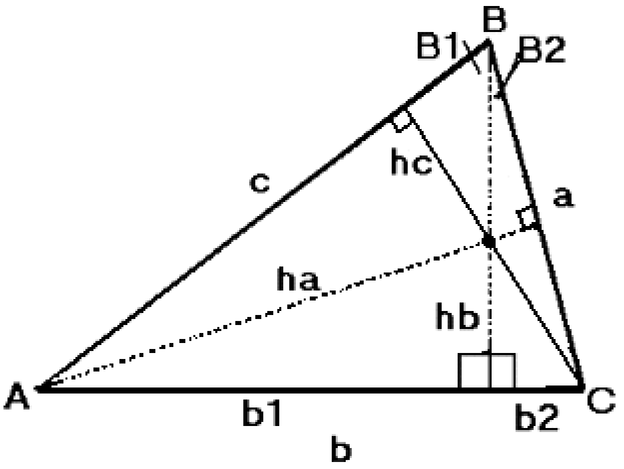
A = ArcTan(Tan A) = ArcTan(0.75) = 36.87°

Since B is a complementary angle to angle A:

A + B = 90°

B = 90° - A = 90° - 36.87° = 53.13°

Ex. Here is another triangle to analyze: [FIG 141]



For this non right triangle, hb=3, b1=4, c = 5. and b2=1. By the values given, the left side portion of this triangle is similar in some ways to the ("3, 4, 5") right triangle given above.

By the Pythagorean Theorem: $a = \sqrt{b2^2 + hb^2} = \sqrt{3^2 + 1^2} = \sqrt{9 + 1} = \sqrt{10} = 3.1622\underline{8}$

To find angle B2: $\tan B2 = \frac{\text{opposite B2}}{\text{adjacent B2}} = \frac{b2}{hb} = \frac{1}{3} = 0.3333$

B2 = arctan(tan B2) = arctan(0.3333) = 18.435°

$\text{Tan } A = \frac{\text{opposite A}}{\text{adjacent A}} = \frac{hb}{b1} = \frac{3}{4} = 0.75$

A = ArcTan(Tan A) = ArcTan(0.75) = 36.87°

By observing the internal right triangle construction, B1 is a complementary angle to angle A:

A + B1 = 90°

B1 = 90° - A = 90° - 36.87° = 53.13°

B = B1 + B2 = 53.13° + 18.435° = 71.565°

Since C is a supplementary angle to (A + B) when considered as one angle value:

180° = (A + B) + C

$C = 180° - (A + B) = 180° - A - B = 180° - 36.87° - 71.565° = 71.565$

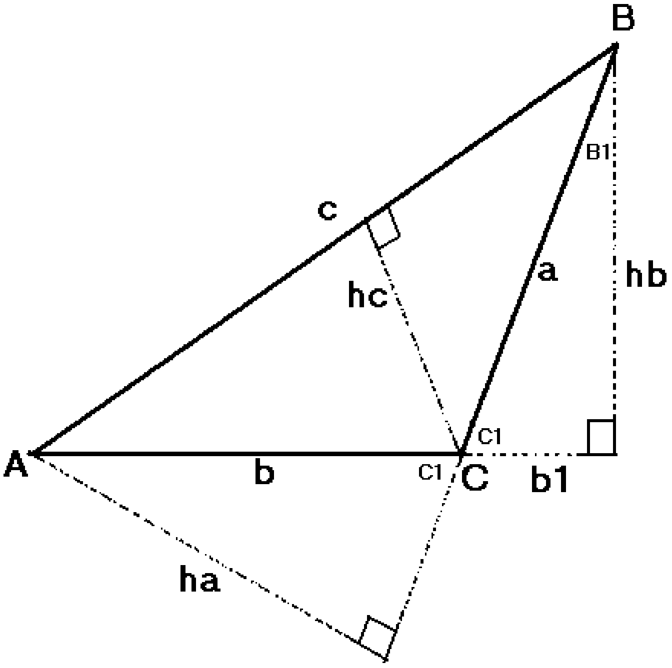
Since angle C = angle B, this is an equilateral triangle with B and C being the "base (side) angles". The base side of this equilateral triangle is side (a). The two equivalent sides are (c) and (b).

The indicated heights can be found from the **equal products of bases** and their corresponding heights:

$a\,ha = b\,hb = c\,hc$: note that (base)(corresponding height) = 2 At

The point of intersection of all three heights is called the **orthocenter**, and it is indicated in the above drawing.

Ex. Here is another triangle to analyze: [FIG 142]



For this triangle, hb=3, b=3, c = 5. and b1=1. By the values given, this triangle is similar in some ways to the ("3, 4, 5") right triangle given above. Since one angle is greater than 90° (here C>90°) two sides are extended to show their corresponding heights.

$$\text{Tan } A = \frac{\text{opposite } A}{\text{adjacent } A} = \frac{hb}{(b+b1)} = \frac{3}{(3+1)} = \frac{3}{4} = 0.75$$

$A = \text{ArcTan}(\text{Tan } A) = \text{ArcTan}(0.75) = 36.87°$

To find angle B1: $\tan B1 = \frac{\text{opposite } B1}{\text{adjacent } B1} = \frac{b1}{hb} = \frac{1}{3} = 0.3333$

$B1 = \arctan(\tan B1) = \arctan(0.3333) = 18.435°$

Since C1 is a complementary angle to angle B1:

B1 + C1 = 90°

C1 = 90° - B1 = 90° - 18.435° = 71.565°

Since C is a supplementary angle to C1:

180° = C + C1

C = 180° - C1 = 180° - 71.565 = 108.435°

Since the sum of a triangles interior angles is always 180°:

180° = A + B + C

B = 180° - A - C or = 180 - (A + C)

B = 180° - 36.87° - 108.435°
B = 34.695°

B + B1 = 34.695° + 18.435° = 53.13°

Notice that the extended sides will create two similar right triangle constructions. Each of these triangles contains angles of 90°, C1, and the complementary angle to c1 which is (90° - c1)° = B1

TO EASILY CONSTRUCT A 45°, 90°, 45° TRIANGLE:

First, before this discussion, a protractor is an angle gauge. It can be used to draw and-or measure angles. This book has an article on making your own protractor.

First draw a square, and then draw a diagonal line within it. This will create two triangles each being a 45°, 90°, 45° right triangle. Each side of this square, and the "leg" sides (a and b) of this triangle, will have the same measurement. As a check for "rightness" or correctness of the right angle, the hypotenuse side (c) of the triangle will be equal the square root of two (about 1.4142) times longer than the leg side; according to the Pythagorean Theorem.

TO EASILY CONSTRUCT A 30°, 90°, 60° TRIANGLE: (and possibly create smaller angles)

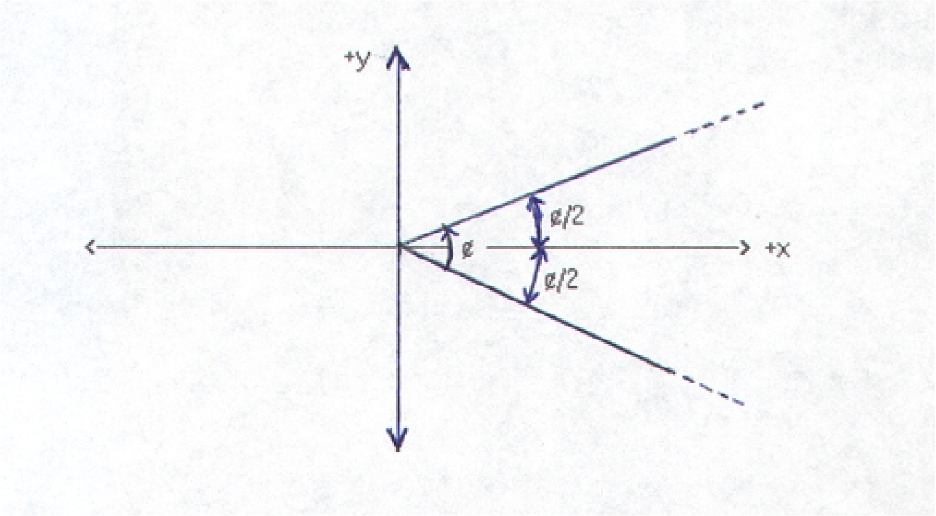
Draw an isosceles triangle. Each angle of an isosceles triangle is 60° Draw an altitude or height line from a base side to the corresponding opposite vertex. This line will divide that base side in half and create two 30°, 90°, 60° triangles. As a check to determine if the isosceles triangle was drawn or constructed right, the height should be about 0.866 times the hypotenuse of that right triangle, or any equivalent side of that isosceles triangle. This can be derived and checked with the Pythagorean Theorem. If smaller angles are needed: If a compass for drawing circles, or arcs of circles, is available, take the 30° angle created and create a 30° circular arc. Draw a ("chord") line at the endpoints of the arc. Divide this line into two, and this will be used to create an angle bisector line. This angle is 15°.

Before we move onto other topics of trigonometry, the concept of triangulation is of interest. **Triangulation** is very useful for when a location and-or direction of some object or event can be determined, such as on a map, by using two or more sensed (ex., eye witnesses) directions, angles, time, etc. Where each of these direction lines intersect in reality and-or on a map, is a very good estimate of a location, direction, angle and-or event. If the map has a scale, and-or distances between two observers are known, distances and angles to the object and-or location in question can be calculated or estimated.

BISECTING AN ANGLE

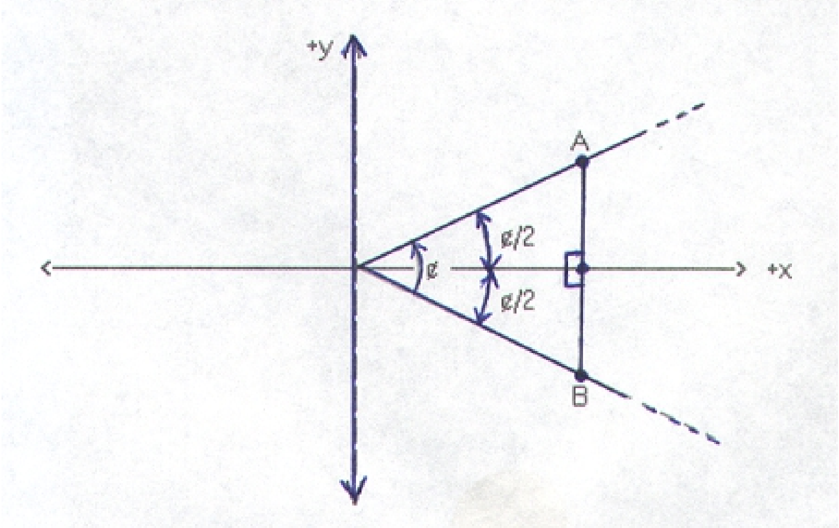
To bisect is to intersect and divide, usually into two parts or sections. The word prefix of: "bi" means two. To bisect an angle is to divide the angle into (usually) two equivalent angles. These two angles are also known as "half-angles" and are often simply expressed as: (¢/2). Below is an example of an angle that is bisected. A method to bisect and angle was previously given in this book during the discussion of how to construct a 30°, 60° and 90° triangle, and that uses an arc drawn by a compass, and half of the "chord" line at its endpoints. The discussion that follows is an analysis and another way to bisect an angle.

For simplicity in the following analysis, the horizontal axis indicates where the angle is bisected. A line that bisects an angle into two equivalent angles is called an angle bisector line. [FIG 143]



How can the angle bisector line or a point on it be found so that the angle can be bisected?

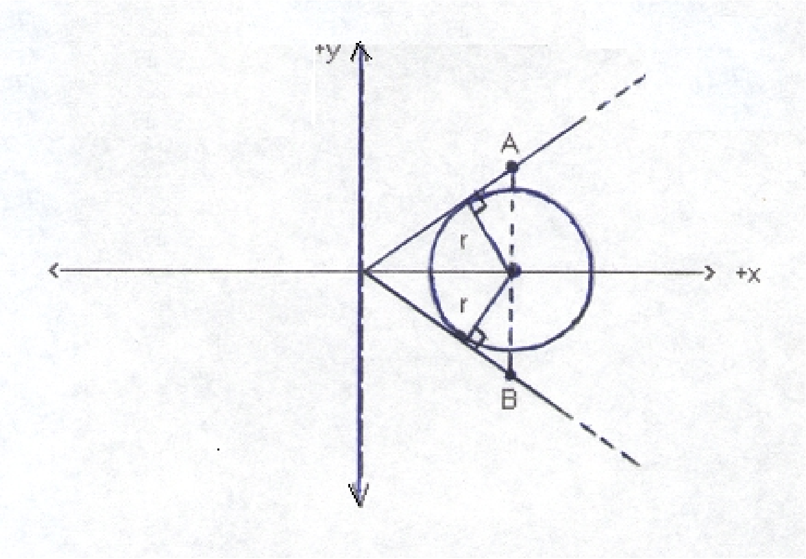
Observer the drawing below: [FIG 144]



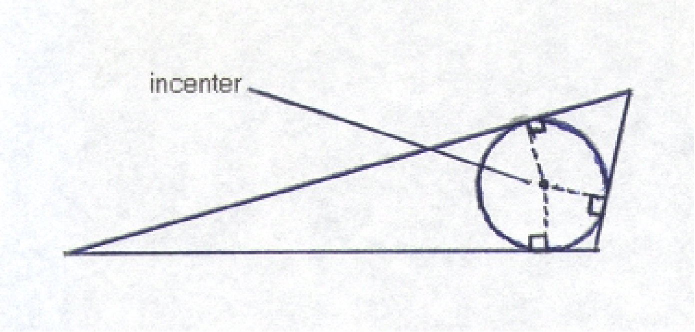
Points A and B are any equidistant (equivalent in distant) points from the vertex of the angle (¢). Here, each point has the same distance from the vertex at (0,0). The shortest distance between any two points, such as A and B, is always the straight-line distance between those points. This line is indicated and it crosses the angle bisector line perpendicularly creating two congruent (identical) right triangles having the same sides and angles. At half the distance on this perpendicular line is a point of angle bisection, that is, it is a point on the angle bisector line. The larger triangle construction is that of an isosceles triangle where the angle bisector line is the height of that triangle, and therefore, it intercepts the base side (here, between points A and B, which are of equal length) perpendicularly. If the triangle was not an isosceles triangle which has two equivalent sides, the angle bisector line would not intercept its opposite side perpendicularly.

In actual practice, if you are trying to find or draw an bisector line and a point on it away from the vertex point of the angle, and where an angle is to be bisected, the longer that the two equidistant adjoining sides of that angle are from the vertex, a greater accuracy can be achieved. Another point(s) of angle bisection can be used as a check of the angle bisector line.

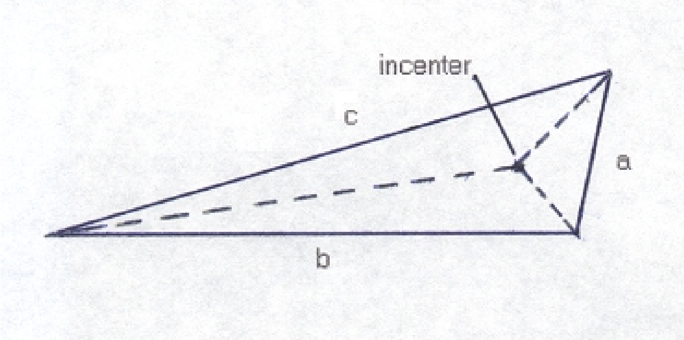
Now that we have found a point of angle bisection, it might be assumed, due to the above discussion, that the (perpendicular, from angle bisector line) indicated distance to point A or point B from the equidistant (from, or to the angles sides) angle bisector point is the shortest distance to the side of that angle. This is an incorrect assumption. In the drawing below, a circle is drawn between the two sides of the angle, and the center of this circle is at a point of angle bisection. The radius line of the circle will intersect the sides of the angle perpendicularly (at 90°), or vice-versa, since the angles sides will be "tangent" (meaning: slightly intercept at one point, but not go through) to the circle at the point of interception. The radius, being a straight line, is the shortest distance from the center of the circle to it's outer perimeter (ie. circumference), and therefore, it is also the shortest distance to the side of the angle. By observation, this perpendicular distance (ie. the radius) is the shortest distance since the other distance indicated is the hypotenuse (ie. the longest side) of the right triangle indicated. [FIG 145]



Any point along the angle bisector line can be the center of a circle whose perimeter (circumference) intersects the sides of the angle. Obviously, the farther that the center of the circle is from the vertex of the angle, the larger the circle, and therefore the larger the radius of that circle. At some point along the angle bisector line of an angle within a triangle, the corresponding circle's perimeter (circumference) will intercept the side opposite that angle. This is the largest possible circle that can be inscribed (scribed [write, draw, scribble, indicate]) within both a triangles angle and entire triangle with three angles. The center point of the largest inscribed circle within a triangle is called the **incenter** of the triangle. All three angle bisector lines will intersect at the (same) incenter point. The incenter is also (perpendicularly) equidistant (having the same distance) from all three sides of the triangle. The drawing below shows the incenter of a triangle:
[FIG 146]



The drawing below shows the angle bisector lines dividing the triangle up into three smaller triangles: [FIG 147]



The height of each of these smaller triangles is the value of the radius (r) of the largest inscribed circle. Remember that the height is perpendicular to the corresponding base (as seen in FIG. 109), and is the distance (here, it's equal to (r)) to the corresponding vertice. The incenter is the vertice point (and only common point) of all three angles that correspond to their base sides, which here, are the sides of the triangle. The total area of the triangle is equivalent to the sum of the areas of these three interior triangles:

$$A = A1 + A2 + A3$$

$$A = \frac{ar}{2} + \frac{br}{2} + \frac{cr}{2}$$: forms of At = bh/2 = br/2, combining fractions:

$$A = \frac{ar + br + cr}{2}$$ factoring out (r) from each term in the numerator:

$$A = \frac{r(a+b+c)}{2} = rs$$ s = (a+b+c)/2 = perimeter/2 = "semi perimeter", solving for (r):
(Extra note: This equation has an essence of Heron's formula for the area of a triangle when given its three sides.)

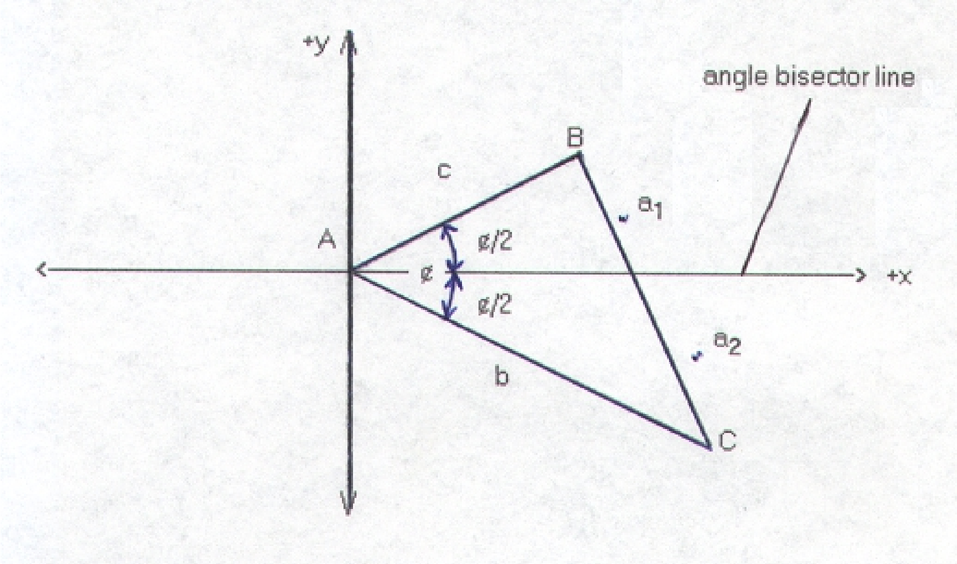
$$r = \frac{2A}{(a+b+c)} = \frac{2A}{\text{perimeter}} = \left(\frac{1}{s}\right)\frac{A}{1} = \frac{A}{s}$$: radius of largest inscribed circle in a triangle, and it's center is the incenter

Since (r) is effectively a height of a (internal) triangle as seen in the drawing, it can also be found using the height formula shown previously in this book. Be careful to use only use the half-angle values in the formula. The total area of a triangle can also be found using Heron's formula that requires just the three side lengths of triangle. Besides the angle bisector lines and incenter, there are several other well known defined lines and points within and outside a triangle.

[This space for book edits.]

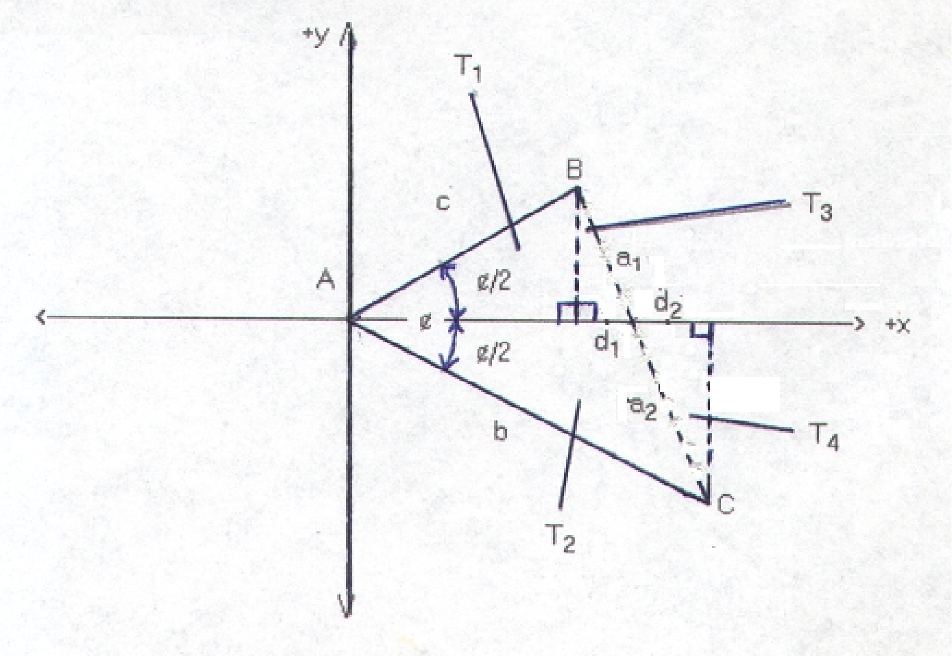
SOLVING A TRIANGLE USING AN ANGLE BISECTOR LINE

This topic shows that there are often some new, insightful and beneficial analysis methods to explore. At the point where an angle bisector line intersects (and not generally perpendicularly at 90°, and-or at half of) the third side of a triangle, it divides that side into two line segments whose ratio is equal to the ratio of the other two sides of the triangle. Observe the drawing below where (side a) = (a1+a2) is to be found: [FIG 148]



$\dfrac{a1}{a2} = \dfrac{c}{b}$ or $\dfrac{a1}{c} = \dfrac{a2}{b}$: note that (a1) and (c) are on the same side of the angle bisector line, and (a1) and (b) are on the same side also.

They are equivalent since these are ratios of corresponding sides of similar (right) triangles. This is verified below: [FIG 149]



Right triangles T3 and T4 are similar due to that they both have a 90° angle, and they also have the same vertical angle (across the angle bisector line), and therefore the third angle must be the same, and due to the complementary angle sum of 90°. They can also be verified as similar triangles due to the extension of the sides of one triangle, and the other parallel sides (some are coincidental or overlap, but they are still parallel lines).

Triangles T1 and T2 (which includes T4) are similar (right) triangles due to that they also have the same angles. Corresponding heights within similar triangles are known to have the same ratio as corresponding sides of those triangles. The heights, h1 of T1 ,and h2 of T2, are also the sides of T3 and T4 respectively. All corresponding sides of T3 and T4 are known to be proportional to each other since they are similar triangles. Summarizing this mathematically:

$$\frac{h1}{h2} = \frac{c}{b} = \frac{a1}{a2} = r$$

Side d1 of T3, and side d2 of T4 are corresponding sides of similar triangles and therefore have the same ratio.

$$\frac{d1}{d2} = \frac{a1}{a2} = \frac{c}{b} = r$$

You can solve for the value of the other "leg" (base side) of the two small right triangles (T3 and T4) by using ("right-angle") trigonometry. If you can find the value of d1 and d2, you can use the Pythagorean theorem to find the hypotenuse sides (a1 and a2) of these two small right triangles (T3 and T4). Summing up these two hypotenuse sides (a1 and a2) will yield the third side (side (a), between B and C) of the triangle being analyzed, and this is also the side opposite the bisected angle. The sum of d1 and d2 is equal to the base side (along the angle bisector) of T2 less the base side (also along the angle bisector) of T1. These base sides can be found using right triangle trigonometry. Once the sum of d1 and d2 is known, here's how to assign each it's proper value:

We now have the facts of:

Eq. 1: sum = d1 + d2 : sum = (base of T2) - (base of T1)

Eq. 2: $$\frac{d1}{d2} = r$$

Hence we have two simultaneous equations. From the second equation we can algebraically get:

$d1 = r\ d2$ creating a solvable equation by substituting this into the first equation:

$sum = r\,d2 + d2$ combining like terms, or factoring d2 from each term:
$sum = (r + 1)\,d2$ algebraically solving for d2:

$d2 = \frac{sum}{(r + 1)}$ d1 can now be found from the first equation:

$$d1 = sum - d2 = sum - \frac{sum}{(r+1)} = \frac{sum\,(r+1) - sum}{(r+1)} = \frac{sum\,(r+1-1)}{(r+1)} = \frac{r\ sum}{r+1}$$

The equations for (d1) and (d2) are nearly identical, except that the equation for (d1) includes a factor of (r), and this implies that d2 is longer, and it is since it is a side of a larger triangle construction as seen in the above figure.

You can also solve for the third side of a triangle using the **Distance Formula**. First find corresponding (x) and (y) coordinates of the endpoints of the third side of the triangle. These coordinates can be found easily by using right-angle trigonometry. In the drawing above, the coordinates of point B will be solved using trigonometry with T1, and the coordinates of point C will be solved using trigonometry with T2.

For point 1: From: $\cos ¢ = \text{adj.} / \text{hyp.} = x / h = x / r$ and $\sin ¢ = \text{opp.} / \text{hyp.} = y / h = y / r$:

$(x1 , y1) = (r1 \cos ¢ ,\ r1 \sin ¢)$: point 1, substituting the values for (r) which is the hypotenuse side (here, using side (b) or (c)) of the two right triangles:

Be sure to use only the half-angle values shown. (r), or radius, is equivalent to the hypotenuse of the right triangle, hence:

$(x1 , y1) = (b \cos ¢ ,\ b \sin ¢)$: point 1, b=length of side b

For point 2:

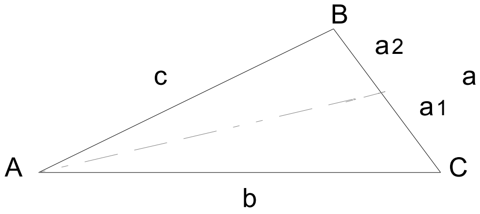
$(x2 , y2) = (r2 \cos ¢ ,\ -(r2 \sin ¢))$: point 2, therefore:
$(x2 , y2) = (c \cos ¢ ,\ -(c \sin ¢))$: point 2, c=length of side c

The negative sign is used since the angle is arbitrarily considered positive in sign or signless for this analysis (often, clockwise angles are considered negative in sign (ie. signed angles)), and (y) coordinates of points are negative in the fourth quadrant (or anywhere "below" the x-axis) Alternatively, you could remove the sign and consider the angle as a fourth quadrant angle (since the ending side of that angle is in the fourth quadrant) where the SIN ¢ values are known to be negative in value due to the signs of the co-ordinates of points in that quadrant. For example: p(5 , -2).

$$\text{distance} = \text{side } a = \sqrt{(x2 - x1)^2 + (y2 - y1)^2}$$

Below is an example of solving for the lengths of the line segments of a side (whose length is already known) intersected (and not necessarily perpendicularly) by an angle bisector line. This method shown does not directly utilize any angles, and it is essentially a simultaneous equation method.

In the drawing below, find the lengths of line segments a1 and a2 created at the intersection of side (a) due to the angle bisector line. [FIG 150]



$a = 3.606$, $b = 6$, $c = 5$

$3.606 = a = a1 + a2$ and from the facts about an angle bisector line and the bisected side:

$\frac{a1}{a2} = \frac{b}{c}$: side divided by an angle bisector line rule

$\frac{a1}{a2} = \frac{6}{5} = 1.2$ solving for a1:

$a1 = 1.2\ a2$ using substitution for a1

$3.606 = 1.2\ a2 + a2$: a solvable equation with one variable, combining like terms:
$3.606 = 2.2\ a2$ dividing both sides by 2.2 and switching sides:
$a2 = 1.64$

$3.606 = a1 + a2$
$3.606 = a1 + 1.64$
$a1 = 3.606 - 1.64$
$a1 = 1.966$

In about 350BC, an ancient and very famous Greek mathematician known as **Euclid** wrote the famous geometry book called "The Elements", in Alexandria Egypt. His book(s), or "volumes", which are still available today, translated to various languages, and it consisted of what was already known (but not yet derived, proved, or analyzed as much as Euclid provided) to the ancient world, and they also include his own monumental discoveries of which he is credited for such as the mathematical understanding of the length of an angle bisector line as shown below, and many other fundamental and useful concepts about geometry. It could be said that Euclid formalized and standardized mathematics and made it available for all others to learn and build upon.

The basic format for the length of an angle bisector line in a triangle is:

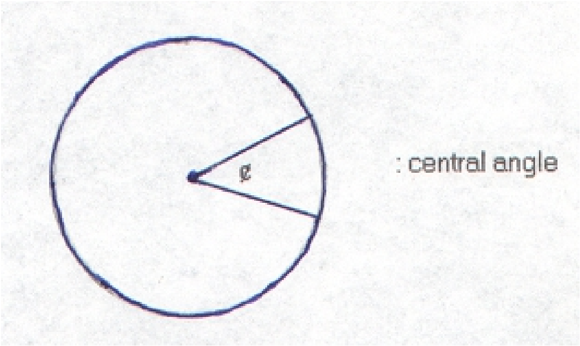
Given the 3 side lengths: side1, side2, side3 of a triangle: (ex. side_a, side_b, side_c),

And s = (side_a + side_b + side_c) / 2 : s = "semi-perimeter" = half-perimeter

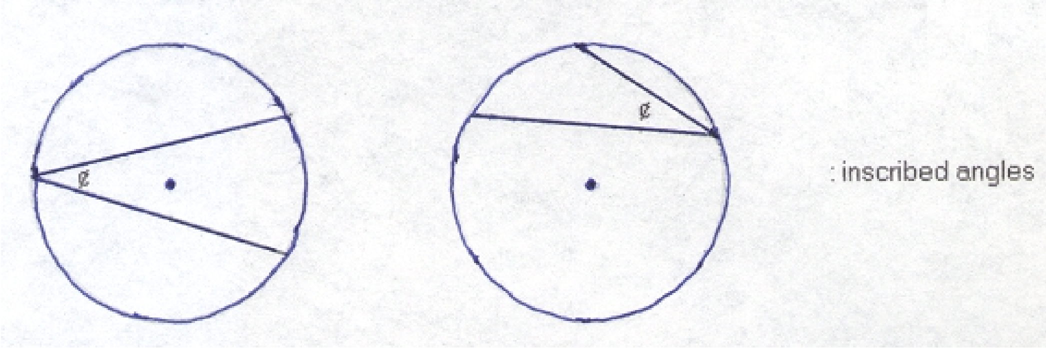
Length angle1 bisector line to side1 = $\frac{(2)\sqrt{s\ (s - side1)\ (side2)(side3)}}{(side2 + side3)}$: length of an angle bisector line to its corresponding side directly opposite that angle.

CENTRAL AND INSCRIBED ANGLES

Central and inscribed angles are formal names given to certain angles because of their position within a circle. A central angle has its vertex located at the center point within a circle: [FIG 151]



An inscribed angle has its vertex located at a point on the circumference of a circle: [FIG 152]



The portion of the circles circumference that subtends (being directly across or opposite to, or beneath) the angles vertex is called an arc (segment of the circles circumference). The angle and its corresponding arc are directly and proportionally (same fraction or portion of the whole or entirety) mathematically related. The greater the angle, the greater the corresponding arc length and vice-versa. For example, if the central angle doubles, its corresponding arc length doubles, This is very similar to that of any angle or triangle; the greater the angle, the greater the side length opposite that angle. Arc length can be calculated easily by setting up an equivalent portions (proportions) or equivalent fractions relationship:

From the ratio of the arc length (s) to the circumference (C, full arc), the corresponding angles have the same ratio value:

$$\frac{C}{360°} = \frac{S}{\text{¢}°}$$

: C = circumference of circle = an arc length of a 360° angle
: S = **ARC LENGTH** (of a central angle, or "centrally inscribed"). Letter S is used since it is technically a semi-perimeter or just a part of the entire circumference. See [FIG 153].
: ¢ is the central angle that subtends the arc S

Mathematically:

$$\frac{S}{C} = \frac{\text{¢}°}{360°}$$

An arc of a circle can be described in various ways such as:
A specific arc length, or the arc due to an certain angle. Ex. "an arc of 10°"

$$S = \frac{\text{¢}°\ C}{360°}$$

: **Arc Length**, this also shows that S is essentially a certain fraction of the circumference C.
Since radians = ((pi) /180°) (degrees) , degrees = (180° / (pi)) (radians) , mathematically:

S = ¢° C / 360° = (180°/(pi)) (radians) C / 360° = **S = C (radians) / 2 (pi)**
S =~ 6.281$\underline{8}$ (radians) C

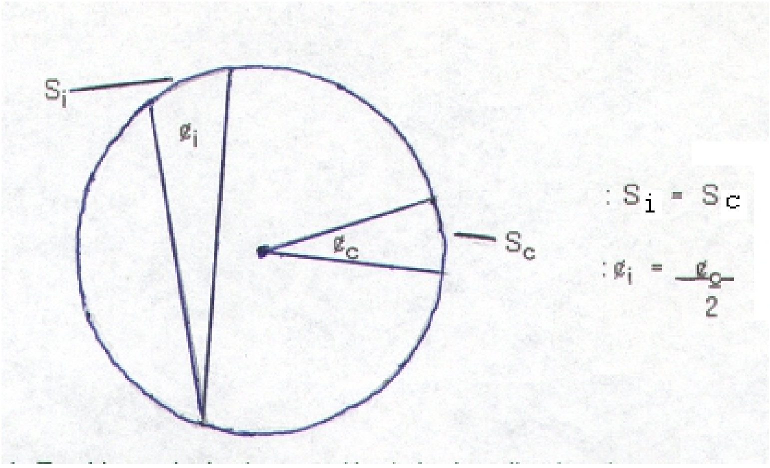
From the above formula for S we also have: S = ¢° / 360° C = ¢° (1 / 360°) C = 0.00027777$\underline{8}$ ¢° C

Extra: While at this topic, if the angle is 360°, then S = C. Since 360° = 2(pi) radians [radians are another unit angle measurement, besides degree units, that is discussed further ahead], and C = 2(pi)r, Substituting these values into the above formula, S = **arc length**, can also be shown to equal (¢r) radians.

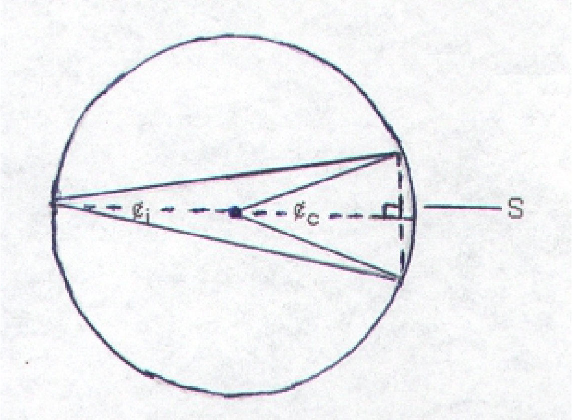
$S = \frac{¢\ (2(pi)r}{2(pi)} = (¢r)\ \text{radians}$

: r = radius length of the circle, ¢=radian angle (not a degrees angle)
: 1 radian or radian angle is the angle that creates an arc length equivalent to 1 radius length long. The larger the circle and its radius, for a certain or constant angle angle, the arc length will be larger. For a given circle with a certain radius, the greater the angle, the greater the corresponding arc length.

If the arc length (Si) subtending an inscribed angle (¢i) is equivalent to an arc length (Sc) subtending a central angle (¢c) of a circle with the same radius, diameter or circumference, that inscribed angle has a value of one-half (1/2) of that central angle: [FIG 153]

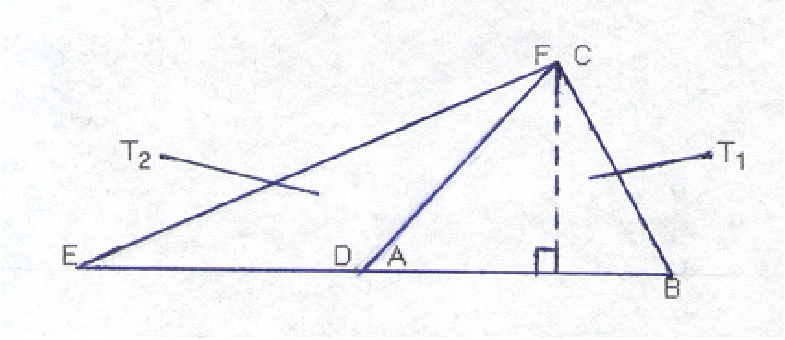


This will now be verified. For this analysis, the equivalent arc (length) of both the inscribed and central angle above are made to coincides at the same portion or arc length (S) of the circles circumference: [FIG 154]



Before the main analysis, if the vertex of each angle (¢i and ¢c) is considered as a center point of a circle, their circumferences will not actually coincide or overlap except for at 1 point only. The larger the radius of a circle, the slower the rate of change of the (y) values to the changes in the (x) values, and therefore, the larger the circle will be.

Also shown above is an angle bisector line that divides both angles in half, and a chord (a line that passes through two points on a circle's circumference; for example, the diameter is the longest chord possible for a circle) line that subtends (here, immediately below or across from) the arc of both angles. To broaden the analysis for use with triangles also, a more general representation using only the half angles is shown below where E = (¢i/2) and A = (¢c/2) : [FIG 155]



The vertex point of angles D and A is the center of the circle as shown in the previous figure, therefore lines ED = AB since they are radius lines of that same circle. It will be shown that angle E is half of the inscribed angle, angle A. By construction, line A to B, or line AB, equals line AC of T1 (triangle 1) since they are equivalent to the radius line of the same circle. Likewise, line DF and line DE of T2 (triangle 2) are also equal. Line EB is equivalent to the diameter of the circumscribing circle shown in the previous figure. Points B, C (and F, which coincides with point C) and E are points on the circumference of the same circle construction as shown in the previous figure above. Lines such as BC which pass through the circle and intersects it at two points on its circumference are often called a **chord line**. This word and term is based on that a piece of string was often called a chord, and of which can be pulled in opposite directions at both ends to made it straight like a line (ie., a chord line). The entire construction shown will create the two (equivalent in length) sides of angle D which adjoin or intersect to the base side EF (E to F) of an isosceles triangle (T2) construction. Note that angles B and C, and the line that joins their vertex point play no specific role in this analysis other than the fact that this line is a side opposite to both angles E and A whose numerical relationship is being found in this discussion. In short, D + A = 180° = E + F + D = 2E + D. Then: E + F = A or= 2E = A , and E = A/2.

Since $E = F$: base angles of T2 (an isosceles triangle)
$E + F = E + E = 2E$

$2E + D = 180°$: T2 interior angular sum of 180°

$D + A = 180°$: supplementary angle sum, therefore:
$D = 180° - A$ by algebraic substitution of D into T2 interior angular sum:

$2E + (180° - A) = 180°$ distribute (+1) to clear grouping symbols:
$2E + 180° - A = 180°$ after transposing +180° :
$2E - A = 0$ solving for E, transposing (-A): so add -(-A) = +A to each side :
$2E = A$ isolating E :

$E = \frac{A}{2}$: verification that an inscribed angle is half a central angle when the arc lengths have the same value

Since half-angles (of both the inscribed and central angles) were considered for this analysis, multiplying each angle by 2 to consider the full angle values, we find:

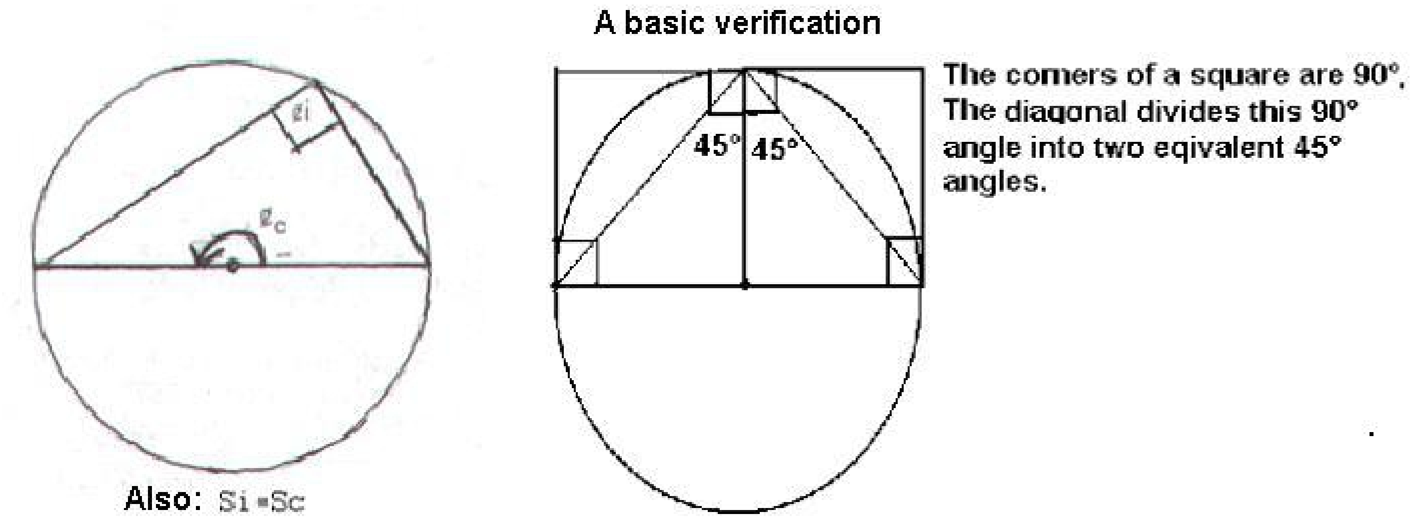
$(2E) = \frac{(2A)}{2} = A$ or: $¢i = \frac{¢c}{2}$: the central angle (¢c) is twice that of the inscribed angle (¢i) of a circle, and they both have the same value of arc length

Also, if not obvious in the above derivation, D is supplementary (sum to 180°) to A. The sum of (E + F) = (2E) is supplementary to D. Since 2E is supplementary to D, and A is supplementary to D, then 2E is equal to A (as expressed above where 2E = A). Extra note: Since the trigonometric functions are said to be non-algebraic (for example non linear mathematical relationship, non standard, not a standard algebraic equation), consider this example as to why:

sin (¢/2) /=/ (sin ¢)/2 : The sine of half an angle is not equal to half the sine of that whole angle.
For reference and to consider with the previous figure: sin ¢ = side opposite / hypotenuse

A general note is that if the base side of an angle doubles, that the corresponding height of it will also double, and this is the essence of making a similar and proportionally sided triangle. In both cases,the angle must remain the same value. For the analysis above, the inscribe angle is half that of the central angle, and this note will then consider the angle bisector line which happens to be the radius or diameter. If a base side of an angle doubles or increases by some factor (n) , then the corresponding height will also double or increase by that same factor (n) in a linear or proportional way, however, the trigonometric values of an angle do not increase in a linear or proportional way. If the base side increases by a factor of (n), but the height stays the same value, then the angle decreases by a factor of (n). In the above analysis for inscribed and central angles, the base side (here, the angle bisector line) of the central angle doubled to have the inscribed angle, but the height remained the same, and therefore, the angle is half that of the corresponding central angle.

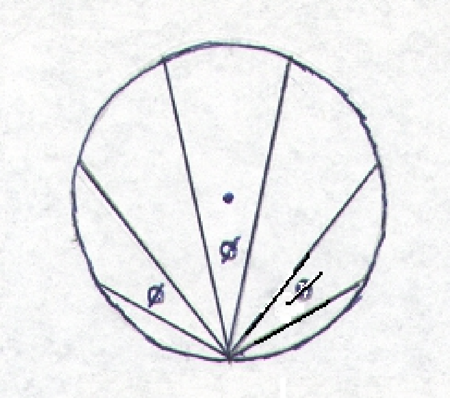
Because of the facts above, any angle inscribed within a semi-circle (half a circle) is a right (90°) angle: [FIG 156]



$¢i = \frac{¢c}{2} = \frac{180°}{2} = 90°$: ¢i and ¢c both have the same arc length of the circle, and: 45° + 45° = 90°
and here its equal to half the circumference

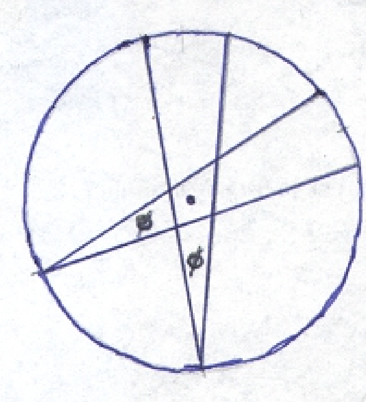
In the above drawing, another trigonometric fact can be easily pointed out here, and it is that the midpoint (shown as the center of the circle and which is equidistant from each point on the circumference) of the hypotenuse side of a right triangle is equidistant from all three vertices of that right triangle. This distance value is equal to the radius of the circumscribed (around, the triangle) circle. They hypotenuse of that right triangle is equal to the diameter of this circumscribing circle, and all three vertice (ie., "corners", where the sides meet or intersect) points of that triangle will coincide with points on the circles circumference.

It is now easy to understand that when you rotate an inscribed angle (or triangle) about the center of a circle that all the arc lengths will be identical. This is easily verified since the sides, chords and angles will still be the same values:
[FIG 158]

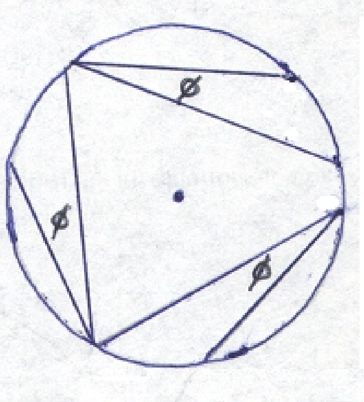


Likewise, the results would be the same if you rotated a circle which included one instance of that inscribed angle, as shown on the right side above.

It is easy to understand that if an angle is rotated about its vertex, that at any part in the rotation, the angle can only be the same constant value, however, as can be seen below, the sides of the angle are no longer the same. One might now ask, is the arc length of each (same) angle therefore different?. You might assume that it is bigger by what you know about angles in general; that the farther the opposite side is from the angle, then the larger that side (or chord of a circle) will be. For the circle construction shown below, this is not the case, and the arc and chord lengths are in fact identical when the inscribed angle is the same angle: [FIG 159]



These inscribed angles and arcs are equal.

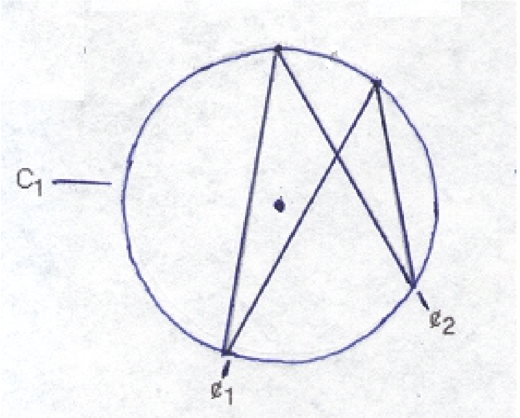


These inscribed angles and arcs are equal.

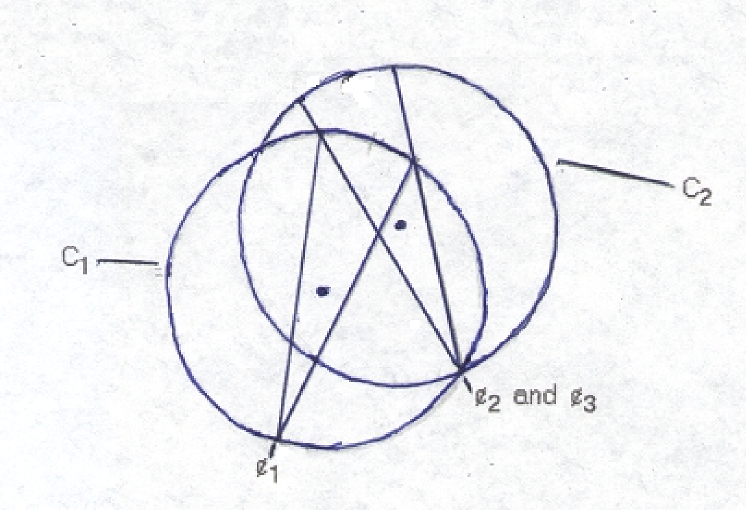
Here is a general verification that as long as the arc lengths remain the same, the corresponding (inscribed) angles are identical. Likewise, as long as the angles remain the same value, their corresponding arc lengths will be identical. For both cases, the circles must be equivalent in size.

Though chord length and its corresponding arc length are not proportional in value, chord length and the central angle are proportional in value. If one changes by a factor of (n), the other will also change by that same factor. Arc length and the central angle are also proportional in value.

In the drawing below, it will be shown that ¢1 = ¢2, and therefore their corresponding arc lengths S1 = S2. Also note that the angle bisector line of ¢1 happens to pass through the center of the circle. For the analysis, both arcs (arc lengths) were made to overlap exactly and can therefore only be the same length: [FIG 160]



In the drawing below, C2 is identical to C1 (as above) and contains the same exact angle as ¢1 of C1. This circle (and angle) is rotated slightly and is offset from C1 in such a way that it's angle (¢3) coincides exactly with ¢2 of C1. That is, ¢3 = ¢2: [FIG 161]



Since: ¢1 = ¢3
And: ¢2 = ¢3 we can conclude:

¢1 = ¢2 : verification : When the arc lengths are the same, the angles are the same. The angles being compared must be both central angles or both inscribed angles.

It must be noted that this verification is more of a "verification by visualization" rather than an "exact" algebraic method.

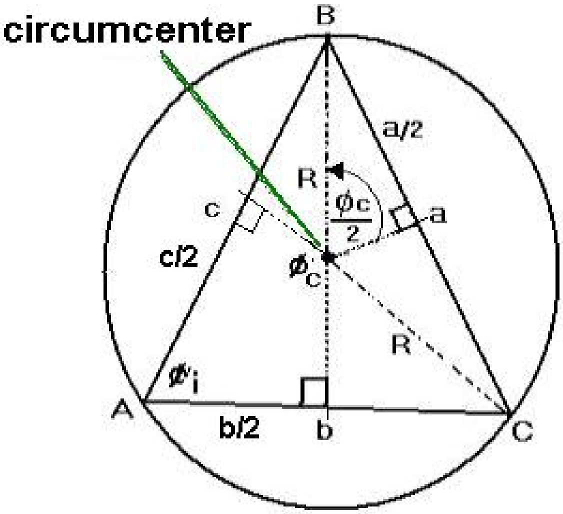
One method to tell if two angles are the same, without using a protractor, is that the distance between a selected point on one side of an angle, and a selected point on the other side of that angle, will be the same for both angles. These selected points along both angles are usually located to be at the same distance from the vertex of each angle. Though the angles might be found to be identical in size, we don't know their specific value without further calculation. As seen with inscribed and central angles having different angle values and yet having the same chord or arc length of a circle, you therefore cannot tell the actual size of any angles that have equivalent chord lengths, opposite [corresponding] side lengths or arc lengths. Other data ,such as side lengths corresponding to that angle must then be considered. Also, for a given circle, each arc length will have a unique corresponding central angle, and an inscribed angle equal to half of it. It is incorrect to consider that chord length and arc-length are (strict) mathematically proportional, other than that they will both increase or decrease by a different factor value each.

Since the incenter of a triangle was already discussed, this is a good place to introduce the **circumcenter** of a triangle. Notice that each side of the (circumscribed) triangle inscribed within a circle [as seen in FIG 157] is a chord of that circle. The perpendicular lines at half of each triangle side (or chord of a circle) will all pass through the center of this circle. This is similar to where tangent lines are always perpendicular to the radius line and vice-versa. This point is called the (or sometimes the "circumference") of the triangle. This point is equidistant from each vertex (located on the circles circumference) of the triangle. Since the excenter of a right triangle lays upon the hypotenuse and in the middle of it, it is relatively easy to see and-or understand that the radius (R) of the circumscribing circle for a right triangle is equal to half the hypotenuse side of a right triangle:

$$R = \frac{c}{2} = \frac{\sqrt{a^2 + b^2}}{2}$$

: radius of circumscribing circle for right triangles,
(equals half of the hypotenuse side, here, side (c))
The illustration is also one way to create and draw a right angle.

This formula below is be used for non-right triangles that are circumscribed by a circle. For acute triangles, the excenter will be within the triangle, and for obtuse triangles (have an ¢ > 90°), the excenter will be outside the triangle. Here is a derivation of a formula for the radius of the circumscribing circle of any triangle: [FIG 162]



The dotted lines indicated in the above image are (side) median lines that are perpendicular to the sides, and intersect at the circumcenter point. Perpendicular median lines do not generally intersect the opposite and corresponding vertex point in a triangle, and are therefore not the same concept as angle bisector lines. Median lines are given a more general discussion after this discussion.

$$A = \frac{¢c}{2}$$

: angle A is an inscribed angle and is equal to half of the corresponding central angle (¢c) which has the same arc length. These angles will have the same trigonometric function values.

$$\text{SIN } A = \text{SIN}\left(\frac{¢c}{2}\right) = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{\frac{a}{2}}{\frac{R}{1}} = \frac{a}{2R}$$

algebraically:

$$R = \frac{a}{2 \text{ SIN } A}$$

likewise:

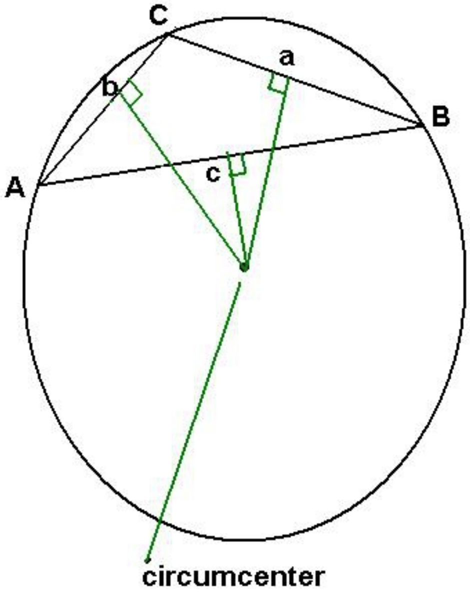
$$R = \frac{a}{2 \text{ SIN } A} = \frac{b}{2 \text{ SIN } B} = \frac{c}{2 \text{ SIN } C}$$

: Radius of a circumscribing circle of a triangle.
(when C=90°, SIN 90° = 1, and we see that R = c/2)

Note also, for example, that SIN A = $\frac{a}{2R} = \frac{a}{D}$: D = diameter of the circumscribing circle.
Also, for example: D = a / SIN A = b / SIN B = c / SIN C

A generalized formula is: $\text{SIN } ¢ = \frac{\text{corresponding side (or circles chord) to that angle}}{\text{diameter of the circumscribing circle}}$

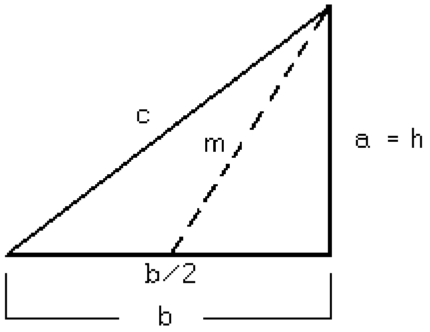
Another viewpoint of the circumcenter point of a triangle is this: If you have a circle and draw any triangle (or any other circular polygon [multi-sided structure]) within it that has all of its vertex points on the circumference of that circle then that circle is said to be a circumscribed circle to, around or about the inscribed triangle. The center point of this circumscribing circle is called the circumcenter of that triangle, and the radius of that circle is called the **circumradius** of that triangle. This circumcenter point can be found at the intersection of the perpendicular lines drawn from the center points of the three sides of that triangle. Due to this construction, each vertex point of the triangle will be at the same distance of: (r) = circumradius from the circumcenter of that triangle. [FIG 163]



Since the triangle in the above figure has an internal angle greater than 90°, it is an obtuse triangle and its circumcenter is a point outside of that triangle. For a right triangle, its hypotenuse side will coincide with the diameter of the circumcircle. For an acute triangle, the cicumcenter will be a point within the triangle.

MEDIAN LINES

A median (m) is a line within a triangle from half (ie. the center or middle (median)) of a given (base) side to the vertex of the corresponding angle opposite that side. In general, median lines are not perpendicular to the base side it intersects and-or originates from and goes to the corresponding vertex point. Any one of the three median lines of a triangle will divide the area of the triangle in half since a triangle with the same height but only half the base will have half as much area. [FIG 164]



The height and the base are the same for both of the two smaller triangles created. Since each has half the base of the original triangle and the same height as the original triangle, the area of each is half of that of the original triangle. Since area = A = (bh)/2 , area is directly related to the base side. If the base is divided by 2, area is divided by 2.

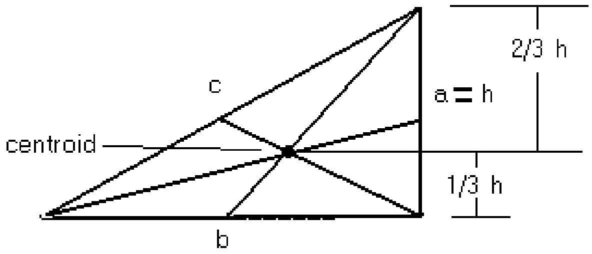
From: $A = \frac{bh}{2}$: Area of any triangle if we divide the base by 2, we need to do it to the other side of the equation also:

$$\frac{A}{2} = \frac{\frac{(b)\,h}{(2)}}{\frac{2}{1}} = \frac{bh}{4}$$

: area of each new triangle that was divided by a median line. This is the same as dividing the area of the original triangle (using it's values) by 2. If the base (b) or height (h) of a triangle is divided by multiplied by a factor (n), the area (A) will also be divided by multiplied by (n). In the formula shown here, (b) and (h) are the values of the original given triangle.

The three medians within a triangle will intercept at a point called the **centroid** of the triangle. Since each median line divides the area in half, the centroid is essentially a "balance point" or center of mass. That is, if a triangle shaped construction was physically constructed entirely of the same material and of the same thickness throughout its entirety, the triangle can be balanced at this centroid point. The centroid point divides a median line into a 2 to 1 ratio = 2:1

The three medians also divide the triangle into three smaller triangles, each being one-third (1/3) of the total area of the entire original triangle. Each of these smaller areas has a side of the original triangle. This side will then be the base side and the medians bounding or subtending that base side will define (be the sides of) the base angles at that side of that internal triangle. Also, do not assume that these are similar triangles. The centroid is located at one-third (1/3) of the way along the median line from each given (base) side of the original triangle. The other segment of each median line is then twice as long since: 1 - (1/3) = (3/3) - (1/3) = (2/3). [FIG 165]



Notice the area of the small triangle created which has (b) as its' base side. Since the base is the same as the base of the total area of the given triangle, to equal (1/3) of the overall area, the height side must then only be 1/3 of the total height. The same can also be said about the other two smaller triangles. Half the area of each of the three small internal triangle constructions is: (total area/3)/2 = (1A/6), or one-sixth of the total area of the original triangle construction, therefore, any two of these smaller areas sum to: (1/6)+(1/6) = (2/6) = (1/3) of the total area, and any three (in particular, those adjoining each other) smaller areas sum to (1/6 + 1/6 + 1/6) = (3/6) = (1/2) of the total area of the triangle.

An ancient mathematician known as Euclid is credited with mathematical understanding of the length of a median line by using the concepts of basic geometry with triangles, and here is a general format for the length of a median line:

$$\text{median length to side1} = 0.5 \sqrt{2\ \text{side2}^2 + 2\ \text{side3}^2 - \text{side1}^2}$$

: **length of a media line in a triangle**
Formula credited to Euclid
of Alexandria city in Egypt.
Note: Can also use 1/2 for 0.5

The formula for the median line is based on the Pythagorean Theorem, Apollonius Theorem, and Parallelogram Law. The derivation is not overly difficult and it is available elsewhere.

As a relatively easy verification to the above formula, you can use an equilateral triangle with sides say of 1 unit, and which also has there internal angles of 60°. Here s1 = s2 = s3 = s, and the above formula will simplify to:

$$\text{median length to any side s} = 0.5\sqrt{3\ s^2} = 0.5\ \sqrt{3}\ \sqrt{3^2} = 0.5\,(1.732051)\,s = 0.86602\underline{5}\,(1) = 0.86602\underline{5}$$

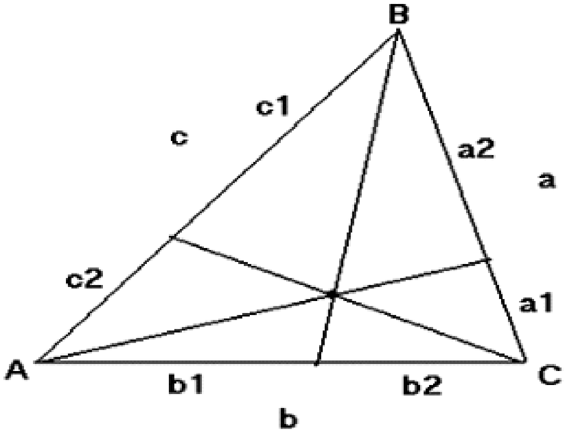
The **Apollonius Theorem** is usually something mentioned in more advanced geometric studies, and it states that given the three sides of a triangle, the sum of the squares of any two sides will equal the sum of the squares of half the third side, plus the square of the median line to that third side.

The **Parallelogram Law** states that the sum of the squares of all the sides of a (four sided) parallelogram will equal the sum of the squares of its two internal diagonal lengths. A parallelogram, being somewhat like a rectangle, will also have two pair of equal sides, and the two diagonals will also be an equal valued pair. If the parallelogram is a rectangle, and if we divide each side of this equation by 2, we could have the familiar Pythagorean Theorem.

With the concept of median lines, the lengths of both (1/3) and (2/3) of it can be found geometrically.

Even though many of these formally defined (interior and-or exterior) triangle lines such as medians, altitudes, and angle bisectors have been known about and studied for hundreds of years previously, any and all lines from a vertex of a triangle to the opposite side (even if extended) of that angle are more recently and formally called a **cevian** ("chevian") line. In 1678, **Giovanni Ceva** published and popularized a theorem and formula for the ratio of the lengths of a triangles side segments intercepted by cevians. **Ceva's Theorem** states that given a triangle with 3 interior and-or exterior lines that intersect at a concurrent (common), interior or exterior, (cevian) point, the product of all the 3 ratios of each two line segments on each side of that triangle is equal to 1. The derivation for this theorem is based on the ratios of the internal

triangle areas. The numerators and denominators of these line segments ratios can be determined by going in a clockwise or counter-clockwise direction. There are many other interesting facts and theorems created by others about cevian lines, unique points, triangles and circles, and are very useful for more advanced geometry studies. The following image shows three random cevian lines that intersect at a common point:
[FIG 166]



$$\frac{a1}{a2}\,\frac{b1}{b2}\,\frac{c1}{c2} = 1$$

$$(a1)(b1)(c1) = (a2)(b2)(c2)$$

$$\frac{a1}{a2} = \frac{(b2)\,(c2)}{(b1)\,(c1)}$$

$$a1 = a2\,\frac{(b2)\,(c2)}{(b1)\,(c1)}$$

$$a2 = a1\,\frac{(b1)(c1)}{(b2)(c2)}$$

If your making some kind of triangle-like analysis and-or construction with internal lengths or beams that intercept at some common point, the above equations will be very useful. For the first equation to be equal to 1, it implies that the numerator is equal to the denominator, and for here: (a1 b1 c1) = (a2 b2 c2)

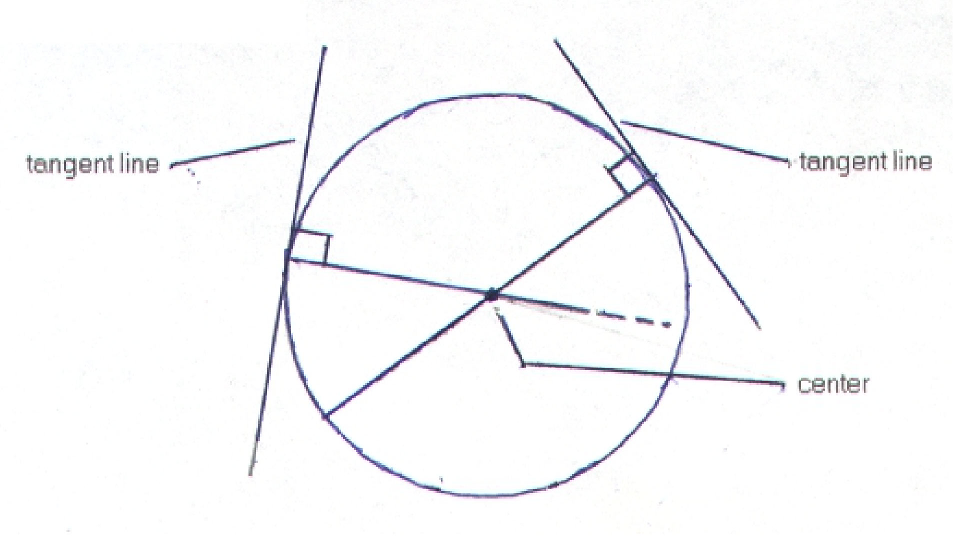
CONSTRUCTING A PROTRACTOR

Below are several methods that you can use as guides for constructing a homemade protractor, however, if you already have access to a protractor, you can use it as a basic template (pattern). The protractors below have a scale from 0° to 90°, hence a "single quadrant protractor". If you want, you can make one with a scale from 0° to 180° (a semi/half-circle protractor), or from 0° to 360° for a full circle protractor. Common protractors have indicated divisions or "graduations" on its' scale as small as 1°. A "rough or close estimate" protractor might only have divisions as small as 5°. You can draw your protractor on paper, cut it out, and then glue it onto a stiff paper or wood backing. Mentioned previously, if you draw an equilateral triangle and divide one side in half, you can easily construct a triangle with angles of 30°, 60°, and 90°. You can then, for example, bisect the 30° degree angle to 15°, and then the 15° angle into three 5° angles.

Method 1:

Draw a quadrant of a circle (typically) by using a device called a compass. A compass is basically anything that can assist you drawing various sized arcs or circles by adjusting the distance (essentially a radius distance) between its two indication or scribing points. To encompass something is to surround or encircle it. If you do not have a compass, you can use anything circular, such as a bowl or cup as a template to trace around. In general, the larger the radius of this circle the more accurate your protractor can possibly be, and therefore, the more accurate the drawn or measured angles The larger you make the protractor, it can also be more precise, perhaps allowing measurements as small as 1°. A radius of about 4 inches is good to start with. Measure the radius of this circle for it will be used in the calculations below. With a compass, the center of the circumscribed circle is clearly marked, otherwise, use something like the following method to find the circles center so as to then find the circles diameter and radius:

A line that intercepts a circle, or other curve, at only one point is called a tangent line, and the line is said to be tangent to the circle. The diameter line or radius line extended (perhaps with the aid of some right-angle, perpendicular guide, or just a plain ruler) to this (tangent) point will always be perpendicular (90°) to this tangent line. Likewise, tangent lines are always perpendicular to the radius line extended to the tangent lines point of interception with the circle. To find the center using a diameter line, draw a (or several) tangent line and then draw a perpendicular (diameter) line to it. Measure and divide the diameter line in half to find the value of the radius and the location of the center. To find the center using the radius line method (no measurement needed), draw another tangent and radius line. The point of interception of both radius lines is the center of the circle: [FIG 167]



Optionally, to find the center of a circle, you can find the circumcenter of a triangle that has all three of its vertices on the circumference of this circle. The circumcenter of the (circumscribed) triangle will coincide (be the same point) with the center of this circle. The circumcenterof a triangle was previous discussed in this book, and if the triangle is a right-triangle, the center of the circle is at half of the hypotenuse side of an inscribed right-triangle.

For each division on the protractor's angle scale, we need to first find the point on the circles arc (portion of its perimeter or circumference) where the ending or terminal side of the angle intercepts it. With this method, it takes two calculations to find the co-ordinates of each point. Also, in order to properly place an angels location point onto your drawing and angle scale, you will need a guide device (ie. something with "square" or perpendicular sides) to draw (perpendicular) lines at right angles with respect to each other.

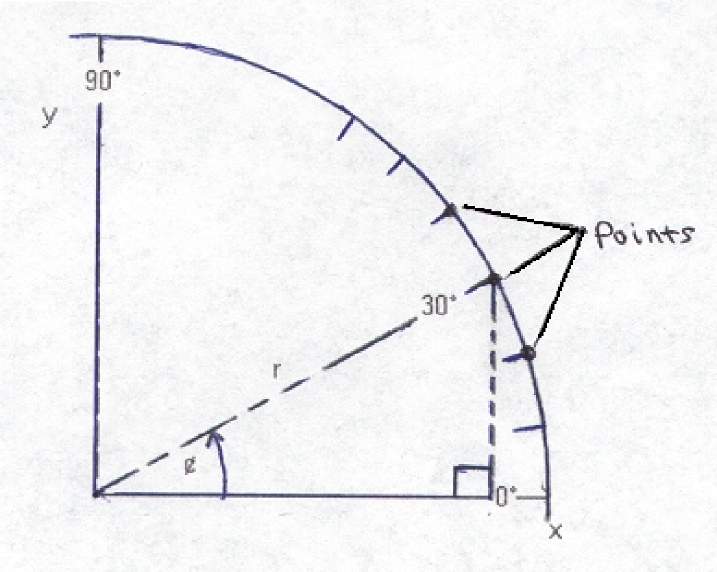
From : $\text{SIN } ¢ = \frac{x}{r}$

$x = r \text{ SIN } ¢$: x coordinate of point. If $r = 1$, then $x = \text{SIN } ¢$

From : $\text{COS } ¢ = \frac{y}{r}$

$y = r \text{ COS } ¢$: y coordinate of point. If $r = 1$, then $y = \text{COS } ¢$

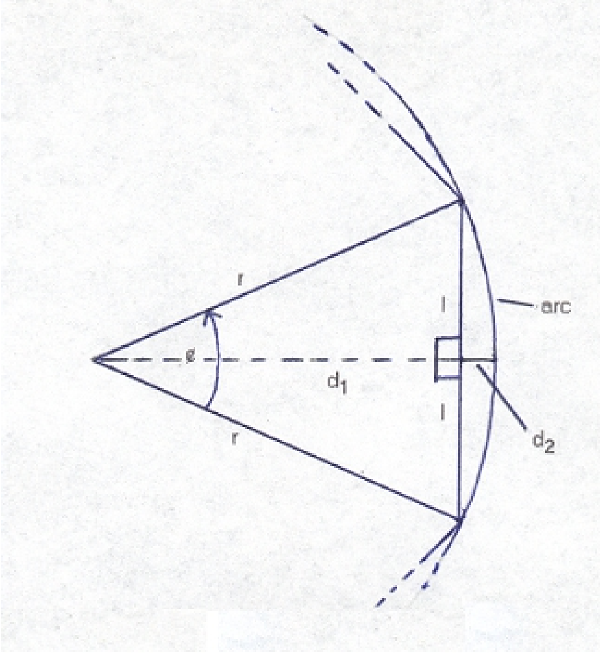
Once you find the co-ordinates of a point, draw a small line segment at the circle's or protractor's edge so as to indicate the angle. This line segment essentially lays on the radius line or angles terminal side at that point. [FIG 168]



Method 2:

If you already drew a small angle on your circular protractor, say 5° or 10°, you can trace it and use it as a template for the remaining angles on the scale of your circular protractor. Simply align the initial side of the template angle's with the terminal side of each successive angle drawn on your protractor, and then indicate (scribe) this new point. Another similar method is to simply trace the angles corresponding arc of the circle and use this "length of arc" as a guide to create similar arcs around your protractor. If you like, rather than use the arc, you can use the straight-line (ie. a chord line) distance between the end points of the arc, and drawing each next chord line segment to indicate additional angles.

While on the subject of arcs and chords, below is a description of how to calculate the chord length beneath the two endpoints of an arc of a circle: [FIG 169]



To make the analysis simple, the angle is bisected into two half-angles, creating two equivalent right-triangles. In the formulas below, use half the angle in question.

From : $\text{SIN ¢} = \frac{\text{opp.}}{\text{hyp.}} = \frac{l}{r}$: here, l is half the length of the chord

$l = r \text{ SIN ¢}$: be sure to use the half-angle value only

Twice the length of (l) is the (chord) length (L) of the line-segment between the endpoints on the arc:

$L = 2l$: Length of the entire line segment "beneath" the arc.
Such a line segment is called a "chord" of a circle.
Note that the (radius) line drawn from the center of the
circle to the midpoint of any chord will be perpendicular
to that chord line. If this line is extended to the circumference
of the circle, it divides the arc in half, and a line tangent to
the circle at this point will be parallel to the chord.

Additionally, if you want to know the length of d1 and d2:

From : $\text{COS ¢} = \frac{\text{adj.}}{\text{hyp.}} = \frac{d1}{r}$

$d1 = r \text{ COS ¢}$: be sure to use the half-angle value only

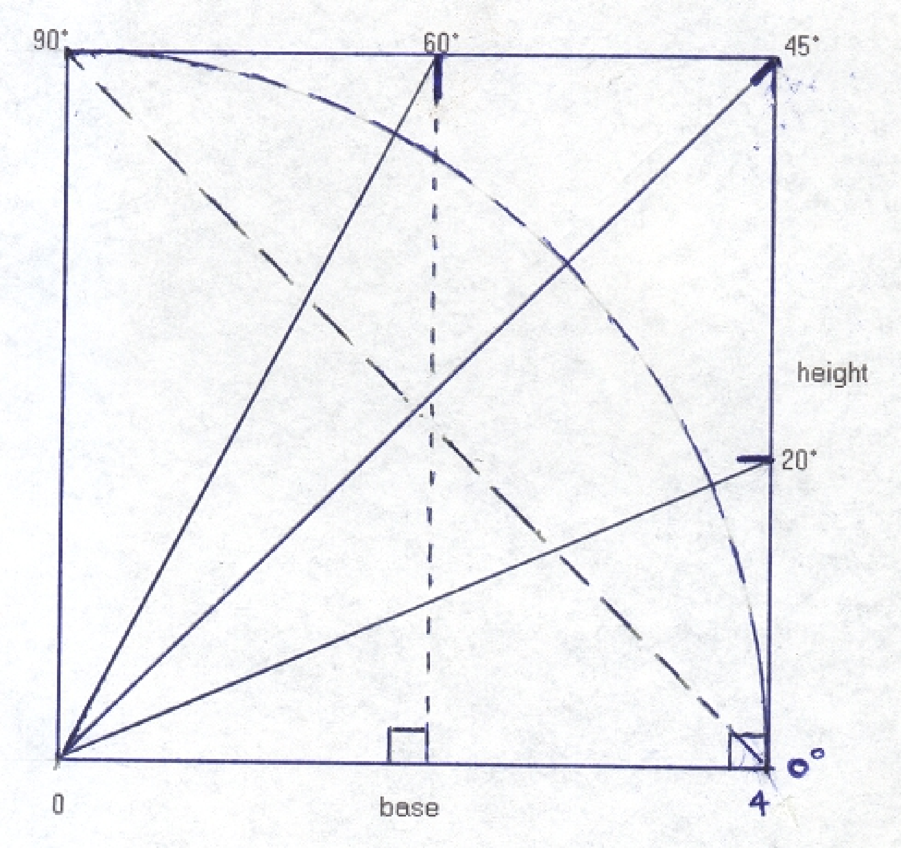
Since: $r = d1 + d2$ therefore:

$d2 = r - d1$

Method 3:

This method shows how to make a protractor with a straight scale rather than an arced or curved scale. However, due to that this scale would very large at the higher angle end past 45°, the scale will effectively be "bent" at a right angle to overcome this potential problem. Due to this modified construction, you now have two other design choices after creating this square scale, as indicated in the drawing below, of either a curved or circular scales, or a triangular scaled protractor.

To construct this protractor, draw a square, perhaps 4 inches on each side. The lower left corner will be the vertex of all the angles. The scale will be along the right side for angles from 0° to 45°, and along the top for angles from 45° to 90°. Each angle is calculated using the concepts of right triangles: [FIG 170]



For angles along the right side:

From : TAN ¢ = $\frac{\text{opp.}}{\text{adj.}} = \frac{\text{opp.}}{4"}$

opp. = 4in. TAN ¢

Ex. For an angle of 20°:

opp. = 4" TAN 20° : the side opposite is equivalent to the height of a right triangle, and 4" is the base side here.
opp. = 1.4559"

This must be done for each angle due to that there is no linear relationship between the side opposite or height of an angle and the adjacent or base side. The only exception to this is that say if you double the base side of a triangle, to make a similar triangle the height is likewise doubled or increased by the same factor. For similar triangles the ratio of all corresponding sides of the two triangles is the same value, and this is due to that each side is a factor increase or magnification of the other. Similar triangles are said to be proportional to each other.

If for example you find that 5° would be a height of 1inch, you cannot use a height of 2 inches for 10° and so on.

Converting the fractional part of this value to a number of 32nds or 64ths of an inch:

Since: $\frac{1"}{32} = 0.03125"$ dividing the fractional part of 1.4559" by this fraction (1/32) of an inch:

$$\frac{0.4559}{0.03125} = 14.6 \text{ , (one) thirty-two seconds of an inch}$$

If you need some more clarification on the result, consider this:

$$\frac{\frac{0.4559 \text{ in.}}{1}}{\frac{1\text{in.}}{32}} = \frac{0.4559 \text{ in } (32)}{1 \text{ in.}} = 0.4559\ (32) = 14.6$$

Or by using proportions:

$$\frac{1 \text{ inch}}{32,\ 32\text{-seconds}} = \frac{0.4599 \text{ inch}}{x\ \ 32 \text{ parts}} \quad : \ 1,\ 32 \text{ seconds} = 1 \text{ of } 32 \text{ parts} = 1/32$$

$$x\ \ 32\text{-seconds} = \frac{0.4599"\ (32\ 32\text{-seconds})}{1"} = 0.4599\ (32\ 32\text{-seconds}) = 14.6 \text{ thirty-two seconds}$$

To convert a number of inches to its equivalent number of thirty-two seconds, we see that you can simply multiply by 32. Using the same reasoning, to convert inches to sixty-fourths, simply multiply by 64.

Using the results above, indicate the 20° angle at 1 inch and 14.6 thirty-two seconds high on the right side.

For angles along the top side:

From : $\text{TAN ¢} = \frac{\text{opp.}}{\text{adj.}} = \frac{4}{\text{adj.}}$

$$\text{adj.} = \frac{4"}{\text{TAN ¢}}$$

Ex. For an angle of 60°:

$$\text{adj.} = \frac{4"}{\text{TAN } 60°} = 2.3094"$$

After converting the fractional portion to its equivalent value with units of thirty-two seconds of an inch, the angle should be indicated at 2 inches and 9.9 thirty-two-seconds rightward on the top side. This is possible on the top side since the top and bottom lines are parallel to each other and both are perpendicular to the left side line.

For a triangular shaped protractor, you can first create the square shaped protractor and draw a diagonal line from the opposite corners so as to create the triangle shaped protractor, otherwise, if it is directly created, you must still calculate each angle and the corresponding height since there is no linear relationship to use a specific amount of distance or length. In the case of the circular protractor, the chord lengths beneath an arc of a certain amount of degrees will all be the same length and distance from the angle vertex and-or center of the circle.

If needed: If the initial square shape is 4 inches, the diagonal (D) length within that square from corner to opposite corner can be found using the Pythagorean Theorem:

$D = \sqrt{4^2 + 4^2} = \sqrt{32} = 5.65\underline{7}$ inches : for a square, the diagonal is always: $D = \sqrt{2\ s^2}$

$D = \sqrt{2}\ \sqrt{s^2}$

$\mathbf{D = 1.41421\underline{4}\ s}$

1 sixteenth of an inch = $\frac{1 \text{ in}}{16} = \frac{(1)}{(16)}$ in = 0.01625 in

5.657 in = 5 in + 0.657 in = 5 in + (0.657in) (1 sixteenth / 0.0625 in) = 5 in + $\frac{(0.657)}{(0.0625)}$ sixteenths =

5 in + 10.512 sixteenths

Extra: Mentioned in this book is that an inscribed angle with its vertex on the edge (ie., it circumference) of a circle, and which has a chord opposite of it equal to the diameter of that circle, then that inscribed angle is a 90° or right angle. Half of this angle will create a 45° angle. A square also has four internal 90° angles.

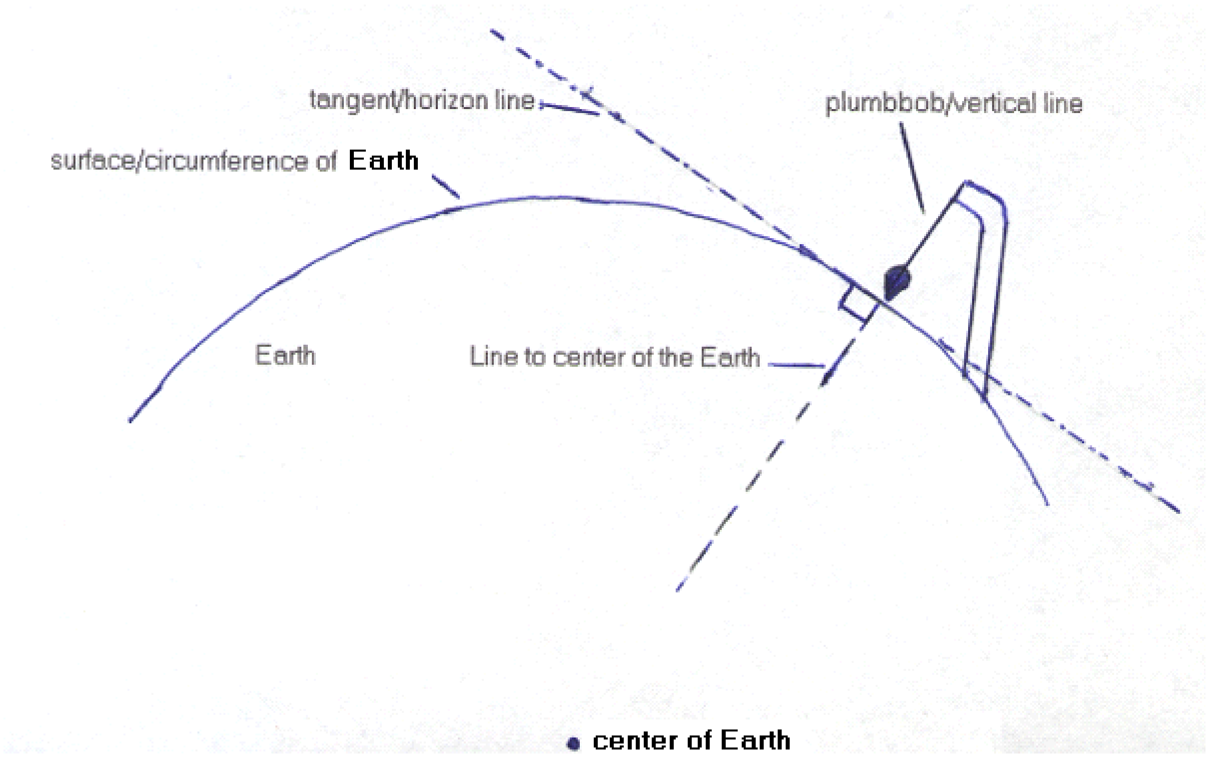
CONSTRUCTING A DEVICE TO MEASURE ANGLES FROM THE HORIZONTAL

A quadrant (a device to measure up to a 90 degree angle), inclinometer (an angle measuring device), astrolabe, sextant (often used for celestial (stars, space,"heavens") navigation which is often used for ship navigation by stars), theodolite, torquetum ["torketum", a device specifically made for celestial star coordinates mapping], or even a protractor-like device are ancient devices which can measure either vertical and-or horizontal angles such as the angle to the top of a building, a mountain, or the angle a star or other celestial object that is "above" or with respect to your (local) horizon or level (technically, a tangent line to the surface of the Earth at a location, and which is perpendicular to a radius line to the center of the Earth). As shown ahead, it basically consists of an angled scale, such as a protractor, and a pointer, aiming or sighting indicator. The sighting indicator device can be a straight and narrow flat surface. For the sextant to work properly it must always be level (parallel) to the ground since the angles will be measured with respect to the ground or any other line or surface near to, and essentially parallel to, the ground or horizon. For additional aid you can place the device on a level surface at the top of a sturdy tripod stand. Once the protractor scale is level (set, calibrated, or indicated to 0° when the sighting board or plane is parallel to the ground or horizon (horizontal line)), the actual object is "sighted" (aimed or pointed to) by the measuring instrument and the angle will be indicated on the protractor that is located alongside the edge of the sighting device. A figure of such a device will be shown further below in FIG 173.

With the aid of a plumb-bob device, see FIG 169, the proper positioning, calibrating or leveling of the protractor is not a concern, that is, it will effectively take place automatically after the calibration (proper initial setup for use) of the device has taken place. The sighting device will remain "fixed" (does not rotate about the vertex to measure the angle), and the protractor effectively rotates vertically. The word "plumb" (or "plum") in the context of a **plumb-bob** device means that which is vertical (ie. perpendicular) to the surface of the earth. If something is actually vertical it is said to be "plum" (meaning "true" to being vertical). A plumb-bob is hung from a thin cord called a plumb-line so as to indicate a true vertical line that is perpendicular (here, vertical) to the horizon line or surface of the earth. The word "plumb" in plumb-bob means a weight, and which was often a lead weight. An old world for lead is actually the word "plumb" (ie., for plumbers, a "true" vertical or horizontal lead pipe) of which now has a periodic table of elements entry identifying it as such: Pb. The word "bob" in plumb-bob means to be movie in an up and down manner as would a (fishing) "bobber" (with a "bobbing motion") used as a float and indicator when fishing. The plumb-line can be used to indicate and-or measure an angle with respect to the local horizontal 0° or vertical reference line. The plumb-bob weight usually has a point at the farthest end (near the ground) for maximum use of the device, however, for the final construction discussed, practically anything can be used as the weight at long as it does not interfere with the free movement of the plumb-line which will indicate the angle. The plumb-line can be made from common household sewing thread or fishing line. The common word "plumbers" who today, describes people who install and fix pipes.

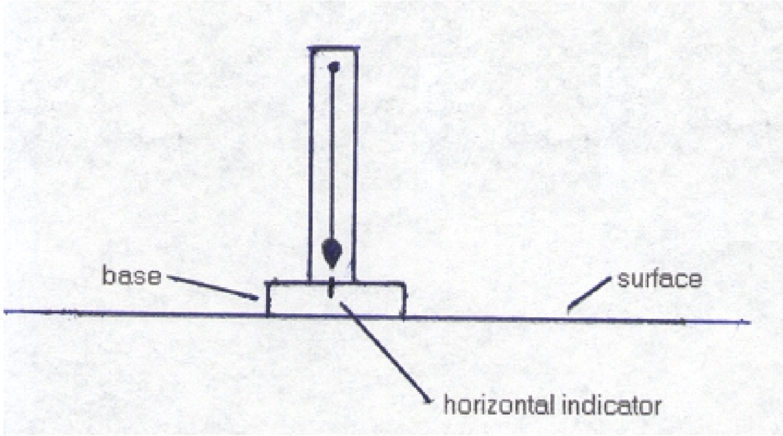
Why is the plumb-line automatically "true" vertically, or always perpendicular (90°) to the ground?

The force called gravity, originating from the matter (ie., materials) of the Earth and concentrated in the direction of its center, will pull the plumb-bob weight towards the center of Earth. If the plumb-bob is suspended by a plumb-line, the line will be made vertical due to gravity constantly pulling upon the plumb-bob and causing a tension force to be applied to the line. This line, if considered greatly extended, will always pass through the center of Earth just like a radius line, and radius lines are known to be are perpendicular to tangent lines. The (true, at the ground level) horizon is actually a tangent line at any point where a vertical line crosses above and below the surface of Earth. A horizontal line is perpendicular to this vertical line through the center of the Earth. As you go farther above the surface of Earth (ie. above sea level) the viewable portion of the surface of Earth will increase since the greatest possible "line of sight" distance between you and the (seen) edge of Earth is now larger. The max. viewable distance is where your line of sight is tangent to the surface of Earth. Since the circumference of the Earth is so large, it usually does not appear to be curved but appears flat when standing on it at a low height such as at sea-level (0ft altitude), and for most applications not involving high altitudes and-or distances, the curvature of the Earth does not need to be considered in any calculations. Due to these facts, any other line (such as the side of a wall or other construction such as a building) that is parallel to the plumb-line will also be vertical. Here is a magnified image of this discussion: [FIG 171]



In the above figure, the plumb-bob (ie., "vertically true" line and weight) is vertical (ie., "straight up and down") at the local area on Earth and the observer, and it is also perpendicular (ie., 90°, a right angle) to the local horizon which is tangent to the Earth at that location, hence the horizontal line is perpendicular to Earth's radius line and vice-versa.

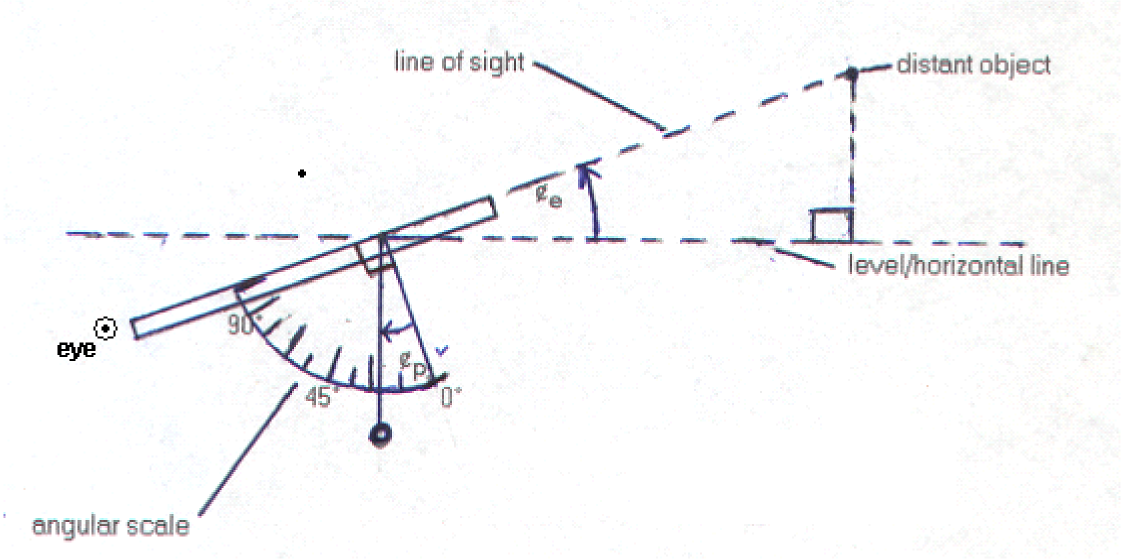
Below is a simple device that can indicate if a surface or line is level, horizontal, or parallel to the Earth's, local horizontal or surface. The working part of the device is a plumb-bob. You can construct such a device out of wood. The longer the plumb-line or string is, the better the accuracy of the device since the side opposite the angle between the plumb-line and true vertical line will be larger, and will then be more observable for small angles when the surface is not level (ie., a 0° angle or offset from the horizontal 0° reference angle). The dimensions of the device depends upon the application. For starters, you can construct a base with a length of about five inches, and a width of about one too six inches. The bottom side of the base should be perfectly flat, and it may need to be sanded flat The board suspending the plumb-bob can be about one foot high. Once constructed, the plumb-bob should swing freely with an arc of about one inch or more at the weighted end. With a stabilized (non-swinging) plumb-bob and the base being upon a surface known to be level or approximately level, calibrate (set-up, adjust for proper operation) the device by marking a point directly beneath the suspended plumb-bob whose pointer end is very close to the surface of the device. This point will be a natural calibrated horizontal or level indicator mark. It is even possible to make or modify the device with another flat surface (or "vertical base" if you will) and-or a vertical, drawn line, perpendicular to the bottom of its base side, so as to sense if another surface, such as a wall, is vertical. **A horizontal level indicator device**: [FIG 172]



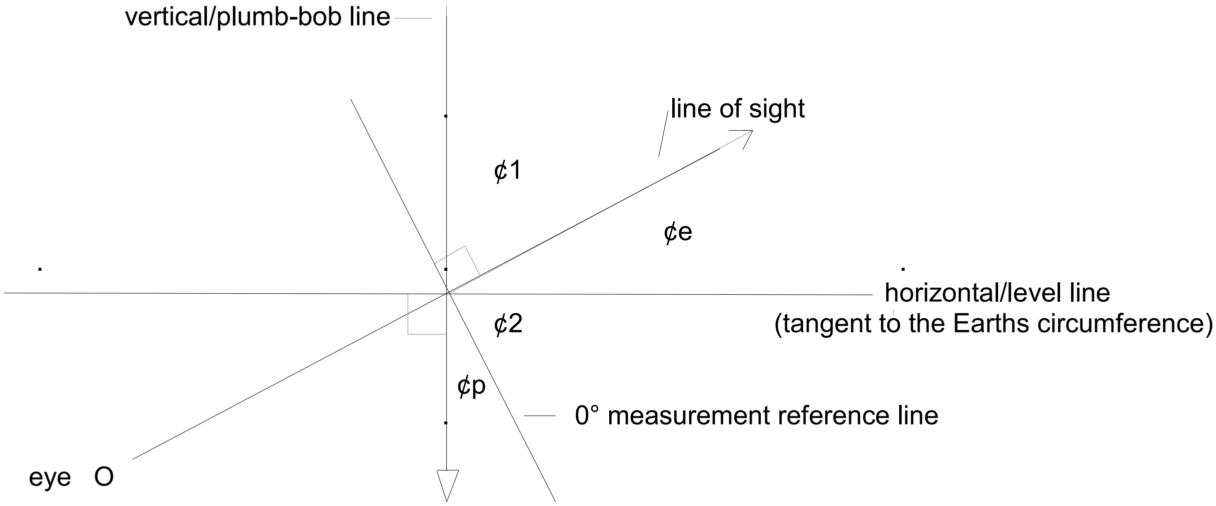
Now that we know the parts and construction of some basic angle measuring devices, the description of its operation is discussed and verified below.

To calibrate the sighting device, set the sighting device in parallel to the ground or horizontal level. The angle indicated should be set to 0° degrees. Note that a floating object of equal dimensions and having a flat surface on top can indicate a line or "level line" (no tilt or angle) that is parallel to the horizontal line at your location.

To use the angle measuring device, view ("line up", "aim") a distance object the "sighting (viewing) edge" of the device. The angle indicated on the angular scale or protractor is the angle between the horizontal (0°, "level" line of reference) and the line of sight to the distant object: [FIG 173]



Below is a verification that the angle indicated on the protractor (¢p) is equivalent to the actual angle (¢e) between the line of sight and the horizontal "level" line of the Earth or any other line parallel to this line. For this example, the angle is an (upward) angle of elevation since the object is above the horizon. To measure a downward angle (where the object is below the ("level") horizon or 0° reference line), you can simply turn the device around, that is, sight the object from the other end of the device, or construct the device to measure all possible (vertical, up and down) angles. [FIG 174]



¢e = angle of elevation above the reference line
¢p = angle indicated on protractor or angle measuring scale

Since the line of sight line is perpendicular to the 0° angle line:

¢e + ¢2 = 90° therefore:
¢2 = 90° - ¢e

Since the plumb-bob line is perpendicular to the horizontal/level line:

¢2 + ¢p = 90° algebraically substituting the equivalent of ¢2:
(90° - ¢e) + ¢p = 90° clearing the grouping symbols:
90° - ¢e + ¢p = 90° after transposing 90° :
- ¢e + ¢p = 0° after transposing (- ¢e) :
¢p = ¢e : angle indicated on protractor = angle of elevation (above the horizon) to object

In short, and as a verification, ¢p and ¢e are both complementary angles to ¢2, hence they must be the same value.

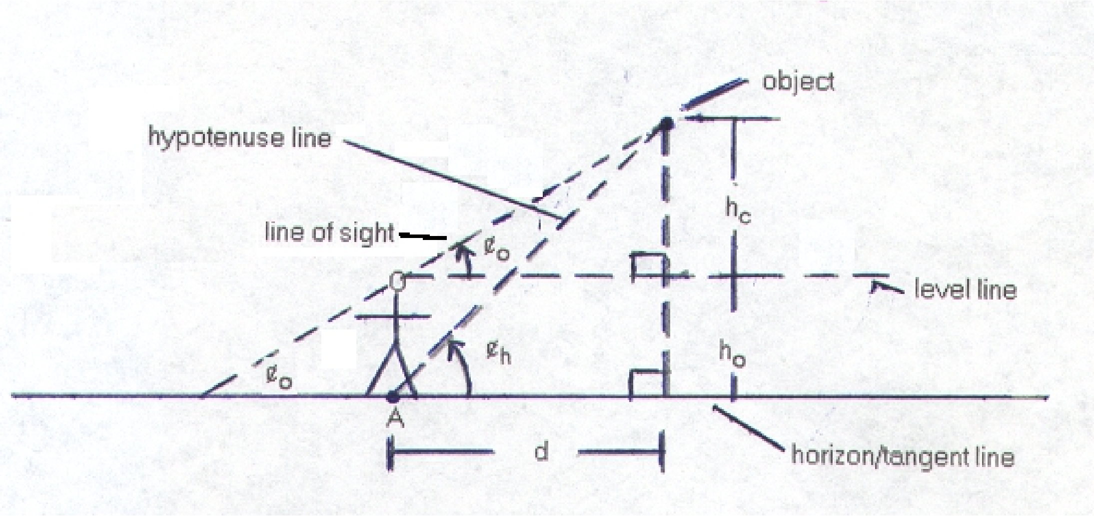
Extra: **Still water will naturally seek the local horizontal level.** A very flat object such as a rectangular block of wood that is floating in it can be used to create a level sighting pointer and-or horizontal reference. As shown previously was a plum-bob in the local force of gravity that be used to show a true, local vertical reference, and 90° from this value is a true, local horizontal reference.

A long (air) **bubble level,** which is also called a **(mineral, oil) spirit level** is often used to determine if a surface is horizontal or vertical. These are available in various lengths: 1 inch long to over 3 feet long. When the air bubble is centered between two indicator lines marked on the small glass cylindrical tube, the surface it is on is either horizontally level, or vertically perpendicular to the horizon, and-or parallel to the surface being checked.

Some modern computer phones can use an application (ie., app, computer program) so as it can function as a basic level indicating device. Another app can make the phone act as a magnetic compass. These apps are low cost or free.

SOME CAUTION WHEN CALCULATING AN OBSERVED HEIGHT

When you are close to an object and are solving for the height of it with the aid of an angle measuring device and (right-angled) trigonometry, you are actually measuring the height that the object is above the your observation point, (eye) level line (parallel to the horizon line) as shown in the drawing below. This topic was also briefly indicated previously in this book: [FIG 175]



The angle (¢o) measured by the observer (O) standing above point A will be the angle between the (eye) level line and the line of sight to the object. The actual angle (¢h), for the actual height of the object above the horizon line as seen at point A, is the angle between the horizontal line and the hypotenuse line intercepting point A as shown. Be sure to notice that ¢o and ¢h do not have the same value.

The calculated height (hc) by the observer will be smaller than the actual height of the object. To correct this, simply add the height (ho) that the observers eye is above the horizontal, base or ground line to the calculated height.

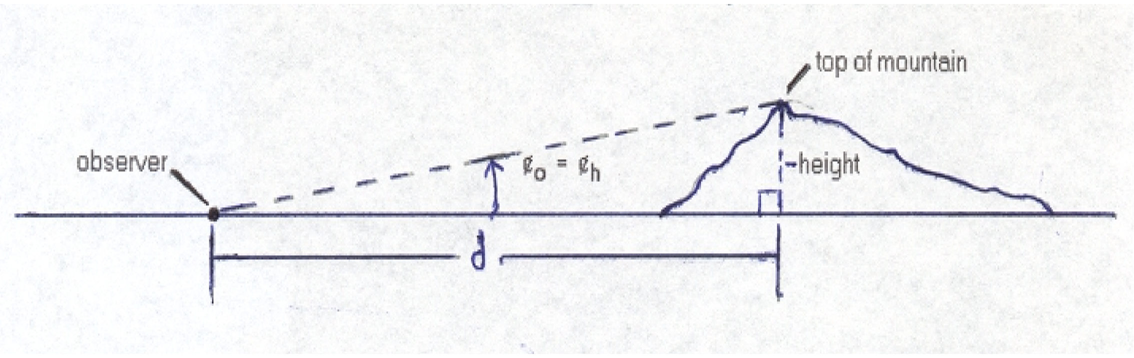
actual height = hc + ho

If needed, the actual angle (¢h) at point A can now be calculated using trigonometry:

$$\text{TAN ¢h} = \frac{\text{actual height}}{d} = \frac{(hc + ho)}{d}$$

¢h = ARC TAN (TAN ¢h)

If the object is very high (as compared to the observers relatively small height above the horizontal base or ground line) and distant, the observers height is practically irrelevant to the objects height and is therefore often omitted from the calculations. In this situation, the hypotenuse line and the line of sight become nearly parallel and along the same line, therefore, the angles (at ground level, and observed) will practically have the same value: [FIG 176]



SLOPE OF THE HYPOTENUSE LINE

The slope, as mentioned previously, is basically a numerical value for the "steepness" of the hypotenuse of a triangle or line being regarded as the hypotenuse of a level, right-triangle construction. Mathematically, in terms of two locations (points) on a graph, it is the vertical (height) change divided by the horizontal (base) change between any two points on a line. The concepts of slopes and-or rates of changes of variables are important and should not to be overlooked, especially if you need to understand basic calculus at some point in your study. Some other names for slope that are occasionally used are "grade", "incline", "inclination", and with the word "rate" (of changes of one variable in reference or respect to another).

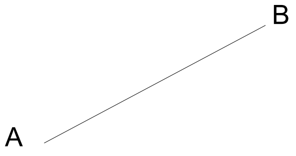
$$\text{slope} = \frac{\text{vertical change}}{\text{horizontal change}}$$

: Rate of the vertical change with respect to the corresponding horizontal change.
Or in more general terms:

$$\text{slope} = \frac{\text{vertical rise or distance}}{\text{horizontal run or distance}}$$

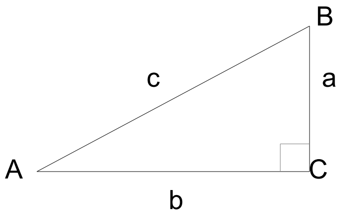
The slope value is meant to be purely numerical (ie., unitless), hence the units of the horizontal and vertical changes must be identical so as the result is unitless and just a numeric value, ratio or factor. As mentioned previously in this book, each line has it's own slope value, and it is a constant value.

Consider finding the slope of the following line segment between points A and B (this line segment may be indicated as: Line AB, or AB with a bar line over it). Let us consider Point A as level with the ground, and Point B as higher in elevation than point A: [FIG 177]



: line AB = $\overline{AB}$

For the slope discussion, consider these points as endpoints of a hypotenuse line and construct a right triangle around it: [FIG 178]



Let: a = vertical change, b = horizontal change, and c = line in question = hypotenuse of the right triangle analysis

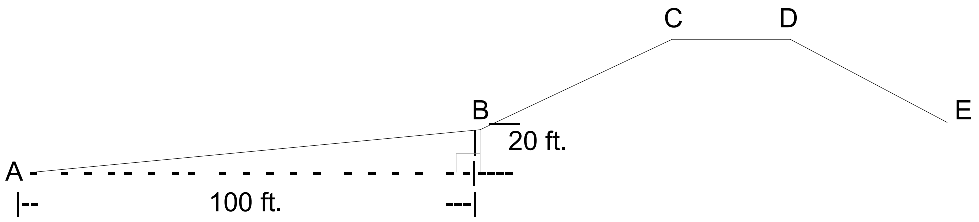
$$\text{slope} = \frac{\text{vertical change}}{\text{horizontal change}} = \frac{\text{rise}}{\text{run}} = \frac{\text{height}}{\text{base}} = \frac{a}{b} \quad : \text{slope of line c}$$

Clearly, this is equal to the TANgent of the angle that the line (c) makes with respect to the horizontal line (b). In this example, it is angle A and it is indicated at or as vertex point A of the triangle.

$$\text{slope} = \text{TAN A} = \text{TAN ¢A} = \frac{a}{b} \quad \text{and:} \quad \text{¢A} = \text{ARCTAN (TAN A)} = \text{ARCTAN } (a / b)$$

The angle and slope values are mathematically directly related. As one gets larger, the other does also. Slopes greater than 0 "slope" or rise upward at an angle with respect to the horizontal ("level-line", 0 slope) or base line. Slopes of 1 correspond to an ¢ of 45°, and the rate of change in the variables is 1 because their changes were the same value. Slopes less than 1, correspond to an ¢ less than 45°. Slopes of 0 indicate a horizontal line. Slopes less than 0 are of lines that slope downward below the horizontal or base line .

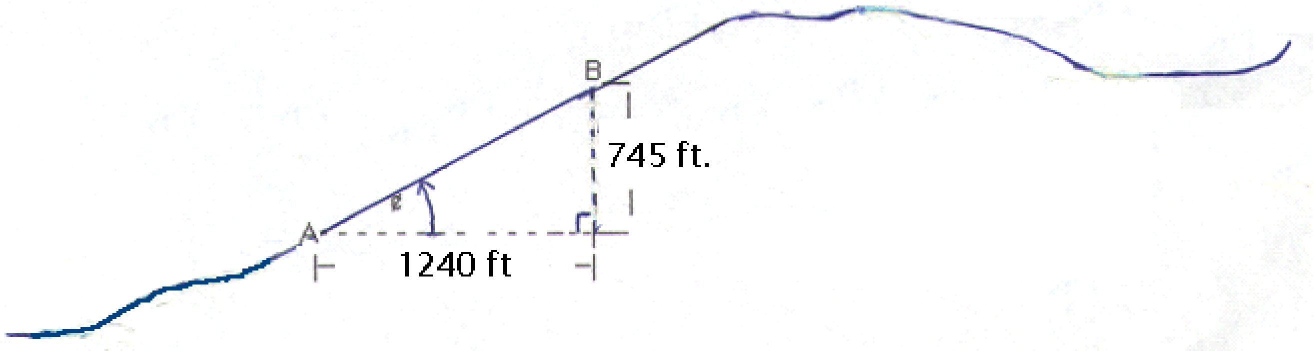
Ex. What is the slope of the line between points A and B, and what angle does it correspond to with respect to the level ground or horizon line? [FIG 179]



$$\text{slope} = \frac{\text{vert. change}}{\text{horz. change}} = \frac{20 \text{ ft.}}{100 \text{ ft.}} = \frac{0.2}{1} = 0.2 = \tan ¢ \quad : \text{the slope between points B and C is clearly more}$$

$$¢ = \arctan (\tan ¢) = \arctan 0.2 = 11.3°$$

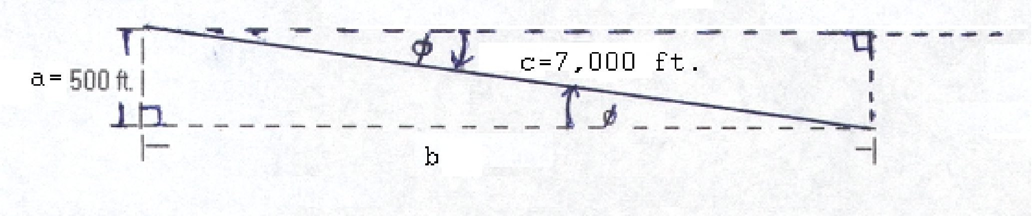
Ex. What is the slope and the angle of the mountain between points A and B with respect to a horizontal level line? [FIG 180]



$$\text{slope} = \text{TAN } ¢ = \frac{\text{vert. change}}{\text{horz. change}} = \frac{745 \text{ ft.}}{1240 \text{ ft.}} = 0.6$$

¢ = ARC TAN 0.6 = 30.96° : ~= 31° " approximately, or about 31° "

Ex. A vehicle went 7000 ft. in distance with a drop in elevation of 500 ft. to reach the bottom of a small mountain. Along its way down, the vehicle went across a few small level bridges and up a couple of small inclines. What was the vehicle's (average) slope over the entire dimensions given? [FIG 181]



Since the (level) bridges and inclines were relatively a small distance to travel, for all practical purposes, they will not change the average slope value by much, and hence those values will not be used for any calculation here.

First, we need to find the horizontal change (b). Considering the mountain structure as a side of a right triangle structure, it can be found using the Pythagorean Theorem:

$$c^2 = a^2 + b^2$$

$$b = \sqrt{c^2 - a^2}$$

$$b = \sqrt{(7000 \text{ ft.})^2 - (500 \text{ ft.})^2}$$

$b = 6982$ ft. : total horizontal distance traveled

Since there is a drop in elevation, this will be noted algebraically as a negative value, specifically (-500 ft).

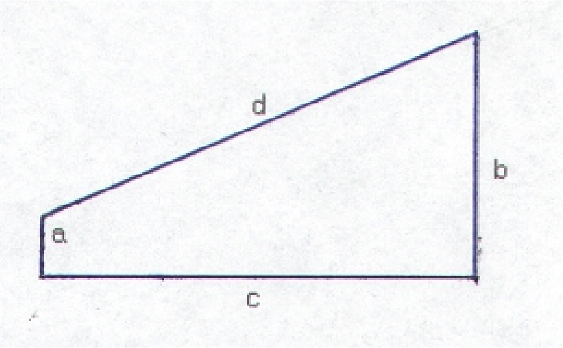
$$\text{slope} = \frac{\text{vert. change}}{\text{horiz. change}} = \frac{-500 \text{ ft.}}{6982 \text{ ft.}} = -0.0716$$

Since slope is equal to the tangent of the angle, slope = TAN ¢, we can find the vehicle's average angle of descent down the mountain.

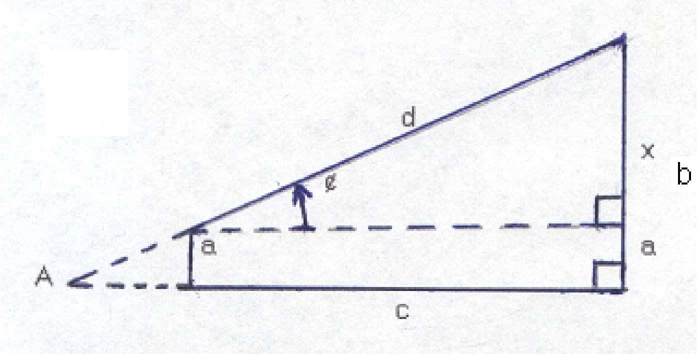
¢ = ARC TAN -0.0716
¢ = -4.095°

The negative result indicates that the angle is below the vehicles horizontal starting position. That is, it is equivalent to the vehicles angle of declination from the initial 0° horizontal or reference line. If the vehicle was going up the mountain, the angle would be a (positive valued) angle of elevation. The angles indicated on the graph are equal due to that they are corresponding angles of identical similar right triangles. The triangles are also identical in this case. The angles are also equal since they are alternate interior angles created at the transversal line across the two parallel "level" lines, and here with the hypotenuse line essentially being the transversal line.

Ex. Below, you are given a drawing of a construction with its' corresponding measurements. This construction happens to be a portion of a triangular shaped construction with an entire "corner" or vertex portion of the triangle removed. Solve for the angle at this removed or unseen vertex. [FIG 182]



Drawing a (dotted) line parallel to line (c), we create a small internal triangle (with sides equivalent to: c, x, and d) that is similar to the entire triangle construction that is being found. [FIG 183]



We also note that line (b) includes the same length of line (a) plus an unknown length that we will call (x) that we can solve for:

$b = a + x$ therefore:
$x = b - a$ also:

This angle can be found from:

From: COS ¢ = adj. / hypotenuse = c / d : when considering ¢ A , and:

¢ = ARC COS (COS ¢)

We could solve for (x) using the Pythagorean Theorem: $x = \sqrt{d^2 - c^2}$

We could also solve for (x) using a trigonometric function:

From: $\text{TAN } ¢ = \frac{\text{opp.}}{\text{adj.}} = \frac{x}{c}$

$x = c \text{ TAN } ¢$

The slope (m) of line (d) is equivalent to TAN ¢ which is also equivalent to TAN A due to corresponding angles of similar triangles:

$$md = \text{TAN ¢} = \frac{\text{vertical rise}}{\text{horizontal run}} = \frac{\text{opposite}}{\text{adjacent}} = \frac{x}{c}$$

: m is often the variable chosen for a slope.
md = the slope of line d

¢ = ¢A = ARCTAN (TAN ¢)

With this information you could reconstruct the entire triangle. If the triangle was not a right triangle, an analysis similar to the above example can be used after dividing the triangle into two right triangles.

The triangle portion removed in the above construction is actually a similar (but smaller) internal triangle, considering triangle (dxc), since its side is parallel to the larger triangle. The (de)magnification value of the smaller triangle is equal to the ratio (r) of any two corresponding sides of those similar triangles. For example: $a/x = r$. Each corresponding part (ie., sides only and not the angles) of the smaller triangle is essentially a (de)magnified construction but still has the same portions (ie., proportions) or fractional values with respect to each other and its whole, as that of the larger triangle and its parts.

The sides of the smaller triangle in the drawing are: $a = r(x)$, $r(d)$, and $r(c)$. These expressions are of the form:

$$\frac{\text{corresponding side of smaller or new triangle}}{\text{corresponding side of larger or reference triangle}} = (r)$$

: r = ratio = construction magnification factor

corresponding side of smaller or new triangle = (r) corresponding side of larger or reference triangle

Further ahead in this book, the slope value will be in terms of variables, and it is very similar this discussion shown above. Slope will be more of a mathematical relationship between the changing values of variables, and it is the rate (ie, a ratio) of change of a value with respect to, or in reference to another value. The slope value is how much the dependent variable (such as y) is currently changing when the independent variable (such as x) is changing. If you like, it could be called the rate or measure ("how fast" or "how slow" numerically) of changing or growing (of the value of the dependent variable). If the slope, the rate of growth or change, is 0, then there is no current growing of the dependent variable taking place even if the independent variable is changing and growing. An example of this is clearly seen for a horizontal line where as (x) is increasing, the corresponding (y) values are not changing. Slope is the amount or rate of the changes of two variables. Mathematically, the slope value is expressed as a (magnification, change, or increase) factor to the value of one variable when the other variable changes.

The change in a variable is the change in the values of that variable, and it is calculated as a difference:

change = a difference in values = (new_value - old_value)

$$\text{slope} = \frac{\text{(the corresponding change in y)}}{(\quad \text{a change in x} \quad)} = m = r = \text{ratio or rate of changes}$$

, mathematically, and showing the rate or slope as a magnification or factor value:

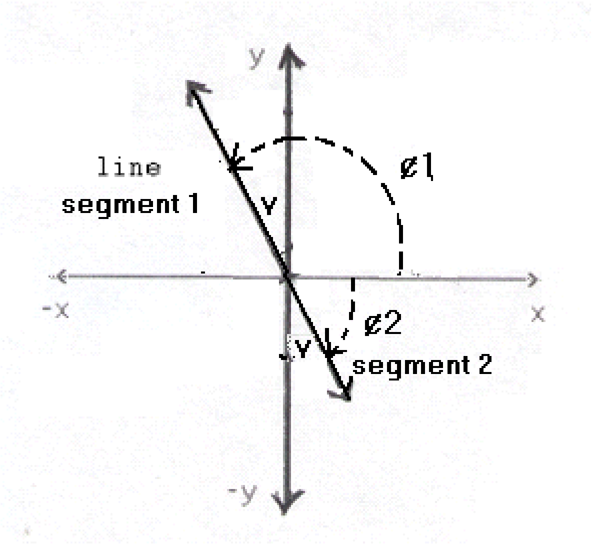
(the corresponding change in y) = r (a change in x)

If the (change in x) = 1, the corresponding (change in y) is (r)(1) = r.

For some equations, such as an exponential equation, where the dependent values are changing in value quickly as the independent variable changes , the slope is not constant and is also changing in value. Then the slope values are rather calculated at a specific instance or value of the independent variable, and therefore for a specific (small) section or point on the curve of the equation. The amount of change to consider for the independent variable when calculating the slope is then to be just a small amount, and if it is a very small change, it is called an instantaneous change, meaning that change happens quickly or in a very small amount or "instant of time".

SLOPES OF PERPENDICULAR LINES, DERIVATION

Before two perpendicular lines are shown, observe the following drawing of a single line that is also indicated as two line segments of that same line. [FIG 184]



v = equal vertical angles

First note that ¢1 and ¢2 are in reference to the exact same line with respect to the x reference axis of angle measurement. The right or positive side of this horizontal or x-axis is considered as the ¢° reference line for measuring angles.

The two angles indicated as (v) are vertical angles, and they are equal in value, and therefore have the same corresponding trigonometric values. ¢1 and ¢2 are supplementary angles, and therefore sum to 180°:

¢1 + ¢2 = 180° , therefore: ¢1 = 180° - ¢2 and ¢2 = 180° - ¢1

Any two angles that sum to 90° are called complementary angles. The trigonometric cofunction values of each complementary angle are equal. For example:

60° and 30° are complementary angles.

$$\tan 60^\circ = \text{cotan } 30^\circ = \frac{1}{\tan 30^\circ} = 1.732$$

Surely since ¢1 and ¢2 refer to the same line, the slopes of the indicated line segments are somehow similar, and it is that the line can be thought of as going in the leftward direction for line segment 1, and also as going in the rightward direction as for line segment 2. It is still the same line so these slopes must be the same value as either would have in reference to only one of those directions. Their slopes are negative values of each others slope value:

slope of any line segment of a line = - (slope of an other line segment considered in the opposite direction).

Lines that slope upward in one direction or angle (¢), will slope downward in the other direction or angle (180° - ¢). From this we can conclude that lines (or segments) that are separated by a 180°, and-or supplementary angles that sum to

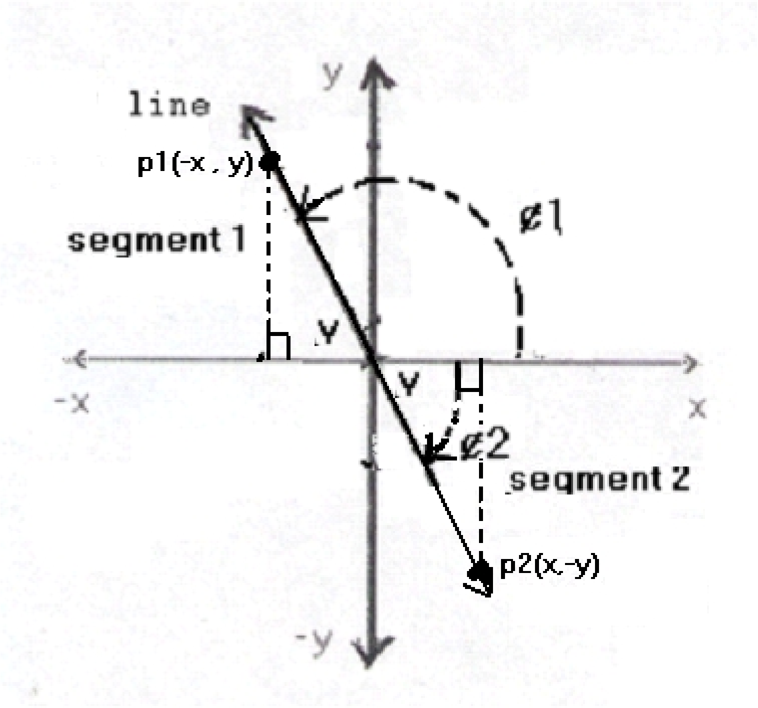
180°, have the same trigonometric function values with just a sign change between them because as one segment or side of the line is sloping upward in one direction, another line segment is also sloping downward in the other direction, and therefore, the slope will be the same value, but each will be negative (ie., "opposite") in sign with respect to each other. For example:

30° + 150° = 180° : 30° and 150° are supplementary angles

tan 30° = 0.577<u>4</u> and tan 150° = -0.577<u>4</u>

Notice that the angle of the line can be measured in two ways with respect to the x-reference axis. The line can be described as having an angle of either ¢1 or ¢2 with respect to the 0° reference axis, here the x-axis.

In the following drawing that is similar to the previous drawing, two points along the line, both being equidistant (equal in distance) from the center of the axis lines were selected. The coordinates of the points therefore have the same value except for their sign - that is, their absoluete values are the same. These coordinates will define an equivalent angle that the line or line segment has with respect to the x-axis. Since the angles are the same, their trigonometric values are the same, except for their sign. We see that the vertical (v) angles are the same, and that ¢2 is the same as the selected vertical angles indicated.
[FIG 185]



¢2 = v since ¢1 + v = 180° , v = 180 - ¢1 , using substitution:

¢2 = 180° - ¢1 : This shows that ¢1 and ¢2 are supplementary angles:

¢1 + ¢2 = 180° : This is verified by the straight line, and of which has a 180° angle about any point on it.

Trigonometric functions of supplementary angles are equal in value. One way to verify this is:

If ¢1=¢1 and ¢2 = (¢1 + 90°) and ¢3 = (¢2 + 90) , therefore: ¢3 = (¢1 + 90°) + 90° = ¢1 + 180°

Therefore, ¢1 and ¢3 are supplementary angles
¢2 is essentially perpendicular to ¢1, and ¢3 is essentially perpendicular to ¢2, and a (180°) straight angle to ¢1.

trig. function ¢1 = trig. cofunction ¢2 = trig. cofunction ¢3

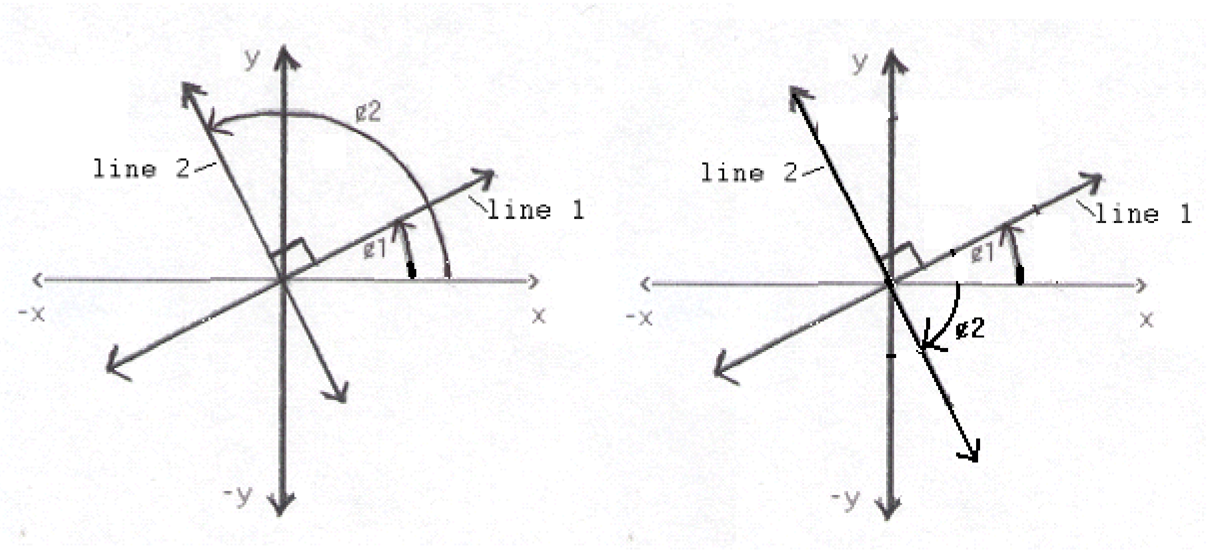
Ex. sin 30° = cos 120° = sin 210°

sin ¢ = sin (¢ + 180°) or sin ¢ = sin(¢ - 180°) : same absolute value, but the signs may not the same

Trigonometric cofunctions of complementary angles are equal in absolute value.

sin ¢ = cos (90° - ¢) or cos ¢ = sin (90° - ¢) : Ex. sin 60° = cos 30° and cos 60° = sin 30°

Now we will consider two lines which cross each other perpendicularly (at 90°) with respect to, or in reference to each other. The left and right images below show two of the many possible ways to analyze this type of situation.
[FIG 186]



By observation, any two lines that cross perpendicularly (at 90°, with respect or in reference to each other), one line will slope upward and have a positive slope value, and one line will slope downward and have a negative slope value. Don't assume that lines always cross at the axis of the coordinate system. The drawing above does not indicate the 0° reference value of the entire coordinate system, and the point of intersection of the two given lines could be any point in the coordinate system. Is there a certain mathematical relationship of the slope values of perpendicular lines? The following analysis will answer this question.

If the two angles (¢1 and ¢2) differ by 90° the corresponding lines are perpendicular. ¢1 and ¢2 are complementary angles that sum to 90°, and their trigonometric cofunctions are equivalent in value.

For example, if ¢1 = 30° and ¢2 = 60° , tan 30° = cotan 60° = $\frac{1}{\tan 60°}$ = 0.5774

Since ¢2 is a fourth quadrant angle, and is counter-clockwise from the x-axis reference line, the value of the angle should be noted as a negative valued angle: -¢2. Since points in this quadrant have a -y value, the tangent and slope values of any angle or line here will be negative in sign. Tan -60° = -0.5774 = slope of line2

Since ¢1 = (90° - ¢2) is the complementary angle of ¢2, and trigonometric cofunctions (complementary functions) of an angle and its' complementary angle are equivalent in value except for the sign as mentioned above:

TAN angle = - COT of the complementary angle:

TAN ¢2 = - COT ¢1 expressing the right side with its trigonometric equivalence:

TAN ¢2 = - $\frac{1}{\text{TAN ¢1}}$ since slope = TAN ¢ = m

$m2 = -\frac{1}{m1}$ multiplying each side by (-1), switching sides, and taking the reciprocal of each side:

$\mathbf{m1 = -\frac{1}{m2}}$ **: SLOPES OF PERPENDICULAR LINES ARE NEGATIVE RECIPROCALS**

SLOPE AS A MATHEMATICAL APPROXIMATION TOOL

Below are several basic methods to approximate a value of any equation where the value to be found is between two other close values that were previously calculated or from a table. An obvious choice of finding the approximate value would be to take the average of the two given values. This will work, but for better results, use something like the more advanced methods described below.

Let's say that you calculated, or found listed in a table, the value of two sine ¢ values or two square root values where the arguments (ie. the independent value or variable of the function) used are close in value. For example:

SIN 36°
SIN 37°

Let's assign (y) as the dependent variable equal to the value of the expression, and we then will have an equation which is often called a function since a variable(s) and its value(s) are essentially processed by the equation to produce a result. The equation is like a machine that applies a certain (preprogrammed, set, determined) process or function to the input values(s) so as to produce an output or result that was partially or significantly determined by that input values(s). Here, with an equation that is like a mathematical machine for an input value, the output is another mathematical value. Here are some ways to express what was just mentioned so as be helpful to its understanding:

input_value -----> process ---------> output value : the input value can be called the independent value
input_value -----> expression -----> output value : the output value can be called the dependent value
input_value -----> function ---------> output value : a function contains expressions that will use the input value
function(input_value) ---------------> output value = "(function) return value" : computer, pseudo or generic code
function(independent value) ------> dependent or return value : computer, pseudo or generic code
The independent value(s) is also called the
"function argument(s)" or "argument(s) sent to the function"

Ex. If the input value, or the value to be put into: (5 + x) is 3, we know that (5+x) is an expression, process or function, and the value of (x) will be set or assigned the value of 3. We can set (y) as equal to the output or resulting value of that equation or function:

input_value -----> expression ----->output value

3 ------> (5+x) ------------> y or expressed more commonly as, in a reverse direction:
y<------- (5+x) <------------ 3 and:
$y = (5+x)$: if, or letting, x=3, inputting, entering, setting, assigning or substituting 3 for x:
$y = (5+3)$
$y = 8$

Ex. $\mathrm{SIN}(x) = y$ or by switching sides:

$y = \mathrm{SIN}\ x$

Formally, (y) is said to be the result of and equal to this particular function of (x). The actual and-or specific value of (y) depends on the specific value of (x) and how it is processed by the entire expression that (x) is in. The mathematical relationship between (y) and (x) depends on the specific expression that (x) is in.

(x) is the independent variable (sometimes known as a declared, formal argument or parameter).
(y) is the dependent variable whose value depends upon the specific value of the independent variable (here, x) and then how it is processed by the equation to produce an output value based on both the equation and the input value (here, x).

We know that for any equation, other than linear (line) equations, that the relationship between the dependent variable and the independent variable is not a linear one. When the relationship is said to be linear, corresponding values of the dependent and independent variables are partially or wholly determined by a constant factor value called a slope (m):

$y = mx + b$: general line equation, m and b are constants, b can be 0.

For each integer increase (ie., 1) in the independent variable (x), the corresponding independent variable (y) can always be calculated from the previous value as (using a generalized notation of):

$y(n+1) = yn + m$: n is a subscript to express or indicate a specific instance of that variable, (here, y and its value). (n+1) indicates another instance, and here, the next instance and value of that variable. Let's begin to verify this expression:

If we took the given function and found two values of it: y1 from its corresponding value of x1 in the function, and then y2 from its corresponding value of x2 in the same function:

y1 = function(x1) and y2 = function(x2) we have found two point or corresponding values or locations. Note for example, if x1=3: y1 = function(x1) = y(x) = function(3) = f(3) = y(3)

point1=p1=(x1,y1) and point2=p2=(x2,y2)

Expressing the difference between the values, so as to find the change in the corresponding values:

(change in x) = (x2 - x1)
(change in y) = (y2 - y1) = function(x2) - function(x1) expressing this using the specific expressions or functions:

$y2 - y1 = (mx2 + b) - (mx1 + b)$: here n=2 in y2, and n=1 in y1. Distributing to clear grouping symbols:
$y2 - y1 = mx2 + b - mx1 - b$ combining the (b) terms:
$y2 - y1 = mx2 - mx1$ factoring (m) from each term on the right side:

$(y2 - y1) = m(x2 - x1)$: "point (and) slope" form of an equation of a line. This has the form of a linear equation: $y = mx$ and specifically: (change in y) = m (change in x) . Mathematically:

$m = \frac{(y2 - y1)}{(x2 - x1)}$: the formula for slope of a line, or the ratio of changes in the corresponding values of two variables. The result is a factor of how (y) will change in value when (x) first changes in value. This factor is therefore called the rate of change.

Now, if the change, or difference, in the (x) values was a constant value of: (x2-x1) = (1), the denominator becomes a constant value of (1), and it can effectively be eliminated, and we get:

$m = \frac{y2 - y1}{1}$ which can be expressed as:

$m = y2 - y1$: When (x) only changes by 1 in a linear equation, the change in (y) has a value of (m). Solving for y2:
$y2 = y1 + m$

That is, the next value of (y) can always be calculated using the previous value of (y) and adding a constant value of the slope (m) to it. It can also be said that when (x2 - x1) = 1, or the (change in x) = 1, the corresponding (change in y) = (m):

$yn+1 = yn + (\text{change in y})$: yn+1 is to be considered as y with (n+1) as a subscript

$yn+1 = yn + m$: when the (change in x) = 1

If (x) were to increment by 1 again (for a total increment or change of 2) the next corresponding value of (y) would be:

$y3 = y2 + m$ algebraically substituting the equivalent expression for y2:
$y3 = (y1 + m) + m$ clearing grouping symbols:
$y3 = y1 + m + m$ combining like terms:
$y3 = y1 + 2m$

This same substitution for y1 can be used to find the next value, y4, and so on. Clearly we see a pattern developing and it is that the coefficient of (m) is equivalent to the (change in x). In general, if (change in x) = c, the corresponding (change in y) equals (cm) and:

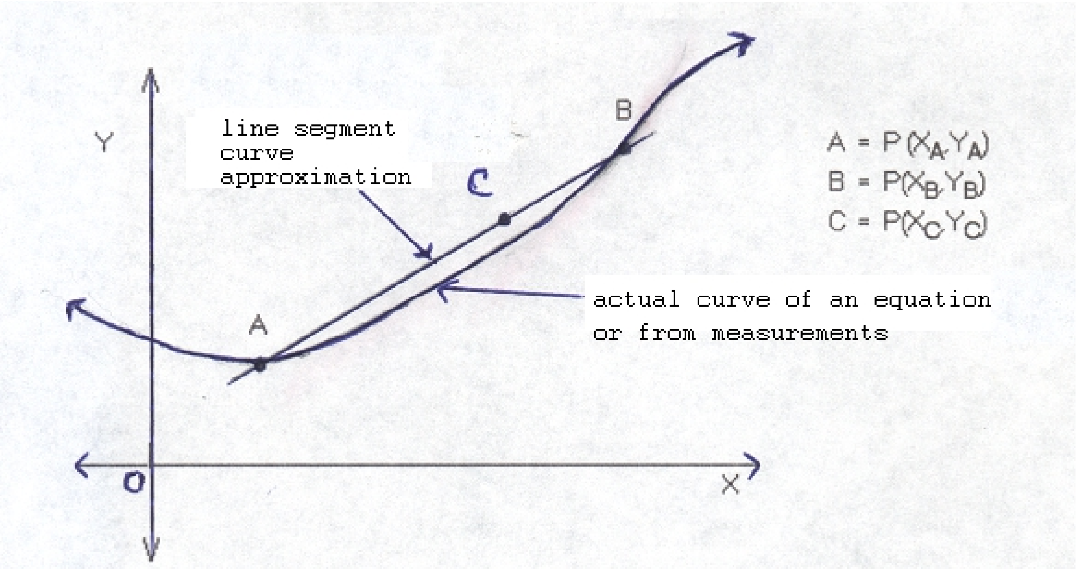
$yn+c = yn + cm$ or by using the commutative law:
$yn+c = mc + yn$: finding (y) given a previous value of (y). This still has the basic line form of: $y = mx + b$

This equation is a linear (line) equation and therefore it should hold valid for all values of (c), and not just for 1 and-or just for integers. This equation will be used ahead when calculating the square root of 10.7 when given the square roots of both 10 and 11.

INTERPOLATION TO FIND A CLOSE MATHEMATICAL ESTIMATE

Linear equations always resemble a line when graphed. Other types of equations resemble different curves when graphed. Depending on the type of equation, the basic shape of their corresponding curve may be predictable Even though they resemble curves when graphed, the closer the points are, the more that part of the curve between those points will resemble a (small and approximate) line segment of a line, hence in that region, the mathematical relationship of the points corresponding dependent and independent values (which determine those corresponding points) becomes more linear in nature. Its possible that a curve can be considered as a larger number of various sloped line segments. The formula shown above cannot be used in general since you will not necessarily be trying to find the value of the dependent variable given the next integer value of the independent variable. Even if you could possibly use it, you would have to know or calculate the slope between those successive values, and on some curves, it can possibly vary widely even between just two successive integer values (ex. between 1 and 2, or 7 and 8, etc.) of the independent variable, and therefore, the slope of the line segment is not even approximating a constant value at all.

If you know two close points on a curve (where the curve segment somewhat resembles a line segment), there is a method called (linear or line-method) interpolation (basically, a mathematical calculation and estimation since the line segment is an estimation of the curve from the given data) that will allow you to easily solve for the approximate corresponding values of a third point that is anywhere between those two points being considered on a (small, segment) line. **Interpolating is like a calculated guess or approximation, and the process can be thought of as being somewhat similar to the concept of finding an average of two values**. To verify this concept, the graphical aid of the concepts of similar triangles where the slope of a side (line) is constant for any given angle, and with the mathematical aid of proportions (equal portions, ratios or fractions of corresponding values) since the ratio of two sides of one triangle construction is equal to the ratio of the corresponding two sides of another similar triangle construction. [FIG 187]



Since we are dealing with a line (here, line AB, as a line segment) that approximates a small portion of the curve, the slope (M) between points A and B on the curve will equal the slope between points A and C, and-or C and B on that same line since the slope for a line is constant between any points on that line.

$M_{AC} = M_{AB} = M$: the slope (here, M) of a line is constant for any segment (between two points) of it.

$\frac{YC - YA}{XC - XA} = \frac{YB - YA}{XB - XA} = M$: equivalent rate of changes or "slope proportions" for the same line

For example, if the Y value of point A represents the square-root of 10, and the Y value of point B represents the square-root of 11, what is the square root of 10.7?

Given: $\sqrt{11} = 3.31662479$: B = point B = PB = Pb = Pb(Xb , Yb) = (Xb, Yb) = ($\sqrt{11}$, 3.31662479)

Find $\sqrt{10.7} =$? : C = point C = PC = Pc = Pc(Xc , Yc) = (Xc, Yc) = ($\sqrt{10.7}$, ?)

Given: $\sqrt{10} = 3.16227766$: A = point A = PA = Pa = Pa(Xa , Ya) = (Xa, Ya) = ($\sqrt{10}$, 3.16227766)

The above data of corresponding values of the square root of 10 and 11 may be from a calculation, a graph, or even from a table of square root values.

From: Y = function (X) : "Y is a function of X" or: "The value of Y is a function of X" or:
"Y is determined by this function of X".
Here, the function of X is the square root function: $y = f(x) = \sqrt{x}$

P = P(X, Y) : a general point notation for any function, and location on a graph.
point = position = location = address = corresponding pair of values
point = p(location) = p(independent value, dependent value) =
= p(input, output) = p(x, f(x)) = p(x,y)

PA = (XA, YA) = (10 , 3.16227766) : previously calculated, or given from a table
PC = (XC, YC) = (10.7, YC) : YC is to be found by calculation
PB = (XB, YB) = (11 , 3.31662479) : previously calculated, or given from a table

Solving for YC:

$$YC = YA + \frac{(YB - YA)(XC - XA)}{(XB - XA)}$$

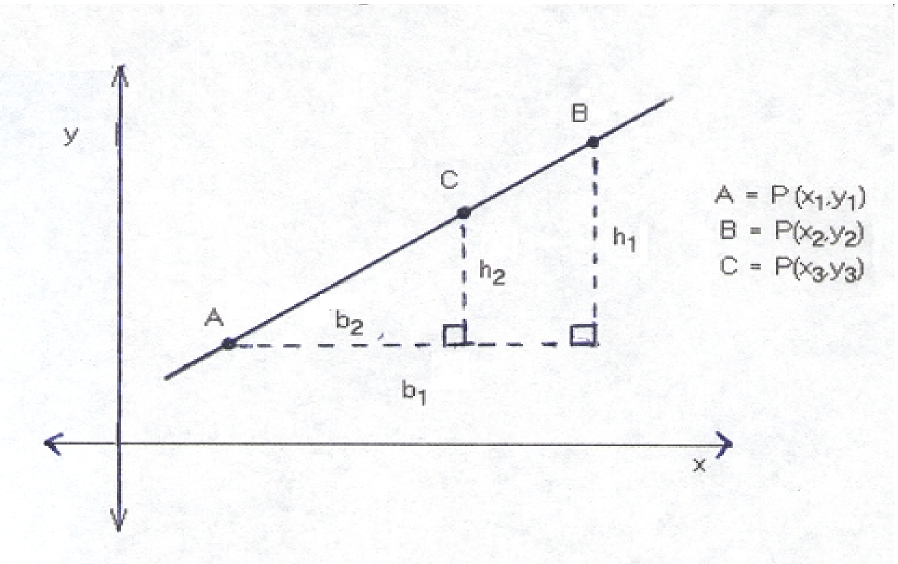
: Interpolating (here, for a corresponding value of point C) using proportions (equivalent fractions) or rates (slopes) of the changes of two points).

$$YC = \sqrt{10.7} = 3.16227766 + \frac{(3.31662479 - 3.16227766)(10.7 - 10.0)}{(11.0 - 10.0)}$$

$YC = \sqrt{10.7} = 3.270320651$: accurate to 2 decimal places beyond the decimal point.
You might think the accuracy should be higher here, but this method assumes there is a linear or constant relationship between the points, and that is not so, since the equation was not a linear equation, and was only assumed to be one for that small line segment approximation for a portion or segment of that curve which actually has a varying slope (m), and therefore, it is not so line-like or linear as when the slope (m) is constant.

.

The concepts of similar triangles can also be applied. However, an adjustment method is used since the triangle, like any line, is not and should not be assumed to be (originate or have a point) at the origin of the system. The adjustment allows the triangles to be anywhere within the coordinate system. The resulting formula is very similar to that shown above. Here, the height (h) of each triangle is the difference of the (y) coordinates of the points, and the base value of each triangle is the difference of the (x) coordinates of the points: [FIG 188]



Since $x2 = x1 + b1$,we get: $b1 = (x2 - x1)$
Since $x3 = x1 + b2$,we get: $b2 = (x3 - x1)$

Since $y2 = y1 + h1$,we get: $h1 = (y2 - y1)$
Since $y3 = y1 + h2$,we get: $h2 = (y3 - y1)$

As like in the above example, we are solving for the coordinates of point C, specifically its (y) coordinate which is y3, however, using similar methods, the corresponding (approximate) (x) coordinate, for a given (y) coordinate, can also be solved for.

Since the triangles are similar triangles:

$\frac{h1}{b1} = \frac{h2}{b2}$: proportions of sides of each given triangle are equal in value to that of any other similar triangle. This value here is also equal to the tangent of the angle between the base and the hypotenuse side of that triangle construction, hence it is equal to the slope (m) of that hypotenuse side or line.

$h2 = \frac{b2\ h1}{b1} = \frac{(x3 - x1)(y2 - y1)}{(x2 - x1)}$: Interpolating using side proportions, and as noted above:

$y3 = y1 + h2$ for the above example:

$y3 = \sqrt{10.7} = y1 + h2$

Since percentages (discussed previously in this book, and sometimes described as "relative values" of the whole = 100% = 1) are a linear concept, they can also be applied to the problem of finding a (approximate) value between two other close values. Given the two points (numerically, the two sets of corresponding values), consider:

If the minimum value is to 0%, its corresponding value is to 0%.
If the maximum value is to 100%, its corresponding value is to 100%.

Given a value that is somewhere between the minimum and maximum value, it is common sense that its corresponding value will be >0% and <100%, or between 0% and 100%, and that it will also be a percentage.

$$\% = \frac{\text{length 1}}{\text{length 2}} = \frac{(\text{max. 1} - \text{min. 1})}{(\text{max. 2} - \text{min. 2})}$$

$$\% = \frac{b2}{b1} = \frac{(x3 - x1)}{(x2 - x1)}$$

Using the last examples values:

$$\% = \frac{(10.7 - 10)}{(11 - 10)} = \frac{0.7}{1} = 0.7 = 70\%$$: 10.7 is 70% of the way from 10 to 11

From the concepts of similar triangles, where to construct a similar triangle, all the parts are magnified by the same value, resulting in that the ratio of corresponding parts of the two constructions is constant and is equivalent to that magnifying or factor value:

If b2 is 70% of b1, (b2/b1) = 0.70, h2 should also be 70% of h1. The resulting equations are similar to the last method.

$$\frac{h1}{b1} = \frac{nh1}{nb1} = \frac{h2}{b2}$$: here, n=0.7 = 70%

$$h2 = \frac{b2h1}{b1} = \frac{(x3 - x1)(y2 - y1)}{(x2 - x1)}$$: Interpolating by equivalent fractions

$$y3 = y1 + h2$$

By having a segment of a line, we can find the equation of that entire line given just a small piece or segment of it. We can find the equation of this line since we are essentially given two points on this line, which will satisfy the minimum number of points needed to define that line and make it corresponding equation. Once we have this equation, any other or "third point" on the line can then be found, and specifically for this discussion, the point must be between the two points which bound (ie. are endpoints of) that line segment approximation of any curve.

The equation we are to write is a simple linear (line) equation of the form:

$$y = mx + b$$: "slope-intercept" form of a line, algebraically:

$$m = \frac{y - b}{x}$$: (m) is a constant for a given line, algebraically:

$$b = y - mx$$: as mentioned previously, (b) is defined as a (arbitrary) constant for a given line. (It could be thought of as the "(initial) height" or starting value of the line when x=0.)

We don't not know yet the value of (b) (technically the "y axis intercept" where x=0, this is point(0,b)) in order to calculate (m). Since (m) is equivalent to the slope of the line, and that we can calculate the slope of any line given two points on it:

$$m = \frac{(y2 - y1)}{(x2 - x1)} = \frac{\text{corresponding change in y values}}{\text{corresponding change in x values}}$$: slope of the line segment between p(x1,y1) and p(x2,y2)

Using the above values:

$$m = \frac{\sqrt{11} - \sqrt{10}}{11 - 10} = 0.15434713$$

$b = \sqrt{10} - (0.15434713)(10)$: from $b = y - mx$

$b = 1.618806358$ constructing the equation of the line:

$y = 0.15434713\,x + 1.618806358$: Equation of the line and a (simple) formula for approximating the square root of values from 10.0 to 11.0 where x=radicand, and y=root. We see that this is a very powerful formula since many approximate values of the square roots of values between 10 and 11 can be calculated from this single formula.

Finding the square root of 10.7, x=10.7, and the corresponding (y) value which is the approximate square root of 10.7 is:

$y = 0.15434713\,(10.7) + 1.618806358$: Interpolating using a linear equation

$y = \sqrt{10.7} = 3.270320649$: accurate to 2 decimal places beyond the decimal point.

For comparison, the actual square root of 10.7 is 3.271085447 and the difference between the calculated (or measured) value and the actual (or reference) value is:

calculated value - actual value = difference
3.270320649 - 3.271085447 = - 0.000764797

The negative sign of the difference indicates that the calculated value was "low", or less than the true (actual) value.

Taking the ratio of the calculated value to the actual value will give us a relative numerical representation for how close the calculated value is to the actual value:

$\frac{3.270320649}{3.271085447} = 0.999766194$: roughly 99.97 % correct

Taking the ratio of the difference value to the actual value will give us a relative numerical representation for the amount of difference from the true or actual value. Since its a relative value, absolute (ie. signless) values will be used:

$\frac{0.000764797}{3.271085447} = 0.000233805$: roughly 0.023 % error, or "off", or percent different.
Note: percent correct + percent different = 1.0 = 100%

As another check to the square root of 10.7, let's use the previously derived formula of:

yn+c = mc + yn : finding (y) given a previous value of (y)

$\sqrt{10.7} = (0.15434713)(0.7) + \sqrt{10}$
$\sqrt{10.7} = (0.15434713)(0.7) + 3.16227766$
$\sqrt{10.7} = 0.108042991 + 3.16227766$
$\sqrt{10.7} = 3.270320651$: correct to 2 decimal places

Here is a relatively easy to understand method of (linear) interpolation (estimating or calculating an unknown value or point that is between two other given values or points), and its based on differences, and it's very similar to one method already shown. This method assumes that the ratio of differences between the same members of two sets (each set (or corresponding pair) has a member of (x) and its corresponding value of (y)) of data values is equal to that of any other two sets of that data. In general, it is assumed that each set of data or points lays upon the same line, and specifically for this type of analysis, a line segment when the points are close so as any other or "third point" between them will also be close in value.

For example, you are given a chart or table of data and are to find a (corresponding) set of data that is between two other sets of data, specifically, you are to find the corresponding (y) value for a given (x) value. You can identify or assign variables to the given sets of data or points, such as: (x1, y1) and (x3, y3), and you are to find the "third, middle or unknown" set of data of: (x2, y2): [FIG 189]

TABLE OF DATA ,OR "LOOK-UP" CHART

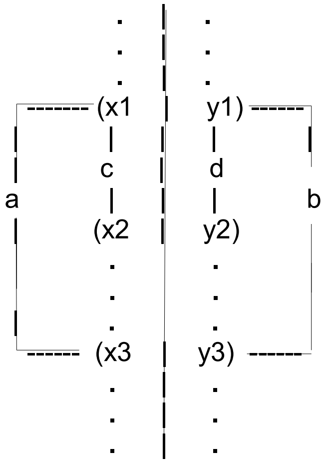
x	y	: corresponding values, or coordinates (locations) of points, of successive data of a curve
.	.	
.	.	
(x1	y1)	: point 1 = P1 , a pair or corresponding set of data
.	.	: the dots represent any possible intermediate values such as between (x1,y1) and (x2,y2)
.	.	
(x2	y2)	: point 2 = P2, which is to be found. x2 is given, and its corresponding value of y2 is to be found
.	.	
.	.	
(x3	y3)	: point 3 = P3
.	.	
.	.	

To help simplify the description and analysis of this method, we will identify the differences between corresponding members of two sets, and we will assign them (the differences) identifiers or variable names. For assistance, look at the drawing below of a portion of a "look-up" or reference table of values:

The differences ((d), "lengths", or "changes") are:

a = x3 - x1 : could also use something like: d1 for a, d2 for b, d3 for c, d4 for d
b = y3 - y1
c = x2 - x1
d = y2 - y1 : y2 is unknown and being solved for. Note that: y2 = y1 + d , [FIG 190]

(x , y) : A LIST OR TABLE OF CORRESPONDING DATA VALUES OR POINTS ON A LINE GRAPH



: pairs of corresponding values, or coordinates (locations) of points, of successive data of a curve, equation, mathematical relationship, or table of "lookup" values

: A typical reference table-list of (increasing or decreasing) data values. We are given two points or sets of corresponding data: (x1,y1) and (x3,y3). Find (x2,y2), the unlisted value being found that is "in-between" the given data.

According to this method of (linear [constant mathematical or numerical relationship] , line, or "equivalent slope") interpolation, and considering the data values, or changes, as sides of similar triangles:

$\frac{a}{c} = \frac{b}{d}$ or-from mathematically: $\frac{a}{b} = \frac{c}{d}$: corresponding ratios, or equivalent fractions, of the differences or changes

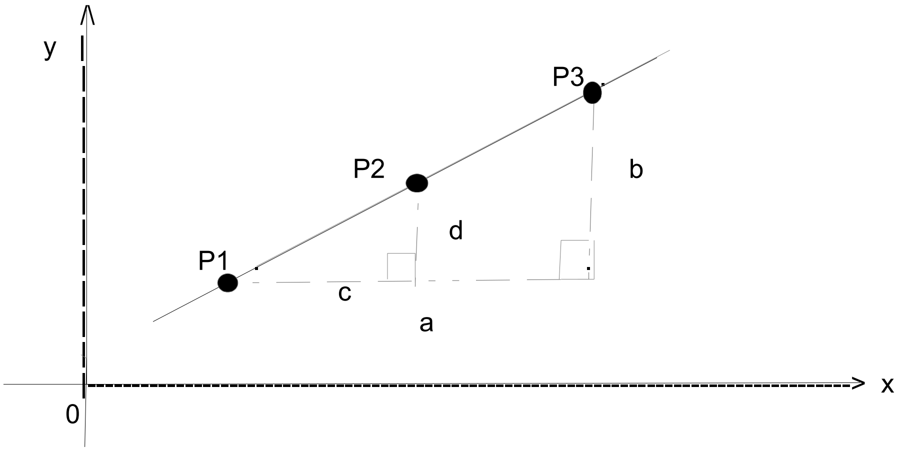
We have equivalent ratios. Each value in the numerator is said to be proportional to the value in the denominator. That is, the value in the numerator represents the same part, portion or fraction of the denominator value. Two or more equivalent fractions are therefore often called "proportions", where the "pro" prefix means to the effect of being or having the proper (equivalent, same) portions.

Here, we are solving for (d) so that it can be added to y1, so as to have y2.

$$d = \frac{bc}{a}$$

$$y2 = y1 + d$$

Here is a general representation of the points (pairs or sets of corresponding data) on a line. The differences calculated above are shown as sides of similar right triangles and can be analyzed as such. The result of this interpolation process is very similar to ones previously shown. [FIG 191]



Expressing some (equivalent) ratios of corresponding sides we have the following proportion:

$\frac{a}{c} = \frac{b}{d}$: the same proportion as above

Notice that the proportion can be algebraically expressed as:

$$\frac{b}{a} = \frac{d}{c}$$

Expressed this way, it is the ratio of the differences of corresponding members of any two sets, and it is equal to that of any other two sets of points on that line, or sides of a similar triangle.

Here, the value of each ratio is actually equal to the slope (m) of the line:

$m = \frac{\text{change in } y}{\text{change in } x} = \frac{b}{a} = \frac{y3 - y1}{x3 - x1}$: slope of all line segments of, or on a line will all have the same value

$m = \frac{\text{change in } y}{\text{change in } x} = \frac{d}{c} = \frac{y2 - y1}{x2 - x1}$: slope of all line segments of, or on a line will all have the same value

Therefore, if you can remember this general formula for slope (m), you can also remember this simple formula for (d), which you can think of as: "the difference":

d = (change in y) = m (change in x) and then:

y2 = y1 + (change in y)

y2 = y1 + d

Or showing this in a more algebraic sense:

$\frac{y2 - y1}{x2 - x1} = m$ therefore:

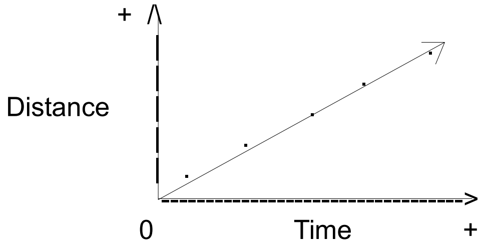
y2 - y1 = m (x2 - x1) : has the basic linear form of: y = mx + b, Transposing y1:

y2 = y1 + m (x2 - x1) : or y2 = y1 + m(change in x) = y1 + d
This has the basic linear form of: y = mx + b , y2 = m(x2-x1) + y1

SLOPES FOR ADVANCED MATHEMATICS

If the rate of change, essentially the slope value, of one variable, say (y), in reference or respect to another variable, say (x), is constant, a straight line will represent this data on a graph or in physical reality.

Ex. Distance = Speed x Time. This is a linear equation when the Speed remains constant. Below is a graph of this equation, and we also see that Distance also increases at a steady or constant rate because of the Speed being a constant value. Time increases at a constant rate automatically: [FIG 192]



; distance is the change or difference in length that an object that has moved [traversed] between two locations or points during a change in time

The rate of a change of distance with respect (in reference) to its corresponding value of change of time is mathematically equal to speed:

$$\frac{\text{change in distance}}{\text{change in time}} = \text{velocity}$$

: we see that this is essentially an equation for the slope of a line:
distance = Speed x Time = velocity x Time
velocity is nearly the same concept as speed, Velocity is basically a certain speed at a certain time, and speed is more like an average value.

$$\frac{\text{total distance}}{\text{total time}} = \text{(average) speed}$$

If the rate was constant, this is an exact value, rather than an average value where the rate value may have changed due to small stops, accelerations (speeding up) or decelerations (ie., decelerating, slowing down, not increasing speed, opposite of accelerating).

$$\frac{\text{distance}}{\text{time}} = \text{speed}$$

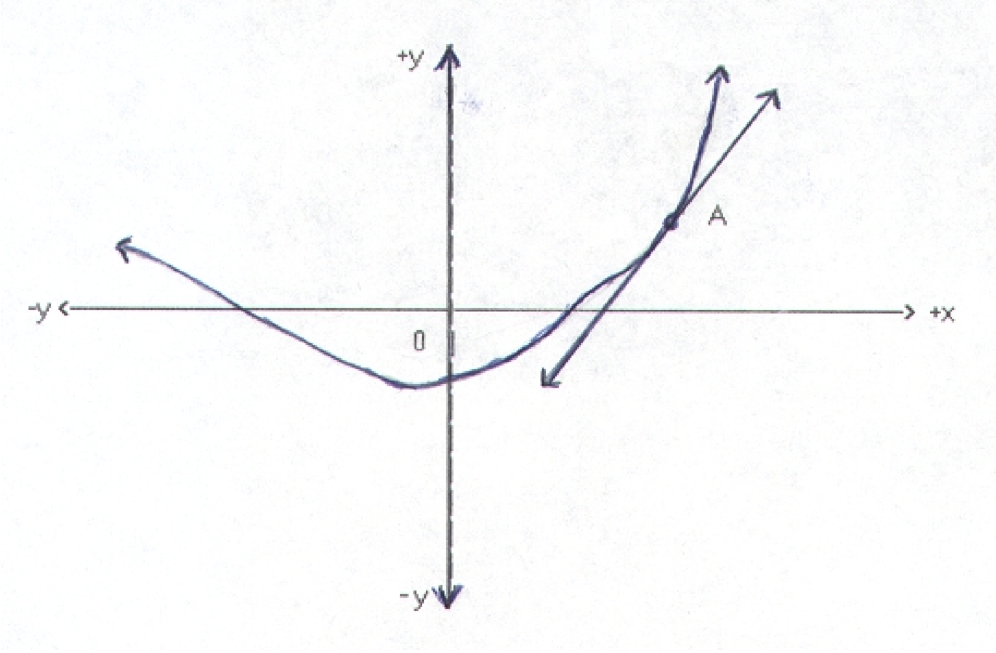
: the common formula for speed
distance = speed x time,
time = distance / speed

We see that speed (ie., "(a measure of) how fast something is going, moving, or traveling") is calculated as a ratio of two changes, and its value is therefore a ratio or rate of changes and speed is essentially equivalent to a slope value of a line. If this rate or slope value is constant, the graph showing the relationship of the variables (here, distance with respect to time, or more correctly due to the equation as distance with respect to both speed and time, however with the slope representing or being indicative of the speed) will be a straight line, and the mathematical relationship of those two values or variables is said to be constant or linear (line-like) relationship. In a linear mathematical relationship, as one value or variable changes by some factor, the other changes by that same factor.

It should also be noted that since the slope is constant, the tangent value of the angle created (between the corresponding (y) and (x) values, or Distance and Time values), is also constant since mathematically, slope = TAN ¢, and if this angle is constant, due to the rate of the changes in those values being constant, the slope is constant, and vice-versa. If the rate (speed for this example above) varies, the slope varies, and a straight line will no longer be produced on the graph of the equation, but a new line or curve (with no constant slope) will. This is true for all curves, even circles where the slope constantly varies (changes). The faster the object goes (ie., its speed), the greater the distance it will travel per unit of time, mathematically giving a greater slope or rate of change of distance with respect to time, and the line will then be steeper on the graph. When an object has a change in speed, this change is called acceleration. It could be either positive, or negative in value such as when it slowed down due to some force acting upon or being applied to it.

The concept of slope is used extensively in understanding the fundamental concepts of a branch of mathematics called calculus, where essentially a whole entire value can be solved for by accounting for all the (infinite number of infinitesimally small) smaller values or parts that make up or define that whole value. Here, the slope value is generally not between any two points on a curve (or a line which can be considered a special curve and-or graph), but between successive (adjacent, infinitely close, "instantaneous", in an instant in time) points. Therefore, these very close (as possible) points essentially (or practically) define very small line segments which compose the entire curve. This change (of the independent values or variables, and then the corresponding change in dependent values or variables) in variables under this condition is very small, which usually occur in a very small change or an "instant" of time. Therefore, the slope value of an equation in calculus is considered as the "instantaneous slope" or "instantaneous rate of change" of one variable with respect to, or in reference to, another variable, rather than an overall average slope value. This slope value is only the slope of the curve at only, or essentially at one particular point on that curve, and is generally not the (variable, changing) slope value for the entire curve. Except for lines with a constant slope, since the slope of a curve is constantly changing, it is variable in value and it could be said that the slope is variable. A constant can not then be used to define a (changing) slope of a curve, but a special and constant (slope) equation can be derived and used for the slope value.

For this discussion, observe the drawing below which indicates the slope of a curve at one point, here point A: [FIG 193]

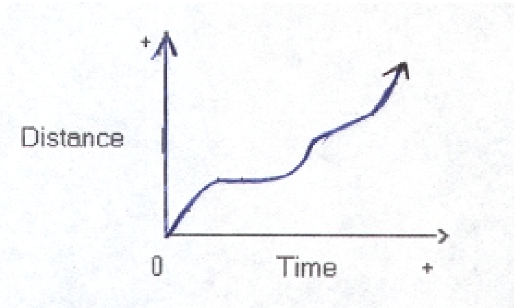


You are to find the slope of the curve at point A. As an aid to the analysis, the line indicated, if properly drawn, is simply an extension of the very small line (segment) created by the two adjacent points located at point A. You could say this is a "tangent line" to the curve at that point, location or section used for this analysis. To find the slope at this point on the curve, any two points on this line, or extended line, can then be utilized to calculate it since the slope of a line is constant at all points along it. In this example, since (x) is the horizontal or independent variable, and (y) is the vertical or dependent variable, the slope at any point on this curve is equal to the corresponding change in (y) divided by its corresponding change in (x):

$$\text{slope} = \frac{\text{change in (y) of the (small) line}}{\text{change in (x) of the (small) line}}$$: The slope at a particular point on the curve is the instantaneous rate of change of (y) with respect to (x)

Since a line was used in this example to find the slope (m) of the curve at a particular point, and that TANgent (of the angle) values are directly related to slope values, lines which intersect a curve at a point are often called "tangent lines". Previously mentioned in this book were lines which intercepted a circles circumference at just one point, hence these lines are also called tangent lines. For a circle, tangent lines will always be perpendicular (90°) to a radius line from the center of the circle to the point (on the circumference of the circle) where intersects the tangent line at the circumference or curve of the circle.

Ex. You are traveling in an automobile of which is constantly going faster (accelerating) or slower (deceleration), that is, its speed is changing and is not some fixed or constant value. The rate of a change of distance with respect to its' corresponding values, or change of time is not a constant value, and the representative curve or graph of this situation may look something like this figure: [FIG 194]



The faster you go, that part of the curve will be more vertical since the slope of that section of the curve, which represents speed, is higher in or during that section of time. If your speed stopped, any increase in distance will stop, and if the value of time keeps increasing, the graphing of this situation would be just a straight, horizontal line

You can find your average speed for the entire time and-or distance traveled using the above graph and-or equation (where change in distance = total distance, and change in time = total time), but for between any specific and-or instantaneous time period, this overall average value may then not even be a close enough representation. For example, there may be times where you are not moving or perhaps going at a very slow speed (hence, probably a much different or lower value than an average (calculated) speed) and the distance traversed is therefore very small. You can, however, find the average speed just between any specific time period or time interval (difference or length of time):

$$\frac{\text{change in distance}}{\text{change in time}} = \frac{\Lambda d}{\Lambda t} = \text{average speed for the specific time interval}$$

As the change in time becomes very, very small, the corresponding change in distance likewise becomes very, very small (regardless of how fast you are actually moving). The speed value at this specific instant of time is often referred to as the "instantaneous speed", or simply as the velocity at that point, location and-or time.

Just as distance can change with respect to speed or time, speed can also change or vary with respect to time. The change in speed (or the slope value) with respect to time is called acceleration. For example if you are going 30 miles and hour, and want to go 50 miles and hour, you must first change (here, increase by 20 miles per hour) or accelerate (ie.,change, increase) your speed by using some amount of energy, force or power until you are then moving 50 miles and hour. Once you reach your desired speed, you must then cease (none) accelerating if you want to stay at that certain speed. Once going that 50 miles an hour in speed, the rate of change of speed with respect to time, of which is called "acceleration", acceleration rate, or rate of acceleration, will be 0, but your speed will still be 50 miles per hour as you travel normally without any extra added energy applied to your motion.

DERIVATIVE

Given a mathematical relationship (expressed as an equation) or function of variables, a single and special equation called a derivative can be mathematically created by deriving it out from that initial equation. The derivative equation will mathematically represent the value of the instantaneous rate of change, or "slope", of variables between any two consecutive (adjacent, near identical) points in question of the function or curve.

For an example of a derivative, velocity is the name often used for the derivative of the speed equation:

$\text{speed} = \frac{\text{distance}}{\text{time}}$, Velocity is the (instantaneous) rate of the change of distance with respect to time: In short, velocity is the speed at only a certain instant of time.

$\text{velocity} = \frac{\text{(instantaneous change in distance)}}{\text{(instantaneous change in time)}}$: clearly , this equation is much like that for the slope of a line, and velocity can be thought of as an instantaneous slope, speed or rate.

Since velocity (or think of speed) can also change with respect to time, another derivative formally called acceleration can be derived which is the rate of change of velocity (or speed) with respect to time. A derivative equation of another derivative equation is mathematically called a "second derivative" since it will be a derivative of the first derivative. The derivative of velocity is called acceleration:

$\text{acceleration} = \frac{\text{(instantaneous change in velocity)}}{\text{(instantaneous change in time)}}$: acceleration could be thought of as the slope of velocity

Whenever an object slows down or speeds up due to some force applied to that object, its velocity will therefore change, and hence there is an acceleration or change in motion and speed. If the object increases speed, the change in speed is called an acceleration, or a deceleration when an object "slows down" or reduces is speed or velocity. When speed or velocity is not changing (ie., not increasing or decreasing) and is staying the same constant value, there is therefore no (0) acceleration happening.

Considering just lines where the slope (ie., "speed" rate) is a constant value, it is not too difficult to realize that the derivative of any line (linear) equation is a constant value equivalent to that slope.

To give you a brief insight on derivatives and inverse derivatives (often called anti-derivatives which are associated with the topic of calculus known as integration or integral calculus which sums all the infinitely small parts of a value, so as to find the entire value, a short, but very powerful discussion related to basic calculus is given below. The discussion will help you understand and give verification to some of the topics discussed further ahead in this book. Be sure to also review the brief discussion about derivatives in the Squares Example previously shown in the Basic Algebra section of this book.

UNDERSTANDING BASIC CALCULUS

The word "calculus" is a form of the word "calculate". Calculus essentially means calculating (mathematically reasoning, quantifying and solving, to calculate, and those who did it often were sometimes called calculators) by using just the small parts or amounts of the whole or entire part. Here, the small parts considered are infinitesimally small ("infinitely small"), and are practically, but not actually equal to 0 so as to be still meaningful. Isaac Newton (1643-1727) from England, and Gottfried Leibniz (1646-1716) from Germany, independently discovered the initial and-or practical mathematical concepts and understandings of the subject formally called Calculus in about the years from 1665 to 1700. With those two people developing these initial concepts, after several hundred years of developments by many, we today have a combined, single and better concept of the important subject of Calculus.

Some of the following concepts and the notation to express them have been given a reasonable mention in a previous discussion in this book about using slope as a mathematical approximation tool. They will be briefly mentioned here also as part of this topic.

If (y) is a function (f) of (x), this can be noted mathematically as: y = f(x). The word function means that the value of (y) is related to or depends upon the value of (x) inside the expression that contains it. A mathematical function is often thought of as a logical (as opposed to physical) device or machine that applies or performs the specified operation(s) upon the variable input to it, and returns, outputs or gives a corresponding or associated value as the result. If the expression containing the (x) variable is 3x , that is f(x) = 3x, and if we set (y), as like a basket or placeholder for the result, equal to this expression we get the equation: y = 3x.

The general processes of finding derivatives is called differentiating which is a somewhat lengthy, but mathematically simple process. The derivative of the function and-or expression of: y = 3x is a constant value equal to 3. The notation for the derivative of a function is often noted as: y' ("y prime") or f'(x), hence y' = f'(x) = the derivative of (y) = the derivative of the function of (x) of which y is equal to. Another notation is dy/dx which means the derivative of (y) (or the equivalent function to which it is set equal to) with respect to the (x) variable in the function. It does not mean "d times y" or (d)(x). More formally or technically, dy or dx mean a differential of (y) or a differential of (x). The word differential means an infinitely small (ie. a very small, nearly 0) difference or change, and this change is mathematically calculated as, and equal to a difference:

$\frac{dy}{dx}$ = "the differential of y, with respect to the corresponding differential in x".
It is expressed as a ratio, and the result is a rate value which is very similar to a (instantaneous) slope value.

(y2 - y1) = difference of the y values = change in y value
(x2 - x1) = difference of the x values = change in x value

You could say dx is the limit of (change in x) as it approaches 0. (ie. (x2 - x1)-->0 , which is necessary for two side by side points so as to find the slope at a particular location or point on a curve, which is the mathematical rate of changes between two values or variables). This small difference is noted as: dx which could be considered as an (infinitesimally) small bit of x. The corresponding (change in y) = (y2 - y1) will then be automatically and correspondingly as small as possible, but not necessarily the same exact value, between those two points, hence it is noted as: dy.

$\frac{dy}{dx}$ = "instantaneous slope" = slope at a specific point on a curve, or the mathematical relationship of two variables at one instance (instant) or specific value, location, or place in time values.

$\frac{dy}{dx} = \frac{\text{very small change in (y)}}{\text{very small change in (x)}}$ = Slope at a particular (single) point on, or instance of the curve.
This would be equal the slope (m) of a tangent line to the curve at
at that specific point.

Since y = f(x), this can also be expressed with function notation as:

$$\frac{dy}{dx} = \frac{y2 - y1}{\text{very small change in (x)}} = \frac{f(x + \text{change in x}) - f(x)}{\text{very small change in (x)}}$$

: This is usually called the "delta process". You can think of delta as meaning a very small change or differential (difference = d).

Above, the words "very small" also mean instantaneous, or infinitely small. For even the smallest change in a variable to occur it will take at least a very small amount of time, and hence the concept of an "instant in time" or something being "instantaneous". An instant of time is a small or "short" or "quick" amount of time. An instantaneous change in (x) will produce a corresponding instantaneous change in (y), however as mentioned, do not assume that this corresponding change in (y) is always equal to that of the change in (x). If they were always equal, their ratio (ie. slope) would always be the constant value of 1 which is not very useful to describe all the various possible curves or mathematical relationships with varying slopes and-or rates of changes between the variables.

If y = 5x^1 , the derivative of this function is: 5x^0 = 5(1) = 5, and this result will be clarified below.

Notation(s) for this derivative: y' = f '(x) = dy/dx = d(5x)/dx = 5. , Also note mathematically: dy = f'(x) dx

Notice that y=5x is a linear equation, and therefore its slope and derivative must be a constant numerical value, and in this example, it's 5. If the equation had an arbitrary constant (such as b) added in to it, the slope and derivative would still be the same. The constant simply shifts (moves) an existing curve "up or down" vertically, and all the corresponding slope values still remain the same. In simple words, the mathematical relationship of the variables and shape of the curve is still the same regardless if it's shifted (moved) up or down vertically.

Below is an example of differentiating the formal (strictly algebraic, ie. with variables only) linear equation of:

y = m x + b : basic linear equation

For showing corresponding pairs of the variables, such as the corresponding coordinates of a point, this equation can be expressed with subscript notation as:

$y_n = m x_n + b$: Basic linear equation, here, n is a subscript value and used to distinguish each instance of pair of corresponding (x,y) variables. Ex. (xn, yn) , (x5,y5), and so on.

The process below will produce the same results if values were used instead of variables, for example:

y = 2x + 3

, however, we are looking for a formal or general expression for the derivative of any linear equation, rather than a specific derivative expression or value of one specific linear equation.

Considering any two pairs or sets of corresponding values of (x) and (y), which defines two points on any curve:

y1 = m x1 + b : for one point, ex.: p1(x1, y1)
y2 = m x2 + b : for another point, ex.: p2(x2, y2) on the same curve from the same equation

Since: (x2 - x1) = (change in x) we have:
x2 = x1 + (change in x)

And: (y2 - y1) = (change in y) we have:
y2 = y1 + (change in y)

With: y2 = m x2 + b using algebraic substitution of the above expressions:

(y1 + change in y) = m (x1 + change in x) + b

Now, the coordinates of the second point are expressed in relation to, or in terms of the first point. This eliminates some variables and will help us below.

Since: y1 = m x1 + b substituting this expression for y1 into the above, and with some simplification:

m x1 + b + (change in y) = mx1 + (m) change in x + b

Solving for (change in y):

change in y = (m)(change in x) dividing each side by (change in x) :

$$\frac{\text{change in y}}{\text{change in x}} = m$$

: Greek letter "delta", is often used to indicate a change, which is essentially a difference. Delta = Δ is sometimes used represent this:
Also note mathematically: (change in y) = m (change in x)

$$\frac{\Delta y}{\Delta x} = m$$

: basic slope equation using "delta-notation"

As the change in (x) approaches the specific limit of 0, being as small as possible but never actually equal to 0 (remember, division by 0 is not allowed, and a value of 0 also means that there wasn't a change at all), the corresponding change in (y) will consequently approach a value of 0 also. The above notation modified to reflect this special condition (where the change is as small as possible) is:

$$\frac{dy}{dx} = m$$

: The ratio or rate of the differentials is equal to the derivative of the line function:
y = mx + b, and is equal to m.
m, the rate of changes, is a constant value. The derivative of a linear equation is equal to the (constant) slope value of the line.

This may also be spoken as: "the differential of, or in, y with respect to the differential of, or in, in x". As indicated above, differential means a very small change (ie. a difference) in a value. You may also read it as: "the derivative of y with respect to x" or "the differential of y with respect to the differential of x". Notice that the constant term (b or = bx^0) of a linear equations plays no role in the derivative other than perhaps the addition of 0 in the derivative which has no effect. The value of b will essentially shift the curve, here, actually a line or "line curve", vertically on the graph by the specific value of b, but the mathematical or numerical relationship between (y) and (x) will remain the same regardless of the specific value of the constant b.

Often when solving for the general or formal derivatives of functions, other than linear equations, using a similar process as shown above, you will arrive at something like the following:

(change in x)^2

Terms containing powers of (change in x) greater than (1), are considered as practically having a value of 0, and are therefore removed when they are encountered. This is so since for derivative purposes, the (change in x) is considered a very small value (ie., a fractional value, and much less than 1), and if it raised to a power higher than 1, the result is yet an even much smaller value since a fraction of a fraction (like some kind of a "second order fraction") is a much smaller value that is insignificant and can be eliminated and-or considered as having a value of practically 0. Even though dy and dx are very small values near 0, they are not removed since they are not raised to a power higher than 1, and their values are still enough to be meaningful, and since they are actually what we are solving for.

Continuing onward with some derivatives of other functions:

If y = 3x^2 , its derivative is 6x^1 = 6x. Checking using the "change" or "delta" process:

$$\frac{dy}{dx} = \frac{\text{(change in y)}}{\text{(change in x)}} = \frac{y2 - y1}{\text{(change in x)}} = \frac{f(x + \text{change in x}) - f(x)}{\text{(change in x)}}$$

(Where for the delta process, and for finding derivatives (a processes called differentiation), (change in x) and hence the corresponding (change in y) is as minute or infinitesimally small as possible. This essentially will give the slope value at a particular point or instance on the curve which visually or graphically shows the mathematical relationship between two variables at that specific location, point or instance).

The right hand expression is all in "terms (expressed as, or with) of the variable", here its (x). Substituting the given values:

$$\frac{dy}{dx} = \frac{3\,(x + \text{(change in x)})^2 - 3x^2}{\text{(change in x)}} \qquad \text{: extending the binomial in parenthesis:}$$

$$\frac{dy}{dx} = \frac{3\,(x^2 + 2x\text{(change in x)} + \text{(change in x)}^2) - 3x^2}{\text{(change in x)}} \qquad \text{distributing 3 :}$$

$$\frac{dy}{dx} = \frac{3x^2 + 6x\text{(change in x)} + 3\text{(change in x)}^2 - 3x^2}{\text{(change in x)}}$$

After canceling like terms, and the fact that (change in x)^2 is a very, very small insignificant value compared to (change in x)^1 which itself is already as small as can be, (change in x)^2 can be considered as practically meaningless and a value of 0:

$$\frac{dy}{dx} = \frac{6x\text{(change in x)} + 3(0)}{\text{(change in x)}} = \frac{6x\cancel{\text{(change in x)}}}{\cancel{\text{(change in x)}}}$$

$$\frac{dy}{dx} = 6x \qquad \text{: the derivative of the function } 3x^2 = dy/dx = 6x \qquad \text{: The (instantaneous, at a specific point) rate of change of (y) with respect to (x) is 6x.}$$

Note that the value of the derivative above is not a constant value like it would be for a linear (line) equation where the slope (= an expressed numerical or mathematical relationship between the variables) is the constant value of (m), but with the above derivative expression of 6x, the slope can vary and now depends upon the specific value of (x). The result on a graph of: y=3x^2 is that the curve does not have a constant slope like a line does, and therefore, the curve will not look straight like a line. The slope of the curve when x=2 is: 6(2) = 12. The slope of the curve when x=3 is: 6(3)=18. Clearly this is not a constant value.

First, another example description of a derivative for further understanding of these things:

Let: y = mx + b = 2x + 1 : this is a linear equation and-or function, and that y is a function of x.

When there is a change in the value of x, there will be a change in the value of y. To find out how (y) changes when there is a change in (x), we can divide the two, and which is essentially a rate since changes take some amount of time, even if infinitely quick, a short or instantaneous amount of time.

$$\frac{\text{(change in y)}}{\text{(change in x)}} = \frac{(y2 - y1)}{(x2 - x1)} \;,\quad \text{if (x) changes by 1: } = \frac{(y2 - y1)}{1} = \frac{(2\,x2 + 1) - (2\,x1 + 1)}{1} =$$

$$\frac{2\,x2 + 1 - 2\,x1 - 1}{1} = \frac{2\,x2 - 2\,x1}{1} = 2\,(x2 - x1) = 2(\text{change in } x)$$, and here = 2(1) = 2 , a constant , and a constant rate

Expressing all this in an equation:

(change in y) = 2 (change in x) and $\frac{(\text{change in } y)}{(\text{change in } x)} = 2$

Regardless of the actual or specific value of (x) or the corresponding (change in x), the corresponding (change in y) will be a factor of 2 times more since the rate of the changes is 2. This can also be thought of as: if (x) changes by 1, (y) will change by 2.

Here are the derivatives of some other functions, and there is a note below this that describes this process:

If $y = x^2$, its derivative is $2x$. , and this can be considered as:

$\frac{(\text{change in } y)}{(\text{change in } x)} = 2x$, and (change in y) = 2x (change in x)

Here, the rate of changes is no longer a constant value, but depends upon the value of (x) considered when a change is applied or added to it. Here, when (x) changes = (change in x) , the corresponding (change in y) will be a factor of (2x) more, and the value of this factor always depends upon the specific value of (x) being considered, hence a better way to think of the above ratio is that this equation and rate applies to only a specific or "instantaneous" value of (x) and or where the change in (x) is so small or "instantaneously small" and-or "infinitesimally small") that the difference or result is practically that same value of (x) being considered:

$\frac{(\text{the instantaneous change in } y)}{(\text{the instantaneous change in } x)} = 2x$: 2x is not a constant, but an equation and variable value that depends upon the value of (x) being considered. The rate of change, here (2x), is not a constant value, but here, the rate of change actually increase as (x) increases in value.

(the instantaneous change in y) = 2x (the instantaneous change in x) : x = the current value of (x)

Or in general: dy / dx = (derivative of the function) = (instantaneous slope) , and mathematically :

(dy) = (derivative of the function) (dx) : a very small or instantaneous change is also called a differential (d)

When the derivative or "instantaneous slope" = ("instantaneous m") is large in value, indicating a high rate of change, and it depends upon the specific value of (x), the (change in y) values will be getting larger, and on a graph, the drawing or curve of the relationship between the variables will be getting more steeper or vertical. For a linear or line equation, the rate of changes is constant.

Ex. When (x) is at or near 1, the corresponding (y) values are changing by a rate, factor or multiplier of: (2)(x) = (2)(1) = 2.
When (x) is at or near 2, the corresponding (y) values are changing by: (2)(x) = (2)(2) = 4.
When (x) is at or near 3, the corresponding (y) values are changing by: (2)(x) = (2)(3) = 6.

If $y = 7x^2$, its derivative is $14x^1$.
If $y = 8x^2$, its derivative is $16x^1$.
If $y = 5x^3$, its derivative is $15x^2$.

If $y = 6x^3$, its derivative is $18x^2$.

If $y = x = x^1$, its derivative is $1x^0 = 1(1) = 1$, a constant. $y = x = x + 0$, a linear equation, with a=m=1, and b=0.

If $y = 3x = 3x^1$, its derivative is $3x^0 = 3(1) = 3$, a constant. Since the derivative is constant, the slope of the curve (here, actually a line) is constant. Since the mathematical relationship between the variables is a constant mathematical relationship, the equation is called a linear equation which also graphs as a line. Note that here, the anti-derivative (ie. finding the source function (F) of which the derivative expression was derived from) of 3 is: $3(1) = 3x^{(0+1)} = 3x^1$

If $y = f(x) = \frac{x^3}{3}$, its derivative is: $\frac{d\,f(x)}{d\,x} = \frac{dy}{dx} = y\,' = f\,'(x) = \frac{3x^2}{3} = x^2$: optionally showing much notation.

Observing the pattern seen in the derivatives of the above type expressions, we find: Multiply the exponent of (x) to the numerical co-efficient of (x), and then reduce the exponent of (x) by one. Knowing such patterns is very practical and commonly used in calculus so as to find quick and practical solutions. This specific pattern just shown is commonly known as the (derivative) "power rule".

In algebraic notation, the derivative of a function of this form or type: ax^n

is: $nax^{(n-1)}$: **DERIVATIVE POWER RULE**

This can be expressed as: Given a function that is a power of a variable: (coefficient) variable^exponent

It's derivative is: (coefficient)(exponent) variable^(exponent-1)

Taking the derivative of this first derivative will give the second derivative of that same function of: ax^n:

$n(n-1)ax^{((n-1)-1)}$

is: $n(n-1)ax^{(n-2)}$

Taking the derivative of the second derivative will give the third derivative of that same function of: ax^n:

$n(n-1)(n-2)ax^{(n-3)}$

Ex. The derivative of the square root, or even the cube root, of (x) can be found using the derivative power rule:

$$\frac{d\sqrt{x}}{d\,x} = \frac{d\,x^{0.5}}{d\,x} = 0.5\,x^{(0.5-1)} = 0.5\,x^{-0.5} = \frac{0.5}{(1)\,x^{0.5}} = \frac{1}{2\,x^{0.5}} =$$

$$\frac{d\sqrt{x}}{d\,x} = \frac{1}{2\sqrt{x}}$$

: this is also the slope at any point (x,y) on the curve of: $y = \sqrt{x}$

For this derivative of a square root equation, you can see that as (x) gets larger, the slope will decrease, hence, here the slope is inversely related to (x). As (x) gets very large, the slope approaches a value of 0 indicating that there is not much of a change in the corresponding (y) values when (x) changes.

You can then use this derivative in the interpolation formula derived previously so as to find a close approximation for the square root of values near to (x). This method of interpolation using a derivative is also demonstrated in some tables shown in this book so as to find an unlisted value that is between two listed, calculated values.

Let d = (change in y) = m (change in x) replacing (m), the slope value, with the above derivative value:
d = a difference in the (y) values of two points.

$$d = \frac{1}{2\sqrt{x}}\text{(change in x)} = \frac{\text{(change in x)}}{2\sqrt{x}}$$

$$y2 = y1 + \text{change in } y1 = y1 + \text{change in } y = y1 + d$$

If you were given any of the derivatives and were to find the **anti-derivative** (sometimes noted as F for the anti or reverse-derivative Function) or expression from which that derivative itself can be or was derived from, there is a reverse pattern: increase the exponent of (x) by one (even if the exponent of (x) is 0, and-or (x) is not even shown since $x^0 = 1$) and then divide the numerical coefficient of (x) by the "new" exponent of x. Showing this algebraically, if given the derivative or function of:

$$nax^{(n-1)}$$

The reverse derivative is:

$$\frac{nax^{((n-1)+1)}}{(n-1)+1} = ax^n$$

The following notation may bring some additional clarity to this process:

Given a function that is a power of a variable: (coefficient) variable^exponent

It's derivative is: (coefficient)(exponent) variable^(exponent-1)

Therefore, when given a function or derivative, to find the anti-derivative, the only indication of what that given coefficient was multiplied by is the value of the given exponent. We know that this exponent is now one less than the original function or anti-derivative, and that the coefficient was multiplied by this given exponent plus one. Therefore we must divide the given coefficient of the variable by the given exponent plus one, and then increase the exponent of the variable by one, so as to have the anti-derivative:

Essentially given: ((coefficient)(exponent)) variable^(exponent-1) its anti-derivative is, after increasing the exponent: by 1, and dividing by the exponent plus 1:

$$\frac{\text{(coefficient)(exponent) variable}^{\text{(exponent-1+1)}}}{\text{(exponent-1) + 1}} = \frac{\text{(coefficient)}\cancel{\text{(exponent)}}\text{ variable}^{\text{(exponent)}}}{\cancel{\text{(exponent)}}} =$$

(coefficient) variable^exponent : the original given function (ie., F, the anti-derivative)

Ex. Given a function or derivative that is: $y=5$, the anti-derivative is: $\frac{5x^{(0+1)}}{1} = 5x^1 = 5x$

Ex. Given: $14x^1$

The reverse derivative is: (or anti-derivative) $\frac{14x^{(1+1)}}{(1+1)} = \frac{14x^2}{2} = 7x^2$

You can check this by taking the derivative of $7x^2$ using the derivative power rule.

In the field of calculus, you will usually see something like this expressed:

$\frac{dy}{dx} = 14x^1$: 14^1 is the derivative of some function of x. Mathematically:

$dy = 14x^1 \ dx$

Expressing the sum of all these bits, or very small changes or parts of the "whole thing", we can find the anti-derivative and the "whole thing" from which all the bits came from. This process is also called integration. To **integrate** is to combine things, and for math, that then means to add things so as to produce a new thing or sum. An integral part of a whole thing is a part that composes that whole thing. We can say that the part has been integrated into that whole thing. In math, the whole thing is called the sum or **integral** (as in calculus) since it is composed of all the smaller parts than have been integrate into it. In calculus, all the parts are generally similar and infinitely small in size and-or value, and this then cause an infinite-like sum since there are so many. A line segment has an infinite number of points, but we know it still has a definite or specific length, unlike a general line of infinite length which can be called an indefinite integral and can only be represented as an equation. The line segment is then analogous to a definite integral, and which can be thought of an isolated or bound part of a line. A line segment is a specific amount of line.

$\int dy = \int 14x^1 \ dx$: $\int$: is a summation symbol, it looks like the letter S and is the first letter of the the word Summation and is the act to, and-or the result of adding and-or combining things and-or numeric values.

$Y = 7x^2$

You might now ask what happened to dx in this process. Just like the sum of all the dy bits is equal to (y), the sum of all the dx or bits of (x) is equal to the whole (x), and this (multiplier) is what increases the power of (x) when it goes through the integration process. The appendix of this book includes more discussion about integration called: Basic Concepts Of Integration. The small bits have been summed and have produced a non-specific sum and-or another equation, as can bee seen due to the variable (x). This is the result of what is called an **indefinite integral** that is unbounded or non-specific and is rather a general representation of the resulting (infinite) sum of terms.

Ex. What is the anti-derivative of $y = f(a) = a^2$?

$F(a) = \frac{a^{(2+1)}}{(2+1)} = \frac{a^3}{3}$ Taking the derivative of this as a check: $\frac{3\ a^{(3-1)}}{3} = a^2 = f(a)$: checks

The derivative of a sum of functions of (x) is equal to the sum of the derivatives of each function of (x). This is known as the **derivative sum rule** and can easily be verified with an example:

If function 1 = $2x + 3 = f1(x) = y$ and:
If function 2 = $5x + 7 = f2(x) = y$

$\frac{dy}{dx} = \frac{d\ (f1)}{d\ x} = \frac{d\ (2x + 3)}{d\ x} = 2$ and:

$\frac{dy}{dx} = \frac{d\ (f2)}{d\ x} = \frac{d\ (5x + 7)}{d\ x} = 5$

$f3 = f1 + f2 = (2x + 3) + (5x + 7)$
$f3 = f1 + f2 = 2x + 3 + 5x + 7$ combining terms:
$f3 = f1 + f2 = 7x + 10$: the sum of the two given functions

$$\frac{dy}{dx} = \frac{d\,(f3)}{d\,x} = \frac{d\,(f1 + f2)}{d\,x} = \frac{d\,(7x + 10)}{d\,x} = 7 = \frac{d\,(f1)}{dx} + \frac{d\,(f2)}{d\,x} = 2 + 5 = 7$$: checks

Ex. Given the general or formal quadratic equation of: $ax^2 + bx^1 + cx^0 = 0$

,with the concepts of derivatives, we can find the equation for the minimum or maximum point of a parabola curve. This min. or max. point is often referred to as the extreme point of the parabola. At the extreme point on a parabola, the slope is 0, hence the derivative at that point is 0 (think of a small line, or tangent line to the curve at that point, and its slope is 0. A line at this point will be neither sloping up or down, but it would be a horizontal line). We can find the derivative of the general quadratic equation above by taking the derivative of each term when considering the function as a sum of two or more other functions:

$$\frac{dy}{dx} = 2ax^1 + 1bx^0 + 0$$

$$\frac{dy}{dx} = 2ax + b$$: notice that the derivative of a second degree equation is a first degree equation

Setting this "instantaneous slope" equation (ie. setting y) equal to 0 since we want to find out at what corresponding value of (x) will be where the slope equals 0, and which is where the location of the extreme point of this parabola is:

$2ax + b = 0$: Setting the slope equal to 0. After solving for x, we find:

$x = \frac{-b}{2a}$: (x) coordinate of the extreme point of a parabola, the corresponding y coordinate of that point can be found by substituting this value of (x) into the original quadratic equation given. This book previously shown an algebraic expression for the corresponding (y) value.

Another very useful rule is for the derivative of a function of another function. This rule is commonly known as the **chain rule**. Let's begin with some notation. If we let (y) equal a function of (x), its' notation can be expressed as:

$y = f(x)$: standard typical function notation

If there is more than one function of (x) being considered, a more compact notation is commonly used:

$y(x)$: compact function notation indicating "y is a function of x": $y = f(x) = y(x)$

Using compact notation, if (u) and (v) are other functions of (x), their notation is:

$u=f(x) = u(x)$ and $v=f(x) = v(x)$: note f(x) is an unspecific notation to represent a function, and here, the function or expression contains the (x) variable. This is similar to how p(x,y) is the general notation for point, or any point.

Then if (v) also happens to be a function of (u), that is, (v) is a function of another function, its' notation is:

1. $v = f(u)$: v is a function of u, and since $u = f(x)$, using substitution:
2. $v = f(f(x))$: u is the "inner function", and v is the "outer function" which is also function of the inner function u: v(u)

(v) is now essentially like the dependent variable of the independent variable (u). Just the same, (u) is essentially the dependent variable to the independent variable (x). Therefore, (v) is also dependent upon (x).

By the first equation, the derivative of (v) is the derivative of the entire equation given with respect to (u) since (v) is a function of (u). By the second equation (which is equivalent to the first equation), it explicitly implies or indicates that the derivative of (v) with respect to (x) is the same as the derivative of (v) with respect to (u), but will also include a factor that is the derivative of (u) with respect to (x) since (u) itself is a function of (x). If we let variable name (y) = (v) for notation conformity to what we have been using up to this point:

1. $y = f(u)$: y is a function of another function (here, function u), and since u = f(x), therefore

$y = f(f(x))$: y is a function of u which is a function of x, y is therefore also a function of x:

$$\frac{dy}{dx} = \frac{dy}{du}\,\frac{du}{dx}$$: **Derivative Chain Rule , The Derivative Of A Function Of Another Function Rule, or the derivative of a function that contains or has another function**

As a simple verification to this formula consider:

Let y = v
v is a function of u, and
u is a function of x

$$y = v = v(u) = v(\,f(x)\,)$$

The derivative of y with respect to x is therefore:

First let:

$$\frac{dy}{dx} = \frac{dv}{dx}$$ continuing:

Since (du/du)=1 (anything divided by itself equals 1), and multiplying the numerator and denominator on the right hand side by du (creating an equivalent fraction), we have:

$$\frac{dy}{dx} = \frac{dv}{dx}\,\frac{du}{du}$$ which can be mathematically expressed as:

$$\frac{dy}{dx} = \frac{dv}{du}\,\frac{du}{dx}$$ Since y = v, this can be expressed as:

$$\frac{dv}{dx} = \frac{dy}{du}\,\frac{du}{dx}$$: derivative chain rule

Ex. If $u = x^2$ and $y = (x^2)^3$: both (u) and (y) are functions of x. u=f(x) and y=f(x)

Clearly, we see that: $y = f(u) = u^3$: y=f(x) = f(u) or y=f(f(x))

$$\frac{dy}{dx} = \frac{dy}{du}\,\frac{du}{dx}$$

$$\frac{dy}{dx} = \frac{d\,(u^3)}{du}\,\frac{d\,(x^2)}{dx}$$

$$\frac{dy}{dx} = \frac{d((x^2)^3)}{du} \quad \frac{d(x^2)}{dx}$$

$$\frac{dy}{dx} = 3(x^2)^2 \quad (2x^1) \qquad : \text{or} = (3u^2)(2x^1)$$

$$\frac{dy}{dx} = 3x^4 \quad 2x^1 = 6x^5$$

Checking: Since $y = (x^2)^3 = x^6$, their derivatives must be the same:

$$\frac{dy}{dx} = \frac{d(x^6)}{dx} = 6x^5 \qquad : \text{checks}$$

Using this example above, another verification to the chain rule is shown which can be further generalized and verified in algebraic terms:

$$\frac{dy}{du} = 3(x^2)^2 = 3x^4$$

$\frac{du}{dx} = 2x$ therefore: $du = 2x\ dx$, using substitution:

$\frac{dy}{du} = \frac{dy}{2x\ dx} = 3x^4$ solving for dy / dx: :

$\frac{dy}{dx} = (3x^4)(2x) = 6x^5$ showing this expression in pure algebraic terms:

$$\frac{dy}{dx} = \left(\frac{dy}{du}\right)\left(\frac{du}{dx}\right)$$

: chain rule
If a function contains a factor that is another function, the chain rule can be utilized.
In the example, the function of (y) contained a factor that is the function of (u).

Ex. We are given the function of: $y = x^3$ and are to find dy/dx. For this example, we can solve this using the derivative chain rule, but could also solve this using the derivative power rule. If this given function contains a factor that is equivalent to another function of (x), we can also use the derivative chain rule to find the derivative (dy/dx) of that initial given function.

If $(x^1)(x^1)(x^1) = x^3$, then x^3 contains a factor of x^1.

Letting: $y = f(x) = x^3$ and $u=f(x)=x^1$, therefore, (y) contains a factor of (u), and $y= f(u) = u^3 = x^1\ x^1\ x^1$

$(y) = f(u)$, and $(u) = f(x)$, $y = f(u) = f(x)$

Since (y) is a function of (u), the derivative of (y) with respect to (x) will then be equivalent to a derivative of (y) with respect to (u), and since (u) is also a function of (x), and that (y) contains a factor of (u), this derivative of (y) will then actually consist of a factor that is the derivative of (u) with respect to (x):

The derivative of (y) with respect to (x) = **(**derivative of (y) with respect to (u)**)** **(**derivative of (u) with respect to (x)**)**

$$\frac{dv}{dx} = \frac{d\,(f(f(x)))}{dx}$$

$$\frac{dv}{dx} = \frac{dy}{du}\,\frac{du}{dx}$$

As an aid to understand this, consider these two functions which are both functions of (x), and that u = f(x) = x^1:

1. y = x^2 , y = f(x) = f(u)
2. z = x^3 z = f(x) = f(u)

Both functions contain a factor of x^1, hence both contain a factor of (u)=f(x) = x^1

Since u=x^1 is the same for both functions, du/dx is therefore the same for both functions, and we also know that the derivatives of both functions can't possibly be the same since those two given functions are different. The derivative of each function with respect to (x) will actually contain (as a factor) the derivative of that function with respect to (u) that is a function of (x).

Consider that since (u) contains a factor of (x), and that (u) is a factor of (y), a derivative of (y) with respect to (x), will contain a derivative of that factor (u) with respect to (x), and a derivative of (y) with respect to (u) will obviously contain a derivative of (y) with respect to (u).

Consider if function2 = (f2) is itself a function of another function, say function1 = (f1). In other words, f2 contains a part of f1, and is dependent upon f1. Since the value of f1 depends on the variables and equation used in that specific function, the values of f2 depends on the variables and equation in both itself, f2, and f1.

A small change in (x) will first cause a small change in (u). The derivative of (u) with respect to (x) will be a certain value: du/dx = slope1 = value1 This change in (u) will cause a small change in (y). The derivative of (y) with respect to (u) will be a certain value: dy/du = slope2 = value2. Therefore, the rate of change of (y) with respect to (x), is also determined by the rate of change of (u) with respect to (x). Therefore, the derivative of (y) with respect to (x) is also partly determined by the derivative of (u) with respect to (x). and value2 is partly determined by value1. One rate of change is party determined by the value of another rate of change. This almost seems like a derivative of another derivative concept here, but as mentioned, the derivative of (y) with respect to (x) is partly determined by both (u) with respect to (x), and (y) with respect to (u), and hence it is partly determined by each.

Considering that a derivative is a form of a rate. Here is a simple way to explain why one derivative is being multiplied by another derivative. and that each is a factor of the result.

value1 = rate1 value2 : note for example, mathematically: value1/value2 = rate1
value2 = rate2 value3

Since value2 is partly determined by value3, and if value1 is partly determined by value2, essentially then, value 1 is partly determined by value3. Because of the rates shown, of which can vary upon each given situation, the values are not completely determined by the other values alone, but also by the (varying or current) rates.

value1 = (rate1 value2) = (rate1) ((rate2) value3) this can be expressed as:
value1 = (rate1) (rate2) value3

$\frac{\text{value1}}{\text{value3}} = \text{rate1 rate2}$: the rate of value1 with respect or in reference to value3 is the product of rates.

Ex. value1 = 50% value2 or: value1 = 0.50 value2
value2 = 30% value3 or: value2 = 0.30 value3

value1 = 0.50 value2 = 0.50 (0.30 value3) = (0.50)(0.30) value3 = 0.15 value3

$$\frac{\text{value1}}{\text{value3}} = (0.50)(0.30)$$

: the ratio of value1 to value3 is much like a fraction of a fraction concept, and here it is expressed as a product of two ratios, or a ratio of a ratio

Or:

$$\frac{\text{value1}}{\text{value2}} = \text{rate1} = \frac{\text{value1}}{\text{rate2 value3}}$$

: value2 = rate2 value3 :

therefore:

$$\frac{\text{value1}}{\text{value3}} = \text{rate1 rate2}$$

With just some basic knowledge of calculus, you can find things such as the area beneath a portion of a curve, or the arc length between two points on a curve. In the Advanced Topics, and Appendix sections of this book, derivatives and anti-derivatives were used as part of the derivation process for many of the very important mathematical series to be presented. The appendix section contains very useful examples of using a derivative as part of interpolation to mathematically calculate an estimate of a value not listed in a table of values.

Here are some more examples of derivatives:

Ex. Find the derivative of the circles circumference (C) formula with respect to a change in the radius (r). This basically will find the equation or constant value of how the circumference will changes when the radius changes by one unit.

C = 2(pi) r Note that this has the form of a linear equation: y = mx , 2(pi) is equivalent to the slope = m variable. C corresponds to y, and r corresponds to x. C = 2 (pi) r = (pi) d

$$\frac{dy}{dx} = \frac{dC}{dr} = \frac{(1)(2)(pi)r^{(1-1)}}{1} = \frac{2(pi)r^0}{1} = 2(pi)(1) = 2(pi)$$

: = about 6.28, a constant

As (r) increases or changes by 1, C will increase or change by 2(pi) = 6.28... :

	r =	1	2	3	4	. . .
C =	2(pi)r =	2(pi)	4(pi)	6(pi)	8(pi)	. . .
C ~=		6.283	12.566	18.85	25.13	. . .

: the difference or change between terms is 6.28... = 2 (pi) , when (r) changes by (1). This is an example of an **arithmetic series** where the difference is constant.

Because the equation had the variable, here (r) raised to just the first power, the ratio of C to (r) also equal to the derivative, and which is a constant numeric value, and as expected for an equation having a linear form.

C / r = 2(pi) : a circles circumference is always larger than its radius by a constant factor of 2(pi) = 6.28...

Ex. From the last equation of a circles circumference, given we can solve for r, and then find the derivative of a circles radius with respect to its circumference:

$$r = \frac{C}{2(pi)}$$

or = ((2)(pi))^-1 C and dr / dC = 1 / (2(pi)) = 1/6.28... = 0.15915... , a constant

This means that when C increases or changes by 1 unit, the radius of that circle has, or must increase or changes by

0.15915...

C =	4	5	6	. . .
r =	0.6366	0.7958	0.9549	. . .

Ex. Find the derivative of the area (A) of a circle, with respect to its radius (r):

A = (pi)r^2 , " dy/dx " = dA / dr = 2(pi)r : = about 6.28r , also: A / r^2 = (pi) =~ 3.14..., a constant
2(pi)r = (pi) D = circumference of a circle

This derivative value is not a constant since it contains a variable, hence the derivative or rate of the increase or change of A with respect to a increase or change in (r) depends on the specific or current value of (r). This derivative is a "first order" or linear equation where the independent variable has a power of 1, and was derived from a "second order" equation where the independent variable has a power of 2.

As (r) increases: When (r) = 1unit, A = 6.28 square-units, and A is increasing or changing by 6.28(1) = 6.28sq-units
When (r) = 2units, A = 12.56 square-units, and A is increasing or changing by 6.28(2) = 12.56sq-un. for each increase in (r). The area, like a distance, is now increasing at a much faster rate (rate) or speed which has been accelerated or increased over 1 time unit which is similar to increasing (r) by 1. In a pseudo-distance equivalence representation: A = (pi)r^2 = distance = (speed)(time^2).

Notice that the derivative for a linear or first-order equation was a number, a constant, and this corresponds to a dimensionless point. We just seen that the derivative of a length, such as a circumference is a constant (here, (2)(pi)). The derivative of a second-order equation was a first-order equation. We just seen that the derivative of an area with two dimensions was a one-dimensional linear equation. Likewise, the derivative of a volume which has three dimensions, is a second-order equation:

V = three-dimensions = (1 dimension)^3 = (1 unit)^3 ,

dV / d (1 dimension) = d(1 unit)^3 / d (1 dimension) = $\frac{\text{2 (1 unit)^2}}{3}$

The equation for the volume of a sphere is: Vs = $\frac{\text{4 (pi) r^3}}{3}$, The derivative of Vs with respect to (r) is:

dVs / dr = (3)(4)(pi)(r^(3-1)) / 3 = 12(pi)r^2 / 3 = **4(pi)r^2** , This value is also equal to the **surface area of a sphere**
It is also equal to **4 times the area of a circle with same(r).**
Extra: **As** = 4 (pi) r^2 = 12.56637061 r^2 =~ **12.5$\underline{7}$ r^2**

If we let r = d/2, As = 4(pi)(d/2)^2 4(pi)(d^2/4) = **(pi) d^2** : Alternate surface area of a sphere formula
Another alternate surface are of a sphere formula is: **As = C D = (2 (pi) R) (2R) = 4 (pi) R^2 = (pi) D^2 = 4 (pi) R^2**
This As = CD derivation of the formula for the surface area of a sphere is mentioned further in this book. This value of 4 (pi) =~ 12.57 is also the number of **steradian** or "three dimensional", solid" angles from the center of a sphere. On a sphere's or spherical surface at a distance of R from the center point, each steradian angle intersects that surface and defines an area of: (length)(width) = (R)(R) = R^2, and where here each length is actually an arc segment of the circles curved surface, but is still equal to R in length.

The derivative of the surface area, (Ss), of a sphere with respect to its radius (r) is:

dSs / dr = d 4(pi)r^2 / d r = 8(pi)r = 25.13274123 r

A fundamental part or lower dimension of a line is a point. A fundamental part or lower dimension of an area (two dimensions) is a line (one dimension). A fundamental part or lower dimension of a volume (three dimensions) is an area (two dimensions).

Extra: The ratio of a spheres volume to its surface area is not a constant value, but depends on its specific radius value:

$\frac{Vs}{As}$ = (4(pi)r^3 / 3) / 4(pi)r^2 = (r / 3) : the volume of a sphere is greater than its surface area by r / 3 = 0.33333 r , also, from this we find:

$Vs = \frac{As\ r}{3}$ = 0.3333 (As r) also:

Extra: **C = 2 (pi) r = (pi) 2r = (pi) d** : **Circumference of a circle** = 3.141592654... d , C = 6.283185307... r

Ac = (pi) r^2 = (pi) (d/2)^2 = (pi) (d^2 / 4) = 0.785398163 d^2 =~ **0.7854 d^2** : **Area of a circle**

$\mathbf{Vs = \frac{4\,(pi)\,r^3}{3}}$ = 4.188790205 r^3 **=~** $\mathbf{4.188\underline{8}\ r^3}$ **=** $\frac{4\,(pi)\,(d/2)^3}{3}$ = $\frac{4\,(pi)\,(d^3/8)}{3}$ = 0.523598775 d^3 **=~** $\mathbf{0.523\underline{6}\ d^3}$: **Volume of a sphere**

Ss = 4 πr^2 ~= $12.5663706\underline{1}$ r^2 :**Surface area of a sphere** , if r doubles to (2r), , (2r)^2 = 4r , hence the surface area will increase by 4.

Also: **Ss** = **4 (pi) r^2** = **C D** = 2 (pi) R (2r) = **(pi) D^2**

Before such formulas as shown above were created, it would have been very practical to measure several examples of circles and spheres so as to come up with some general ideas, conclusions and formulas to consider. If a person was to measure the circumference of a circle, it would always be slightly more than 3 diameter (d) length units long:

C =~ 3 d

With the same reasoning as mentioned above, the area of a circle, volume of a sphere, and surface area of a sphere could be measured just the same so as to have some general ideas, and that some constant value, fraction or multiple of (PI) and power of (r) is in the measured result.

Some thoughts on the surface area of a sphere:

It is now known that the **surface area of a sphere** is 4 times the area of the largest disk or surface area of the circle. Consider looking at a flat disk or sphere from a distance that appears to be a disk, and it has two sides (front and back) of equal area. The surface area of a sphere is at least twice the area of this disk shape seen, but it is actually larger since the sphere is curved and is therefore longer than the diameter seen from a distance, and the value of this distance on the sphere is actually half of the circumference (2 (pi) r) of that sphere, and which is then (C/d) = [2 (pi) r] / 2 r = (pi) times longer. According to the surface of the area of a sphere formula, the "flat" area ((pi) r^2) of each side seen as a flat disk area from a distance is actually twice that same area on the actual and larger curved surface of that side of the sphere, and that value is: 2 (pi) r^2. To then account for the other side of the sphere, twice this value is the surface area of the sphere: 4 (pi) r^2.

> You can also consider the surface area of a sphere as being an infinite number of thin rectangular segments or strips having a length of (C) fully around the circle, and over a width of (D) and so as not to overlap and include any area twice. If the sphere is cut along one side and laid flat, a rectangle can also be conceived at having and infinite number of thin strips having a height of (D), and over a width of (C). The results are also that: **Ss = CD**

Extras: Ac = (pi) r^2 = (pi) (d/2)^2 = (pi) d^2 / 4 = $\frac{(pi)}{4}$ d^2 = $0.78539816\underline{3}$ d^2 = $0.785\underline{4}$ (4 r^2)

From this we can also conclude: d^2 = 4 r^2 , and that the surface area of each side of the sphere is (pi) / 2 times more than this value, or that the total surface area of the sphere is (pi) times more.

A / C = (pi) r^2 / 2 (pi) r = r / 2 , mathematically: A = C r / 2 = C d / 4 = (3.14 d) d / 4 = 3.14 (d^2 / 4)
A = 3.14 (0.25 d^2) = (pi / 4) d^2

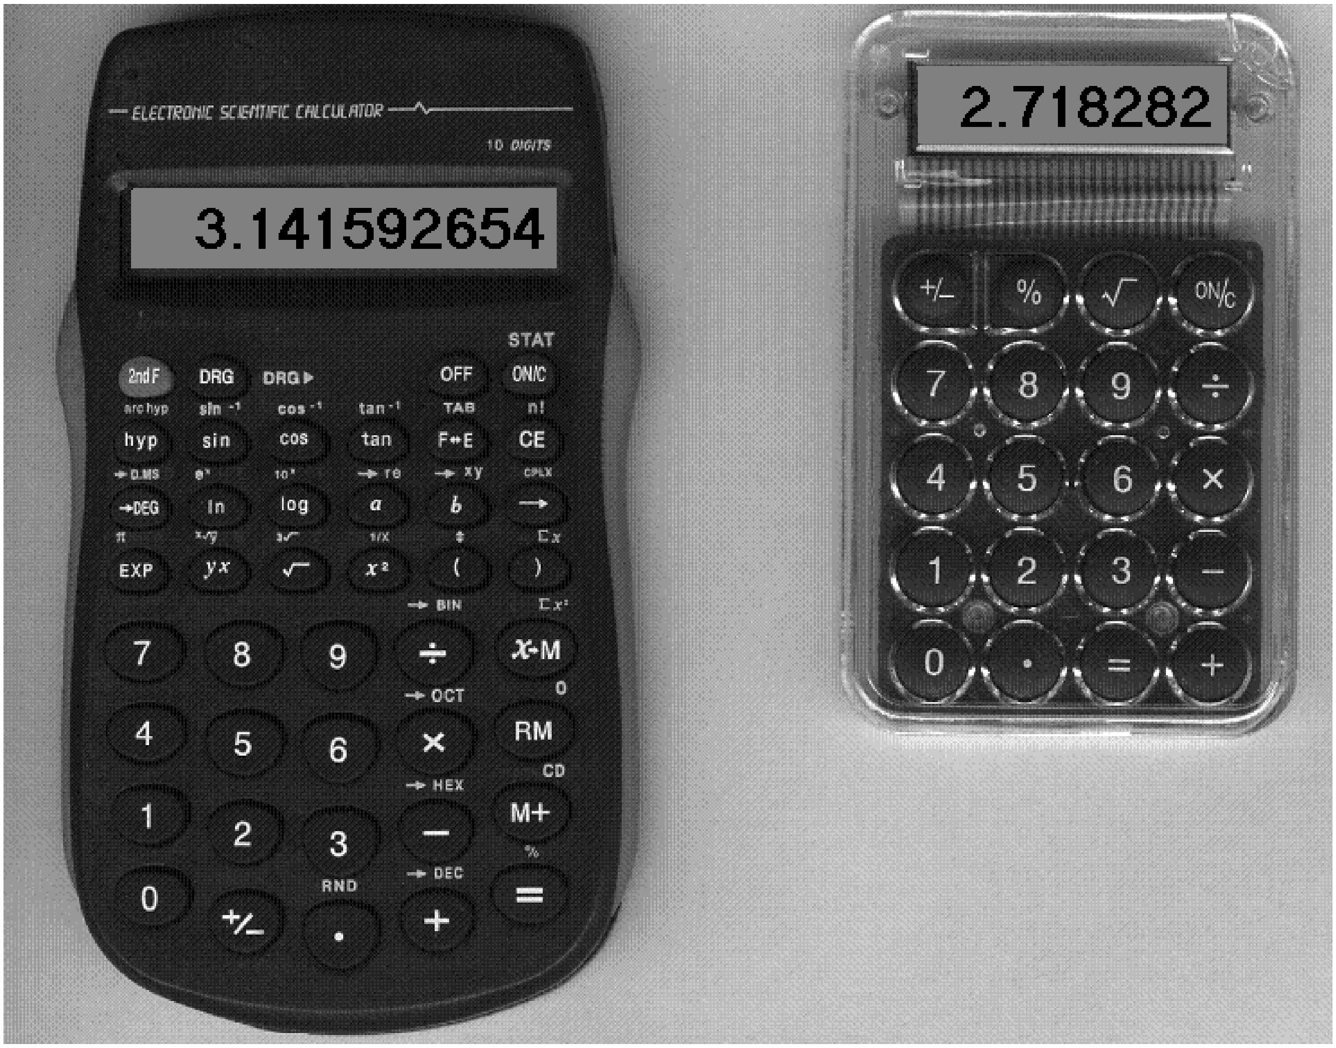
C = 2 (A / r) = 2 (pi) r = 2 (pi) (d / 2) = (pi) d and r = 2 (A / C) and d = 2r = 2 [2 (A / C)] = 4 (A / C)

Extra: If the radius or diameter of a circle changes by a factor of (n), the circumference will change by that same factor value of (n), and the area will increase by (n)^2. C = 2 (pi) r = (pi) D , and if we multiply each side by (n): (n) C = (n) 2 (pi) r = (n) (pi) D. Given: Ac = (pi) r^2 , (n^2) Ac = (pi) (nr)^2 = (pi) n^2 r^2 = n^2 (pi) r^2

If the radius or diameter of a circle, or side of a square increases by sqrt (n) , Ex: $\sqrt{2}$, its area will increase by (n):
Ac = (pi) r^2 , 2Ac = (pi) ((sqrt 2) r)^2 = (pi) 2 r^2 = 2 (pi) r^2 , also : As = s^2 , 2As = ((sqrt 2) s)^2 = 2 s^2

SECTION 4: ADVANCED TOPICS

This section is about making some important calculations when a scientific calculator or reference ("look-up") table(s) is not available. Specifically, this section shows you how to calculate logarithms, antilogarithms (inverse logarithms), trigonometric functions values of an angle, and inverse trigonometric functions, that is, calculating the corresponding angle given its corresponding trigonometric function value. Actually, this section could be called "Required Topics" since how could you perform these crucial mathematical operations out of "thin air", without a "look-up" table, or some direction as to how to proceed in their calculation? Since these calculations (especially division) could become tedious when repeatedly performed with hand, pen and paper, something such as a modernly inexpensive 4-function, home-use type of electronic calculator can be utilized to its fullest potential as if it were practically a full-function scientific calculator. Many of these types of electronic calculators also have a generous square-root, "fifth-function", key which is of great aid, especially for calculating some trigonometric values. Much of this section can also be adapted for computer programming languages that may or may not have these preprogrammed functions. In the image below, on the right is a typical 5-function "home-use calculator". On the left is an example of a scientific or multifunction calculator. Today, calculators are often inexpensively available at thrift stores, and some have a solar power option. There are also calculator apps for phones. [Image magnified about 25%]
[FIG 195]



Before the invention of electric or electro-mechanical calculators there were helpful mechanical devices such as the **abacus**. The abacus was used by most people who had one, so as to add and subtract, but it could also be used for multiplicatoin and division. The main concept of the abacus is using moveable or slideable beads on a rod or in a slot. It is a very old device, first used in about 2500BC in Sumeria - Mesopotamia (ie., the ancient Irak region), and was then used in some form in many parts of the "old-world" (the eastern hemisphere of Earth). It is still in minimual use, and even as a "converstation piece".

RADIAN ANGLE MEASUREMENT

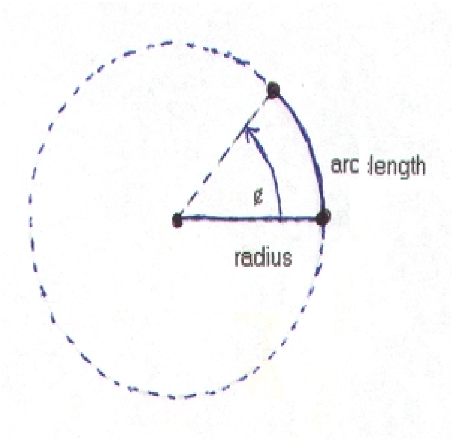
Just like degrees is a unit of measurement for angles, radians is also a unit of measurement for angles. The word radian is derived from the word "radius" of a circle. A radian angle measurement is natural or inherent to every circle's construction and is therefore a way to measure angles in contrast to the various man made values and units such as degrees (360), grads (400), revolutions (revs or turns), percent of a rotation, etc.

A radian angle is defined and measured using only the natural physical properties of all circles. All circles have the same shape and are all similar in many ways mathematically, and specifically, the ratios of parts within each circle's construction is the same as that for any other circular construction. For example, since C = circumference = 2(pi)(radius), the ratio of the circumference of a circle to the radius of that circle is always: (circumference)/(radius) = 2(pi) =~ 6.28 , hence the circumference is always about 6.28 times longer than its radius.

A degree angle measurement is the amount of parts, or the fractional value, of a full rotation that is defined as equal to 360 parts or degrees. 1 degree = 1° = the portion or fraction of: (1/360 = 0.0027777...) of a full or complete circle or rotation having a total angle of 360° A radian angle measurement is the ratio (ie., or the "number of times") of the length of an arc on the circumference of a circle with respect or in reference to the radius length of that circle.

An angle made when one point rotates about another "fixed" point, such that the point being moved describes (defines) an arc that is equal to that of the distance (ie., radius of rotation = radius of the circle) between those two points, is defined as an angle of one radian (or rad). For a give circle, the greater the arc length, the greater the angle, and vice-versa.

For this discussion about radians, consider that the point rotating or orbiting about another point, is located at the end of the radius line of a circle, and that the point is rotating about the center point of that circle. An arc is a portion (or "segment") of a circles circumference, and has an arc length, "length of arc", or distance associated with it. [FIG 196]



Expressing this using a mathematical equation:

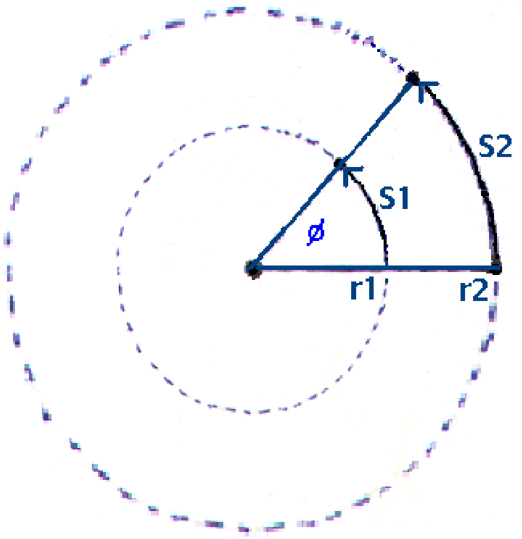
$$\text{¢} = \text{¢ radians} = \frac{\text{arc length}}{\text{distance between points}}$$

: arc length is often noted as the letter S
S = (¢ in radians) (r)

Radius length (r) is often substituted for distance from the center of rotation to a point on the circumference or path of rotation, and this is where the word "radians" originates:

$$\text{¢} = \text{¢ radians} = \frac{\text{arc length}}{\text{radius}}$$: When S = r, the angle is 1 radian.

Note that a radian angle generally has nothing to do with the actual size of a circle or the specific distance (ie., radius) from the center point of rotation. All the possible and different arc lengths of concentric (have the same center) paths or orbits of points with each having their own corresponding distance (ie., radius) from the center point of rotation, can describe the exact same angle. For the same fixed or given angle, the farther a point is from the center of rotation, the greater the corresponding arc length corresponding to that angle, and this is similar to how the corresponding side opposite an angle in a triangle also depends on the size of that angle and the distance from it's vertex: [FIG 197]



This figure above shows that different arc lengths and radius values can correspond to the same angle, and vice-versa. This is due to that all circle constructions are similar and the internal proportions of one is the same as that as another. Specifically, as an example for this discussion of concentric circles:

(arc length) / (radius) = a constant ratio value equal to the (radian) angle.

Since arc length and radius length have the same units, their units will be canceled during the division, hence radian angle measurement, in a strict sense, is a (strict) "numeric only" or unitless quantity, and is often indicated that way as just a (ratio) value without any indicated units. Generally, if an angle measurement does not have a degree symbol (°) or some other indication that the units are degrees, it could then be considered as a radian angle measurement. Many scientific calculators have a radian or degree angle, working mode setting (button, key, switch) for entering (as operands) angles, and displaying angles (the results). From the above equation we mathematically have this handy formula:

arc length = ¢ (radius) : ¢ is a radian angle , If the arclength = C , ¢ = 2(pi) = 6.28... radians

s = ¢ r

We see that arc length is directly related to the angle and the radius. If either the angle or radius changes by a factor (n), arc length also change by that same factor. For example, if the angle doubles (multiplied by 2) the corresponding arc length will also double. If the radius, orbit, or rotation distance doubles, then the corresponding arc length will double:

(n) arc length = ¢ (n) radius : for example, for a given angle, if the radius is halved by multiplying by 0.5, the corresponding arc length will be halved. This equation can also be expressed as:

(n) arc length = (n) ¢ radius : for example, for a fixed (in value, constant) specific radius, if the angle doubles, the corresponding arc length doubles, or vice-versa

We see that arc length is directly related and proportional (ie., same portions of parts in each similar construction, and therefore, the same ratio) to both the angle and the radius.

Given an arc length, the corresponding sector area can be calculated, and vice-versa, and a discussion of this has been included as part of the topic of: Surface Area Of A Cone, and it is given further ahead in this book.

The circumference (C) of all circles can be divided by its respective diameter (D) a total of π ("pi") times. pi is a value of about 3.14. π is a constant value and classified as an irrational value since this value cannot be fully or rationally represented mathematically as the quotient of one value divided by another, as like a rational value could be represented. For example, 5 is a rational value since 5/1 , 10/2 , and 2.5/0.5 can be used to represent it, or in other words, these division problems have a definite quotient which is 5.0. Irrational values such as π have an endless and non-repeating digit pattern to the right of the decimal point. The approximate value of π correct to fifteen decimal places is:

$$\pi = 3.141592653589793...$$

For any and all circles, the ratio of its circumference to its diameter is a constant value equal to pi:

$\frac{C}{D} = \pi$ therefore mathematically: $C = \pi D$ and $D = \frac{C}{\pi}$

Since the diameter of a circle equals twice the radius of a circle (D=2R):

$C = \pi D = 2\pi R$ therefore, $\frac{C}{R} = 2\pi$: ~ $2\pi = (2)(3.14) = 6.28...$

If an arc length is equal to the circumference of the circle, there are 2π radians in a circle:

$¢ = \frac{\text{arc length}}{\text{radius}} = \frac{C}{R} = 2\pi$ (understood as 2π radians or "rads") : equivalent to a 360° angle, or full rotation. 360° = 2π , 360 degrees = 2(pi) radians

We are now at a point where we can convert between radian and degree angle measurements.

Given 360° = 2π radians after dividing both sides by 2π :

57.29577051° = 1 radian after dividing both sides by 1 radian :

57.29577051° / 1 radian : 57.29577051 degrees per radian

Or given: 2π = 360° (remember, the "radian units" are not often indicated since the values are "numeric" or unitless)

Solving for (1) radian(s):

$\frac{2\pi \text{ rads}}{2\pi} = \frac{360°}{2\pi}$ after canceling:

$1 \text{ rad} = \frac{180°}{\pi}$: about 57.29577951° , or ~ 57.3° as indicated above

Hence, to convert radian angle measurement to its equivalent degree angle measurement, it's simply a matter of repeated addition, or multiplication (to both sides of the equation as shown below), multiply the radian angle measurement by (180°/π) or = 57.29577951°. For example, to convert 0.5 rads (radian units of angle measurement) to it's equivalent amount of degrees, multiply each side of the above equation by 0.5:

Ex. $0.5\ (1) \text{ rads} = 0.5\ \frac{(180°)}{(\pi)} =$ about 28.648° : For a radians to degrees conversion, use the "degrees on top" from the fraction (180°/π) for the multiplication. This is easier to remember than 57.29577951

Given 2π = 360°, solving for (1) degree:

$360° = 2\pi \text{ rads}$ dividing each side by 360:

$\frac{360°}{360} = \frac{2(pi) \text{ rads}}{360°}$ after canceling:

$1° = \frac{\pi}{180} \text{ radians} =$ about 0.017453292 radians. Here, it is obviously easier to remember the numerator and denominator of this fraction, rather than remember this quotient value. If using this quotient value: radians = (0.017453292) (degrees angle)

To convert a degree angle measurement to its equivalent radian angle measurement, multiply the degree angle measurement by (π /180°) = 0.017453292.

Ex. $10°\ (1°) = \frac{10°}{1}\ \frac{(\ \pi\ )}{(\ 180°\ )} = \frac{\pi}{18} =$ about 0.1745 radians : For a radian to degree conversion use "degrees on top"

This is equivalent to multiplying both sides of the previous equation by the same value (here, 10°).

¢ degrees = $\frac{180°}{(pi)}$ (¢ radians) : **radians to degrees conversion**, use "degrees on top".
degrees = 57.29577951 (radians)

¢ radians = $\frac{(pi)}{180°}$ (¢ degrees) : **degrees to radian conversion**, use "pi on top".
radians = 0.017453292 degrees , degrees = radians / 0.017453292

Using a full circle as a starting reference, here's how you can get a perspective of corresponding radian and degree values:

From: 360° = 2(180°) = 2π (about 6.28 radians) : full circle, an angle of a "full turn" or rotation

Dividing by 2 to find out the amount of radians equivalent to 180°:

180° = 1 π = π (about 3.14 radians) : half a circle : = "two quarters" = 50 percent of a circle
π , "pi", as an (radian) angle, can be thought of as half a "full turn" or rotation.

Dividing by 2 to find the radian angle equivalent of 90°:

$90° = \frac{\pi}{2} = 0.5\,\pi$ (about 3.14 / 2 = 1.57 radians) : "one quarter" (25 percent) of a circle

Since 270° = 90° x 3 , and 90° = π/2 we have:

$$270^\circ = \frac{3(\pi)}{(2)} = 1.5\,\pi$$ (about (3)(1.57) = 4.71 radians) : "three quarters" (75 percent) of a circle

Below is a table that summarizes these values:

A TABLE OF CORRESPONDING DEGREE AND RADIAN ANGLE MEASURMENT VALUES

degrees angle = radian angle = (approximate value)

$$90^\circ = \frac{\pi}{2} = \pi/2 = 1.57$$

$$(2)90^\circ = 180^\circ = 2\,\frac{\pi}{2} = 1\pi = 3.14$$

$$(3)90^\circ = 270^\circ = 3\,\frac{\pi}{2} = 1.57\pi = 4.71$$

$$(4)90^\circ = 360^\circ = 4\,\frac{\pi}{2} = 2\pi = 6.28$$

A non-radian analysis of an arc length of a circumference:

Ex. Given a circle, the arc length of a quarter (90°) of its circumference is obviously a quarter (1/4) of that circumference length, hence (1C/4), and since: 360°/90° = 4 :

$S = C/4 = 2(\text{pi})\,r/4 = (\text{pi})\,r/2 = 1.570796327\,r \;=^{\sim}\; 1.570\underline{8}\,r$: for a 90° rotation

For other angles that are not 90° , what is their arc length? We can put that value in terms of what we know with the 90° angle or rotation. For example if the angle is 45° which is half of 90° , we should expect that its corresponding arc length is also half. This is a linear relationship. Expressing this concept in a formula, we have:

$$S = \frac{1.5708\,r}{\left(\frac{90^\circ}{\text{¢}^\circ}\right)}$$

The (straight) diagonal line and-or chord length near and within a 90° arc length part of the circle obviously has a (slightly) shorter length than that of the arc length or portion of the circles circumference:

$$\text{diagonal length} = \sqrt{r^2 + r^2} = \sqrt{2r^2} = \sqrt{2}\,\sqrt{r^2} = 1.414213562\,r$$

SERIES

A mathematical, or numerical series or progression is a sequence (or "string") of numbers or terms that are mathematically related in some way, where either or both the next term or previous term in that specific series can be calculated by knowing the mathematical relationship (ie., a mathematical pattern) between, or of those ("adjacent") numbers or terms.

Every and all terms in a series can be formally represented or expressed algebraically by a single representative term that expresses the general format of each successive term in that series.

Formulas can also be developed to calculate the value of any specific term of a series, or for the sum of a certain number of terms in that series. Later, some very important series will be developed to allow us to calculate things such as trigonometric, natural logarithm, and natural anti-logarithm values from the sum of the terms of these special series.

Here is a pseudo-algebraic description of a series (of mathematically related terms or values):

term1
term2 = mathematical operation(s) applied to term1 : Though the mathematical operation(s) is constant, the
term3 = mathematical operation(s) applied to term2 result of that mathematical operation(s) that is to be
term4 = mathematical operation(s) applied to term3 applied to each term is not necessarily a constant value.
(termN or term(N) using a special notation (and which is not multiplication) and so on for other terms of the series.)

We see that the general format of each successive, or next, term is:

term(n+1) = mathematical operation applied to term(n)

For example, if given a term value of 5, and we keep adding 2 to each term so as to find the value of the next term, we will have this series:

successive term numbers = n: 1 , 2 , 3 , 4 , . . .

successive term expressions: 5 , 5+2 , (5+2)+2 , ((5+2)+2)+2 , ... : (term n+1) = (term n)+ 2 , or:
"next term" = "current term" + 2
Mathematically:
(term n) = (term n+1) - 2 , or:
"previous term" = term - 2

Simplifying the expressions:

successive term values: 5 , 7 , 9 , 11 , , . . . : a portion of an odd numbers series

A certain mathematical operation was applied to a term so as to find the next term. If given that value of the next term, and so as to find the value of the previous term, the inverse, "reverse" or "undoing" operation of that given operation is to be applied to that given term value. The operand will be the same value as that first applied. This can be expressed as:

(term)----> operation -----> (next term) therefore: (next term) -----> inverse operation ------> term
or=: term ------> inverse operation ------> previous term

Ex. 5 -------> +2 -------> 7 therefore: 7 ---------> -2 --------> 5 : checking: 5 + 2 = 7, and 7-2 = 5.
Subtraction and addition are inverse
operations with respect to each other

Since the expressed operation indicated above included both the operand and mathematical operation to apply to the term (which could be either a single value or possibly an expression considered as a single value), another notation is:

(term)-----> function -----> (next term)   therefore: (term) <------ inverse function <------- (next term)
or =:   (next term) -------> inverse function ------> (term)

ARITHMETIC SERIES

In an arithmetic series, successive term values are separated by a value called the difference (d). We are all familiar with the arithmetic series formally known as the counting (whole and integer) numbers where the difference (d) between successive terms is 1:

. . . -3, -2, -1, 0, +1, +2, +3 **. . .**   : integer number series where each term differs by (d=1)

In the "even series": 2, 4, 6, 8, 10, and so on, the change or difference between successive terms and-or between the value of a term and the previous term is always 2. Likewise, for the "odd series": 1, 3, 5, 7, 9, etc. (and so on), as was previously shown, the difference is also always 2. If the difference is not known, it can be found from subtracting the current term from the next term in the series since:

from: current term value + difference = next term.   and   previous term = current term - difference.

difference = next term - current term   difference = current term - previous term

Since a series might not be an ascending (term values increasing as the term number increases) series, but a descending (values decreasing) series, perhaps a better name to use than difference, would be (a signed) change (c) since the value to be added to find the next term may be either positive for an ascending series, or negative as for a descending series. The concept of a difference can still be used, but it must be considered as a "signed difference" so as to be more algebraically and mathematically useful:

next term = current term + change

The actual value of the variable, here called: (change) can be either positive or negative in sign. Any variable(s) such as the ones shown here should be considered as having either a negative or positive sign. This is so because a placeholder is not the actual value, and that what it holds or contains is, and the sign is actually a part of that unique number. Solving for change:

change = next term - current term

Since a value (either positive or negative in sign) is added to a given term so as to find the next term of an arithmetic series, an arithmetic series can be considered or thought of as a "basic addition series".

When the next term becomes, or is now considered as the "new" current term in question, the "old" current term effectively becomes the previous term. Substituting this into the above expression:

change = current term - previous term   solving for previous term:

previous term = current term - change

This can be expressed in a more general way as:

If you were to add the same value (here, d) to each new term or sum created, this can be expressed as:

$\text{value}_{(n+1)} = \text{value}_{(n)} + d;$: n = the corresponding term number , or since the values are the values of the terms, (n+1) would correspond to the next term, and (n-1) would correspond to the previous term. (n) would correspond to the current term:

. . . , "previous terms" , term , "next terms" , . . .
. . . , value(n-1) , value(n) , value(n+1) , . . . or:
. . . , term(n-1) , term(n) , term(n+1) , . . .

Solving for the added in constant value, or (d):

value(n+1) - value(n) = d Given a term in this series and solving for the previous term value:
or: value(n) - value(n-1) = d

value(n+1) - d = value(n) : since value represents the value of a term, the word "term" can be used instead
or: value(n) - d = value(n-1) of the word value:

term(n+1) = term(n) + d

term(n)
term(n+1) = term(n) + 1d
term(n+2) = term(n+1) + d = (term(n) + d) + d = term(n) + 2d

Ex. The whole number series where d = +1:

0, 1, 2, 3, 4, 5, . . . : an ascending (increasing in value) series

Ex. The integer number series where d = +1:

. . . , -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5, . . .

Ex. In this series, d = +2 : :the "even series"

0, +2, +4, +6, 8, . . .

Ex. In this series, (d) is also = +2 : :the "odd series"

+1, +3 , + 5 , +7, . . . : with d = +2, this very similar to the "even series", except that the first term here is 1

Ex. In this series, d = -2 :

. . . , +8, +6, +4, +2, 0, -2, -4, -6, . . . : a descending (decreasing in value) series

Ex. In the series below, d = +2.5 :

. . . , 0, 2.5, 5.0, 7.5, 10.0, 12.5, . . .

For the series above, what is the next term after 12.5?

next term = current term + change

next term = 12.5 + (+2.5)
next term = 12.5 + 2.5 after combining:
next term = 15.0

For the series above, what is the next term after 30?

next term = current term + change
next term = 30.0 + (+2.5)
next term = 30.0 + 2.5 after combining:
next term = 32.5

Let's express the terms of an arithmetic series in a pure (without using actual number values) algebraic format:

term(n), term(n+1), term(n+2), term(n+4), . . . or:

term1, term2, term3, term4, . . . using algebraic substitution:

term1, term1+d, term2 + d, term3 + d

term1, (term1+d), (term1+d)+d, ((term1+d)+d)+d simplifying:

term1, term1+1d, term1+2d, term1+3d

Note that all the terms now contain the initial, reference or (considered as the) "first" term of: (term1), the first term, as part of the expression that represents the value of that specific or current term in question. Each expression for the next term also contains another term added in that is the product of the term number (N) less one, and the difference. Expressing this:

termN = term1 + (N-1)d or: termN = firstterm + (N-1)d : first_term is the value of any term of a series that is being considered as the start, current, or reference term of that (infinite) series of terms

Ex. Here is the expression for the value of the 10th term of an arithmetic series, given the first term:

term10 = term1 + (10-1)d simplifying:
term10 = term1 + 9d

As an example, here is a series where the difference is +3, and if the first term is +2, what is the value of the 10th term?

term10 = term1 + (10-1)d = +2 + (10-1)(3) = 2 + (9)(3) = 2 + 27 = 29 checking:

N = 1 , 2 , 3 , 4 , 5 , 6 , 7 , 8 , 9 , 10
term = 2 , 5 , 8 , 11 , 14 , 17 , 20 , 23 , 26 , 29

Below is another, perhaps similar and simpler form of the above simplification:

Here is a simple method to find the difference (d) between each term of an arithmetic series when two consecutive terms are not even known so as to quickly find the common difference value of that series. Now, rather than have been given two consecutive terms, you are given any two terms of that series and their term numbers Since the difference (d) is added to each term to find the next term and so forth, the total sum of these differences can be expressed with multiplication since multiplication is repeated addition:

(number of terms from an initial term)(d) = (total difference in the terms values) therefore:

$$d = \frac{\text{total difference in terms values}}{\text{number of terms from an initial term}}$$

Ex. What is the common difference (d) of a series if the first term is (considered as) 6 and the fourth term is 10.5?

$d = \frac{10.5 - 6}{4 - 1} = \frac{4.5}{3} = 1.5$, A partial (fragment, portion, section, or segment (of the)) series with this is shown below:

. . . 6, 7.5, 9, 10.5 , **. . .** : d = 1.5

You can also find (d) by writing an equation. If the first term is 6, then the second term is (6 + d), the third term is ((6 + d) + d) = 6 + d + d , or after combining like terms: third term = 6 + 2d. Since we know that the value of the fourth term is 10.5, we get:

term in question - first term = total difference to term in question algebraically:

first term + total difference to term in question = term in question which can be expressed as:
first term + (number of terms from initial term)d = term in question

$6 + 3d = 10.5$ solving for (d), we get:

$3d = 10.5 - 6$
$3d = 4.5$
$d = 4.5/3 = 1.5$

Considering what has just been discussed, a simple formula to find the nth term of an arithmetic series is derived as follows:

Let n = nth term in question
Let F = value of the first or initial term taken, given or considered as the first term of the series

n	=	1	2	3	4	. . .	n	: term number
Term	=	F	(F+d)	(F+d)+d	((F+d)+d)+d	. . .		clearing grouping symbols :
Term	=	F	F+1d	F+2d	F+3d	. . .	F + (n-1)d	: after combining like terms

By observing the above sequence for any patterns, we can arrive at a general (algebraic) formula for the nth term. Notice that the numerical coefficient of d is 1 less than the term in question, hence:

nth term = F + (n-1)d : **FORMULA FOR THE nth TERM OF AN ARITHMETIC SERIES**
Since a series can have an infinite number of terms, there may not be a first term or start of that series, so (n=1) is the number of the term that is taken or considered as the first term of this particular string or segment of terms under consideration.

Using the last example's series, what is the value of the 5th term?

4th term = 6 + (4-1)1.5
4th term = 6 + (3)(1.5) distributing:

4th term = 6 + 4.5 combining:
4th term = 10.5

Checking by adding d=1.5 to the previous or fourth term:

5th term = 4rd term + difference
12.0 = 10.5 + 1.5 :checks

Finding the 5th term directly from the equation:

5th term = 6 + (5-1)(1.5) = 6 + (4)(1.5) = 6 + 6 = 12

Checking:	(n):	1	2	3	4	5	. . .
	term:	6 ,	7.5 ,	9 ,	10.5 ,	12 ,	. . .

Now that we know the formula for the nth term of an arithmetic series, we can also use this with the concept of simultaneous equations so as to find the value of the difference (d) between terms, even though a formula for (d) has already been shown.

Ex. Find the difference (d) if the third term is 6 and the tenth term is 20.

This information can be expressed as a system of simultaneous equations:

third term: F + 2d = 6 : First term + total difference to the 3rd term = third term
tenth term: F + 9d = 20 : First term + total difference to the 10th term = tenth term

Algebraically solving for F in the third term equation:

F = 6 - 2d algebraically substituting this value of (F) into the equation for the tenth term:

F + 9d = 20
(6 - 2d) + 9d = 20 removing parentheses (distribute +1):
6 - 2d + 9d = 20 combining like terms:
6 + 7d = 20 transposing terms which do not contain the variable (d) in question to the other side of the equation:

7d = 14 dividing the left and right side by 7 to isolate (d):
d = 2

The two simultaneous equations above were solved using an algebraic substitution method, however, the addition and subtraction method, or any other possible method could also have been used.

At this point, you can also find the value of the first term (F) by substituting (d) into any of the original simultaneous equations:

F + 2d = 6 F = value of the first timer. Solving for F, after transposing (2d):
F = 6 - 2d substituting the calculated value for (d):
F = 6 - 2(2) distribute to clear grouping symbols:
F = 6 - 4 combining:
F = 2

Here is the partial series:

Term n :	1	2	3	4	5	6	7	8	9	10 . . .
Term value:	. . . 2 ,	4 ,	6 ,	8 ,	10 ,	12 ,	14 ,	16 ,	18 ,	20 , . . .

Though less used, to solve for previous terms in an arithmetic series, the change (regardless if its positive or negative in value) is not added, but subtracted instead since:

From: next term = previous term + change , and if the next term becomes the new current term of reference:

current term = previous term + change therefore:
previous term = current term - change or:

current term = previous term + d therefore:
previous term = current term - d

With F still considered as the first term, this leads to a slightly rewritten formula for the nth (previous) term of an arithmetic series:

first term = F : n=0
first previous term = (F - d) : n=1
second previous term = (F - d) - d = F - 2d : n=2

nth previous term = F - nd : **FORMULA FOR THE nth PREVIOUS TERM OF AN ARITHMETIC SERIES**

As a final note, considering any three consecutive terms of an arithmetic series, the second term, or "middle term", can be found without knowing the difference (d) between any terms.

Term #:	n	n+1	n+1	considering term n as the first term for this specific analysis:
Term:	F	F+d	F+2d	

Adding or "summing" the first term and third term (essentially, the previous term and next term considering if they were in reference to the second or middle term):

Sum = F + (F + 2d) clearing grouping symbols:
Sum = F + F + 2d combining like terms:
Sum = 2F + 2d factoring 2:
Sum = 2(F + d) dividing both sides by 2:
$\frac{\text{Sum}}{2} = (F + d)$: We arrive at the value of the second term. This derivation indicates, that the middle term can simply be found using the arithmetic mean of the two given terms.

Note also that (d) can be found by:

$d = \frac{\text{Sum}}{2} - F$: due to the derivation, as noted above, Sum = previous term + next term, when considering the (middle) term between those two terms in the series. Essentially, three consecutive terms of the series will be found: first, second or middle, third or terms: n , (n+1), (n+2)

Subtracting the first term from the third term, (2d) and also (d) can be found:

2d = (F + 2d) - (F) Let 2d equal the total difference between the first and third terms. Distributing (-1):

$2d = F + 2d - F$ combining like terms:
$2d = 2d$ after solving for (d) by dividing by 2:
$d = d$

Ex. If the first term (or any term considered as the first) is 5 and the third term is 15, what is (d)?

$15 - 5 = 10$: $10 = 2d$

$$d = \frac{10}{2} = 5$$

The above concepts can be expanded into another general formula to find (d) :

Considering one term as the first term (F) and the nth term as $F_n = F + (n-1)d$ and subtracting the two values to find the total difference:

nth term - First Term = total difference

total difference = $F + (n-1)d - F$ combining like terms:
total difference = $(n-1)d$ isolate (d) by dividing by its multiplying factor of (n-1):

$$d = \frac{\text{total difference}}{(n-1)} = \frac{(n-1)d}{(n-1)} = d$$: or in general:

$$\mathbf{d = \frac{Fn - F}{n-1}}$$: this is similar to an average formula, here, an average difference or change from F to Fn, and (n-1) is the "number of differences". (Fn - F) is the total difference or change.

Ex. If the first term is 3 and the fifth term is 15, find (d).

$$d = \frac{15 - 3}{5-1} = \frac{12}{4} = 3$$ here is the partial series:

. . ., 3, 6, 9, 12, 15, . . . : $d = 3$

A method to find the nth previous term of an arithmetic series can be developed which uses the same formula to find the nth next term of an arithmetic series, however, the change or difference used in the formula will be noted as the "inverse", "reverse", or negative of the difference = $-(d) = -d$:

next term = term + d or next term = previous term + d mathematically:
previous term = next term - d or previous term = term - d the next previous term is:
previous term - d = (term - d) - d = term - d -d = term - 2d = F - 2d observing the pattern:

nth previous term = $F + n(-d) = F + n(-1)(d) = F + (-1)nd =$ **F - nd : nth previous term of an arithmetic series**

The appendix contains a discussion about summing consecutive terms of an arithmetic series.

GEOMETRIC SERIES

In a geometric mathematical or number series, successive or adjacent terms or numbers differ or vary by a constant factor value. This factor is simply called the ratio (r). To find the next term of a geometric series, multiply the current term by the common ratio value between the terms. In a reverse type of manner, to find the previous term of a geometric series, divide the current term by the ratio value. If the ratio for a geometric series is not known, it can be found by dividing the next term by the current term in the series, or dividing the current term by the previous term.

(term) x (ratio or multiplier) = (next term) : letting (term) = (current term) in question or as reference to both the (previous term) and (next term)

$$\text{ratio} = \frac{\text{next term}}{\text{term}} = \frac{\text{term}}{\text{previous term}}$$

If the next term is now considered as the current term, the "old" current term effectively becomes the previous term:

previous term x ratio = term solving for previous term:

$\text{previous term} = \frac{\text{term}}{\text{ratio}}$ or = term/ratio = (term) (1/r) = term or current term times the reciprocal of the ratio. In one direction, to find the next term, we multiply by (r), and to find the next term in the other direction, we multiply by (1/r), the reciprocal value, which is the same as dividing by that ratio value. Still, in either way or direction, the multiplier is the essentially the reciprocal of the value used for the other direction.

This can be expressed in a more general way as:

value(n+1) = (r) value(n) : n = the corresponding term number , or since the values are the values of the terms:

term(n+1) = (r) term(n) mathematically:

$\frac{\text{value2}}{\text{value1}} = \frac{\text{term(n+1)}}{\text{term(n)}} = r$ mathematically:

$$\frac{\text{term(n+1)}}{r} = \text{term(n)}$$

Ex. In a series, the first term is 3, and r = +2:

For one direction: multiplier = factor = r = 2

term x multiplier = next term

3
3 x 2 = 6
6 x 2 = 12
12 x 2 = 24
24 x 2 = 48

. . . , 3, 6, 12, 24, 48, **. . .** : an ascending (in value) series, since: (r > 1)

For the other direction: multiplier = factor = (1/r) = 1/2 = 0.5 : multiplying by (1/r) is the same as dividing by (r)

term x multiplier = next term

48 : here, considering 48 as the first term, but any term in the (ascending) series could be used
48 x 0.5 = 24
24 x 0.5 = 12
12 x 0.5 = 6
6 x 0.5 = 3

. . ., 48, 24, 12, 6, 3**, . . .** : a descending (in value) series, since: (r < 1)

Ex. Here is another series where r=+2:

1, 2, 4, 8, 10, **. . .** : r = +2

Ex. 1.5, 3, 4.5, 6.75, 10.125, **. . .** : r = +2

Ex. In the series below, r = +0.5

. . . , 100, 50, 25, 12.5, 6.25, **. . .** : a descending series, r < 1 , here the multiplier = +0.5, but in the other direction the multiplier to find the next term is (1/r) = (1/0.5) = 2 , since 2 > 1, the value of the terms will increase or "ascend".

Ex. In the series below, r = -2

. . . , +100, -200, +400, -800, **. . .** : an "alternating series". This description is in reference to the alternating sign of the terms, where the terms alternate or change in positive or negative sign. Considering just the absolute or signless value of each term, it is an ascending series. This is because the absolute value of (r) is still greater than 1.

Here is a method to find the common ratio (r) between terms of a geometric series when two successive or consecutive terms are not known:

Let n equal the term number in question. Let F equal the value of the first, or any term considered, taken or given as the first or reference term of the series in question.

n	=	1	2	3	4	**. . .**	
Term	=	F	Fr	(Fr)r	((FR)r)r	**. . .**	after simplification:
Term	=	F	Fr	Fr^2	Fr^3	**. . .**	

By observing the above sequence for any patterns, we can derive or develop a general formula for the nth term of a geometric series. Notice that the indicated power (the exponent) of (r) is 1 less than the term number in question, hence:

nth term = Fr^(n-1) : **FORMULA FOR THE nth TERM OF A GEOMETRIC SERIES**

Ex. If the first term of a geometric series is 2 and the third term is 18, what is the second term?

To solve, first find the value of (r) for this particular series. We know:

F = 2 : first term, and where n=1: Fr^(n-1) = 2r^(1-1) = 2r^0 = 2(1) = 2

Fr^(3-1) = Fr^2 = 18 : third term

Choosing to solve these simultaneous equations for (r) by algebraic substitution:

Fr^2 = 18 substituting the known value of the first term:
(2)r^2 = 18 solving for (r)

r^2 = $\frac{18}{2}$

r^2 = 9 taking the square root of both sides of the equation:

r = $\sqrt{9}$ = 3

The second term is therefore:

Fr^(2-1) = Fr^1 = 2(3^1) = 6

And the (partial) series is shown below:

. . ., 2, 6, 18, . . . : r=3

When r<1 and positive (usually indicated as 0<r<1, ie. a fraction of 1, since it is less than 1), that the values of the next terms will get smaller and smaller till they are effectively meaningless or practically equal to zero. If the terms of this type of series are summed from any point (ie. a term) in that series, the sum of those terms will approach a definite or specific value. The sum is said to converge or "zero-in" (having only a small negligible difference, practically 0) to a certain value. This type of series is called a converging series. Even with this said, it is possible for the terms of some geometric series to get smaller and smaller and yet the sum does not converge to a specific value. These types of series are called diverging or divergent series. When making calculations where only one specific value is being sought, converging series will obviously be utilized.

There are many other useful formulas for working with series, such as the sum of the first (n) terms of a series that is shown in the appendix section of this book. This basic discussion on series is meant to prepare you for the discussions that follow in this book. It should also be mentioned that the series, such as the trigonometric series, to be discussed further ahead, do not have a constant difference or ratio between successive terms. Each term is still predictable due to a pattern and can be calculated (ie. via an algebraic formula), and that the sum of these series still converges to a specific value. This specific value of the sum of terms depends upon the specific value of the independent value or variable used in the terms that are to be summed. This calculation using a series of terms is still an approximation (ie., not "algebraic" or exact as with a simple formula) of the true result, and as close (ie., acceptable precision, fineness) as desired.

How do I solve for a previous term of a geometric series?

Though less used, the method to solve for the previous term of a series is based on the same method to find the next term of a series:

From: (term) (r) = (next term) mathematically:

$$r = \frac{\text{next term}}{\text{term}} \quad \text{or=} \quad \frac{\text{next term}}{\text{current term}} \quad \text{or=} \quad \frac{\text{current term}}{\text{previous term}} \qquad \text{mathematically:}$$

$$\text{term} = \frac{\text{next term}}{r} \quad \text{or:} \quad \text{previous term} = \frac{\text{term}}{r} \quad \text{or:} \quad \text{previous term} = \frac{\text{current term}}{r} = \text{current term } (1/r) \text{ , therefore:}$$

The ratio of the previous term to the current term is (algebraically solving for it):

$$\frac{1}{r} = \frac{\text{previous term}}{\text{current term}} = r\text{^-1} = (1/r)$$

This is essentially the inverse or "reverse" of the ratio of that of when finding the value of the next term in a geometric series. This reciprocal of (r) can still be >1 or <1, and it depends if the initial series was an ascending (r>1), or descending (r<1) series.

$$\text{previous term} = \text{current term} \; \frac{(\,1\,)}{(\,r\,)} = \text{current term } (r\text{^-1}) = \frac{\text{current term}}{r}$$

Ex. If the 7th term of a series is known to have a value of 64, and (r) is known to have a value of 2, what is the 3rd term?

Since we are to find a previous term, we can essentially construct a new series using the inverse or "reverse" ratio:

$$\frac{1}{r} = \frac{1}{2} = 0.5 \qquad \text{or:} \quad \text{new r} = 1/\text{old r} = r\text{^-1} = 1/2 = 0.5$$

Since (r) is now less than 1, the value of the next following terms in this new series will decrease.

Considering F as the first term of this new (reverse) series, the second term in this new series is Fr. The next or third term is the value of the second term times (r): (Fr)r = Fr^2. Observe the pattern: the exponent of (r) corresponds to the nth previous term of the original series.

nth previous term = Fr^n : **FORMULA FOR THE nth PREVIOUS TERM OF A GEOMETRIC SERIES**
(Note: here r is the "inverse", reciprocal or reverse ratio of the original series)

From the given series, the 3rd term is (7 - 3) = 4 terms lower (ie. the 4th previous term) than the 7th term that is considered as the first term in this analysis:

nth previous term = Fr^n considering 64 as the first term:
4th previous term = 64(0.5^4)
4th previous term = 64(0.0625)
4th previous term = 4

Another analysis to find the nth previous term of a geometric series is as follows:

Since: (term) (r) = next term , or: (previous term) (r) = term , Considering term = first term = (F) :

$$\text{previous term} = \frac{F}{r}$$

Dividing the previous term by (r) so as to find the term that preceded it (ie., the 2nd term in this series):

$$\frac{\frac{F}{r}}{\frac{r}{1}} = \frac{F}{r^2}$$

Continuing this process of dividing by (r) so as to find the next previous term, we note a pattern that the resulting or indicated power of (r) and the term in question are the same, and we arrive at a formula for the nth previous term:

nth previous term $= \frac{F}{r^n} = Fr^{-n}$: **FORMULA FOR THE nth PREVIOUS TERM OF A GEOMETRIC SERIES**
(r is the normal ratio of the series, n corresponds to the nth previous term)

Here is a simple verification to this formula: Consider the "formal" or algebraic expressions for the terms of a geometric series:

$\ldots,\ Fn,\ Fr^{(n+1)},\ Fr^{(n+2)},\ Fr^{(n+3)},\ \ldots$ for our purposes here, letting n=0:

$\ldots,\ F,\ Fr^1,\ Fr^2,\ Fr^3,\ \ldots$

Now, consider any term as the first term. It is quite obvious that the power of (r) of the next term is one higher, and that the power of (r) in the previous term is one less. Letting **Fr^0 = F** be the first term or reference term:

previous terms $\ldots,\ Fr^{-3},\ Fr^{-2},\ Fr^{-1},\ \mathbf{Fr^0},\ Fr^1,\ Fr^2,\ Fr^3,\ \ldots$ next terms

$$\ldots,\ \frac{F}{r^3},\ \frac{F}{r^2},\ \frac{F}{r^1},\ \mathbf{F},\ Fr^1,\ Fr^2,\ Fr^3,\ \ldots$$

We see that the first previous term has the divisor of (r) to the first power, the second has (r) raised to the second power and so on.

From the last example given, the 3rd term is (7 - 3) = 4th previous term:

4th previous term $= \frac{F}{r^4} = \frac{64}{2^4} = \frac{64}{16} = 4$:checks

As a final note for this discussion about geometric series, if given any three consecutive terms of a geometric series, the second term, or "middle term", is the geometric (as opposed to arithmetic) mean of the first and third terms. Mathematically, a geometric mean of two values is the square root of the product of those two (factor) values:

Term #:	1	2	3
Term:	F	Fr	Fr^2

Multiplying the first and third terms:

$(F)(Fr^2) = F^2r^2$

Taking the square root of this value, we arrive at the value of the "middle" term, and we verify the definition:

$$\sqrt{F^2 r^2} = \sqrt{F^2}\,\sqrt{r^2} = Fr$$

Mathematically, we also see that a geometric mean is also the product of the square roots of both factors or terms.

Ex. Suppose that there are squares with areas of: 2, 4, and 8. This is a geometric series with $r=2$. The geometric mean of 2 and 8 is:

$\sqrt{(2)(8)} = \sqrt{2}\,\sqrt{8} = \sqrt{16} = 4$: the geometric mean of the areas is 4

$\sqrt{(2)(8)} = \sqrt{16} = 4$

Notice that the value of 4, or the ratio (here, $r=2$) between terms was not needed in this calculation.

If given a value (considered as the first term) and another value (considered as the third term) you can find the value of the ratio by the following fact:

$\frac{\text{third term}}{\text{first term}} = \frac{Fr^2}{F} = r^2$ and:

$$r = \sqrt{r^2} = \sqrt{\frac{\text{third term}}{\text{first term}}}$$

Ex. If the first term is 3 and the third term is 75, what is the second or "middle" term, and what is (r) ?

$\text{second term} = \text{geometric mean} = \sqrt{(3)(75)} = \sqrt{225} = 15$

$r = \sqrt{\frac{75}{3}} = \sqrt{25} = 5$: = third term / second term = 75/15 = second term / first term = 15/3

The second term can also be found from: $Fr^1 = (3)(5) = 15$

Using these facts, it is now possible to solve for (r) given any two terms, that are not necessarily separated by only one term, of a geometric series (without using simultaneous equations as previously shown):

Ex. If the first term is considered F, and the nth term is $Fr^{(n-1)}$, we have:

$$\frac{Fr^{(n-1)}}{F} = r^{(n-1)}$$

To isolate (r), that is, the base of this indicated power value, take the (n-1) root of this power:

$$r = \sqrt[(n-1)]{r^{(n-1)}} = r^{((n-1)/(n-1))} = r^{(1/1)} = r$$

Ex. If the first term is 1000 and the thirteenth term is 2000 find (r).

$\frac{2000}{1000} = 2 = r^{(n-1)}$ since the nth term is term 13, and $(n - 1) = 12$, taking the 12th root of both sides:

$r = \sqrt[12]{2} = 1.059463094$: An important musical constant, as shown previously in this book

Ex. Here is a series where r=2:

. . . , 2, 4, 8, 16, 32**, . . .**

Note here that you can find the value of (r) by several ways. You can divide any term by the previous term, or consider the values somewhat like the corresponding values in the equation to find the slope (m) of a line since the ratio (r) is the (constant) rate of change for a line and for a geometric series of terms. That is, r=m:

First let: $y1 = m\,x1$ and $y2 = m\,x2$: linear equations, $m = r = yn/xn$

$y1 = r\,x1$ and $y2 = r\,x2$

Ex. $4 = (2)\,2$ and $32 = (2)16$: these values in the series above
p1(x1,y1) = p(2,4) and p2(x2,y2) = p(16,32)

$$m = r = \frac{y2 - y1}{x2 - x1}$$

Ex. $$m = r = \frac{16 - 4}{8 - 2} = \frac{12}{6} = 2$$

Checking: $$\frac{(n\,r\,r\,r) - nr}{(n\,r\,r) - n} = \frac{nr^3 - nr}{nr^2 - n} = \frac{r\cancel{(nr^2 - n)}}{\cancel{(nr^2 - n)}} = r$$: For the specific example: F = n = 2

Extra: If the sum of 4 consecutive terms of this series is 30, what is the first term of those 4 consecutive terms if r=2?

$n1 + n2 + n3 + n4 = 30$ considering n1 as the first term, we can express each term in terms of n1:
$n1 + n1r + n1r\,r + n1\,r\,r\,r = 30$
$n1 + n1r + n1r^2 + n1r^3 = 30$ dividing each term by n1 :
$n1\,(1 + r + r^2 + r^3) = 30$ and if r = 2:
$n1\,(1 + 2 + 2^2 + 2^3) = 30$
$n1\,(15) = 30$ solving for n1:
$n1 = 30/15 = 2$

The appendix contains a discussion about summing consecutive terms of a geometric series.

FIBONACCI SERIES

The Fibonacci number series was known to the mathematicians in India long ago, but today, it is usually credited to Leonardo (Fibonacci) of Pisa due to his work with the Golden Ratio (a special value of about 1.6180...) and the fact that this simple series has many properties that involve this ratio value. Fibonacci is also credited to spreading the knowledge of the decimal number system (first developed and used by the people in India, and then into the refined and popular symbols and some basic algebraic use with the Arabs) into Europe in about 1202AD as a better alternative to the commonly used and awkward (for advanced calculations and mathematical advancements) Roman numeral system.

The Fibonacci series is not a simple arithmetic series where there is a common (constant) difference between successive terms, and it is not initially a geometric-like series with a common (constant) ratio between successive terms. The terms of this series are from the whole, counting or "natural (as often found in nature)" numbers (ie., 0, 1, 2, 3, 4, 5 ... up to infinity). The specific values actually used in this series are often found in nature, such as the number of petals on flowers, naturally arranged rows of fruits and seeds, and other natural arrangements. Each next term of the series is quite simple to calculate and it is simply the sum the two previous terms. The first term of the Fibonacci series is 1. Here are some of the initial terms of the Fibonacci series:

0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, 377, 610, 987, 1597, 2584, . . .

An expression for each next number (or term n) in this series is: $Fn = F(n-1) + F(n-2)$

Ex. What is the next term after 2584 in the above series?

From: $Fn = F(n-1) + F(n-2)$
$Fn = 2584 + 1597$
$Fn = 4181$

The higher the term number, the ratio of the value of a term to the previous term approaches the value of the Golden Ratio (about 1.6180...).

Ex. $\frac{4181}{2584} = 1.618034056$ we will use G to represent this value here:

The higher the term number, this equation approaches a value of G:

From: $\frac{F(n+1)}{Fn} = G$, mathematically:

$F(n+1) = G\,Fn$: as (n) increases, and for practical purposes as (n>=10), this approaches a geometric series where Fn is essentially the previous term of the term F(n+1), and that the common ratio becomes a value that approaches G = the golden ratio =~ 1.618...

The Fibonacci series found in nature can be described as that it expresses the essence of undying, ideal life, and which reproduces and-or divides into 2, and then summing up that which was previously born so as to have the total.

SIN ¢ SERIES

The SIN ¢ series is presented below. Of all the various trigonometric series, it is a good idea, at some point in your mathematical journey, to try memorize the basic format of the SIN ¢ series, and so as to always have a mathematical foundation to find the various trigonometric values of an angle. The COS ¢ and TAN ¢ values can also be calculated from the SIN ¢ value. This is so, since any angle has a specific set of corresponding (SIN, COS, and TAN) trigonometric values associated with it. The appendix also contains a few more series such as the COS ¢ series, and a derivation of the SIN ¢ series. Here is the common "formula" for the SIN ¢ series:

$$\text{SIN } X = \sum_{n=0}^{n=\infty} \frac{(-1)^n \; X^{(2n+1)}}{(2n+1)!}$$

: X is a radian angle. The ∞ symbol means "infinity". Though infinity does not have a specific value, it indicates an endless process, and here, an endless number of terms to be summed together, in theory, are needed for the true result, In practice, the number of terms used is relatively few due to that the sum is converging or becoming equal to the true value very quickly with only a few terms with just a small difference between them, and therefore, only a small difference between the sum and the true result. The expression on the right is the general format for each term that is to be summed together.

To properly use this series, X must be a radian angle measurement. Radians (units) is a natural or inherent (to the circle, or rotating points) measurement for angles, but degrees (units) are not totally natural since they are man made units for the measurement for angles, specifically with the near random value of 360.

The symbol that looks like a large S alphabetical letter is called "Sigma" and is to be considered as the symbol and first letter for summation. Here, mathematically related terms are to be summed, and the basic format for each term is shown to its right side. (n) is a variable value that will change in the expression for each next term by an increment of 1. That is, n is the term number, and for the first term n=0 (as indicated immediately below the summation symbol). For the second term, n=1, for the third term, n=2, and so on till (n) is equal to infinity (∞) as indicated at the top side of the summation symbol.

In short, the notation means: "evaluate the terms from n=0 to n=∞, and sum them". Usually, far fewer terms than an infinite number of terms will be utilized for the sum since the value of the "next" terms get significantly smaller and rapidly converges or approaches to being a value close to 0 and meaningless, and the sum of those limited number of terms then rapidly converges or approaches a specific numerical value. The actual number of terms to be utilized for the sum depends on the number of correct (ie., accurate) decimal places (ie., the "precision", preciseness or fineness) desired.

As a basic rule for this series, for (x) decimal places of accuracy, sum (x+2) terms. When X < (π /4), (about 0.79), equivalent to an angle of: ¢<45°, fewer terms are usually required. The value of the factor (-1)^n will produce alternating (positive and negative) signs or values of the terms, hence an "alternating series". **!** (an exclamation point) is called the **factorial** symbol. It is the accepted symbol used to indicate the product of all integers from 1 up to and including the indicated value that precedes it:

n! = product of all integers from 1 up to and including n : n! is read as "n factorial"

Ex. 4! = 1 x 2 x 3 x 4 = 24 : "4 factorial"

Ex. 5! = 1 x 2 x 3 x 4 x 5 = 120

A factorial of a number (N) can easily be found by taking the previous integer factorial and multiplying it by that number:

$$N! = (N-1)!\,N$$

Ex. $5! = (5 - 1)!\,5$
$5! = (4!)\,5 = 24\,(5) = 120$

Checking: $5! = 1 \times 2 \times 3 \times 4 \times 5 = 120$ which can be expressed as:
$5! = (1 \times 2 \times 3 \times 4)\,5$ the value within the grouping symbols can be expressed as:
$5! = (4!)\,5$: this checks or corresponds with that shown above

Note: $(A!)(B!) = A!\,B!$ does not equal $(AB)!$ or $(A + B)!$.

For example: $2!\,3!$ /=/ $(2 \times 3)!$ /=/ $(3 + 2)!$
$(2)(1)\,(3)(2)(1)$ /=/ $6!$ /=/ $5!$
$(2)\,(6)$ /=/ 720 /=/ 120
12

However since 3! contains 2! as a factor:

$$2!\,3! = 2!\,(2! \times 3) = (2!)(2!)(3) = (2!)^2\,(3) = 2^2\,(3) = 4(3) = 12$$

As you can see, you can treat the entire factorial expression (and not just the numerical coefficient of the ! symbol) as like a variable, for example, Let $3! = A = 6$, and then: $A! = (3!)! = (6)! = 6! = 720$.

Here are the first 20 factorials:

1! = 1
2! = 2
3! = 6
4! = 24
5! = 120
6! = 720
7! = 5,040
8! = 40,320
9! = 362,880
10! = 3,628,800 : = 9! (10)
11! = 39,916,800
12! = 479,001,600
13! = 6,227,020,800 : = (62,270,208)(100) , can use this for some calculators with a limited number of digits
14! = 87,178,291,200 for each factor or entry.
15! = 1,307,674,368,000 : = (12!)(13)(14)(15) = (12!)(2730) = (479,001,600)(2730)
16! = 20,922,789,888,000
17! = 355,687,428,096,000
18! = 6,402,373,705,728,000
19! = 121,645,100,408,832,000
20! = 2,432,902,008,176,640,000 = 19! (20)

"Expanding" the SIN ¢ series by substituting values for (n) and expressing the sum of each term:

$$\text{SIN } X = X^1 - \frac{X^3}{3!} + \frac{X^5}{5!} - \frac{X^7}{!} + \frac{X^9}{9!} - \frac{X^{11}}{11!} + \frac{X^{13}}{13!} - \frac{X^{15}}{15!} \ldots$$

Notice that terms of the expanded series can easily be memorized as having this general form:

$\pm \frac{X^{odd}}{odd!} \ldots$: A simplified formula for each term of the SIN X series.
odd = odd numbers starting at number 1.
The first term is positive.

To assist calculations, the factorials were evaluated (simplified) in the series of terms below:

$$\text{SIN } X = X - \frac{X^3}{6} + \frac{X^5}{120} - \frac{X^7}{5{,}040} + \frac{X^9}{362{,}880} - \frac{X^{11}}{39{,}916{,}800} + \frac{X^{13}}{6{,}227{,}020{,}800} - \ldots$$

For the 7 terms shown, an accuracy of 9 correct significant decimal digits for angles between 0 and 90 degrees can be achieved by using a computer that can perform computations with 16 digits. Further terms used in the sum will result in the next accurate (correct) significant digit(s) with a descending or less decimal weight of which you may then compare to the previous sum. The smaller the angle, the fewer the terms required for a given precision. It is also possible to use the reciprocals of the denominators as factors (multipliers) in the numerators; (1/denominator), if you prefer multiplication rather than division.

Ex. What are the sine, cosine, and tangent values of 60°.

Converting 60° to its equivalent radian angle measurement required for the SIN X series or formula we find:

60° = about 1.047 (radians or rads)

Since only 3 decimal places are utilized for the angle's approximation, the best accuracy, and practically regardless of the number of terms evaluated, that can be expected for the SIN 60° result using the SIN ¢ series (or even from a calculator) is only about 3 decimal places.

Substituting 1.047 for X in the SIN ¢ formula, and using only the first 4 terms of its expansion (ie., as a sum of terms):

$$\text{SIN } 1.047 = \frac{1.047}{1} - \frac{(1.047)^3}{6} + \frac{(1.047)^5}{120} - \frac{(1.047)^7}{5040} + \ldots$$

Here, it is easier to simplify each fraction rather than trying to add them all using a common denominator.

SIN 1.047 = 1.047 - 0.1913 + 0.0105 - 0.0003 : using approximate values of the terms

SIN 1.047 = 0.8659

Hence, SIN 60° = SIN 1.047 = $0.86\underline{6}$

From COS ¢ = $\sqrt{1 - \text{SIN}^2 ¢}$: finding the COS ¢ using the corresponding SIN ¢

COS 60° = $\sqrt{1 - (\text{SIN } 60°)^2}$

COS 60° = $\sqrt{1 - (0.866)^2}$

$\text{COS } 60° = \sqrt{0.25}$ (rounded)

$\text{COS } 60° = 0.5$:actually, this happens to be exact (due to the rounding), but in general, the result should be considered as only an approximation as noted above)

An alternate method to find COS 60° is from the fact that complementary angles have the same trigonometric co-function values.

$\text{COS } ¢ = \text{SIN } (90° - ¢)$: ¢ and (90° - ¢) are complementary angles. They sum to 90°.
$\text{COS } 60° = \text{SIN } (90° - 60°)$
$\text{COS } 60° = \text{SIN } 30°$: This indicates that you can calculate SIN 30° so as to find COS 60°. Since 30° is a smaller angle value than 60°is, it will cause the series to converge to a specific value (result) faster (fewer terms required).

From $\text{TAN } ¢ = \frac{\text{SIN } ¢}{\text{COS } ¢}$: Finding TAN ¢ given the angles corresponding SIN ¢ and COS ¢ values.

$\text{TAN } 60° = \frac{\text{SIN } 60°}{\text{COS } 60°} = \frac{\text{SIN } 60°}{\text{SIN } 30°}$: optionally finding Tan ¢ using only SIN ¢ values

$\text{TAN } 60° = \frac{0.866}{0.5} = 1.732$: approximately

If you have an 8-digit display calculator, or are performing the calculation completely by hand (where multiplication may be preferred over division), you may prefer to use the SIN X series expressed in this form:

$$\text{SIN } X = X - \frac{X^3}{6} + \frac{X^5}{120} - \frac{X^7}{5{,}040} + \frac{X^9}{362{,}880} - \frac{X^{11}}{39{,}916{,}800} + \frac{X^{13}}{6{,}227{,}020{,}800} - \ldots$$

$$\text{SIN } X = X - \frac{X^3}{6} + \frac{X^5}{120} - \frac{X^7}{504\ (10)} + \frac{X^9}{36{,}288\ (10)} - \frac{X^{11}}{399{,}168\ (100)} + \frac{X^{13}}{62{,}270{,}208\ (100)} - \ldots$$

$$\text{SIN } X = X - 0.1666667\ X^3 + 0.0083333\ X^5 - 0.0019841\ (0.1)\ X^7 + 0.000{,}027{,}6\ (0.1)\ X^9 - 0.000{,}002{,}5\ (0.01)\ X^{11} + 0.000{,}000{,}02\ (0.01)\ X^{13}$$

For an angle of 90° you can expect about 6 decimal places of accuracy. As the angles get smaller, you can expect better accuracy. For example, with all the terms shown, you can expect about 8 decimal places of accuracy for angles around 45°, and 4 digits of accuracy using only three terms. Don't expect too much more accuracy for smaller angles since only 8 digits of the reciprocals of the denominators of the original series are shown and will be used in the calculations. Some of the reciprocals were also rounded. If you have a 10-digit display calculator, you may wish to rewrite the SIN X formula in a similar manner using 10 digit values.

The appendix contains a computer program to calculate the sine of an angle.

TRIGONOMETRY OF ANGLES GREATER THAN 90°

One might logically think that since SIN 90° = 1, that the SIN value of angles greater than 90° is greater than 1. This is however not so since the maximum SIN value, regardless of the angle, is always 1.

$$\text{SIN } ¢ = \frac{\text{side opposite the } ¢}{\text{hypotenuse}}$$: Trigonometric values are formally defined using a right triangle.

And we know that in a right triangle:

hypotenuse > side opposite and hypotenuse > side adjacent ,

that is, the hypotenuse is always the longest side, and using this fact in the SIN ¢ definition above, the numerator will always be smaller than or equal to the denominator, and therefore, this ratio is always less than or equal to 1 mathematically. Only when the angle is 90°, the side opposite this angle will then be equal to the length of the hypotenuse side.

From 90° to 180°, the SIN values start to decline in a corresponding "reverse" (or "mirror image") type of manner and are equivalent to what would be for the (declining) SIN values of angles from 90° back to 0°. This is indicated in the figure below as the angle of (90°- Q1), which is also the complementary angle value to Q1. That is, each obtuse (>90°) angle has an equivalent SIN value of an (corresponding or trigonometrically equivalent) acute angle between 0° and 90°. After calculating this corresponding acute angle, you can use it as an (trigonometrically) equivalent angle of reference, or reference angle, to calculate the trigonometric values of angles greater than 90°.

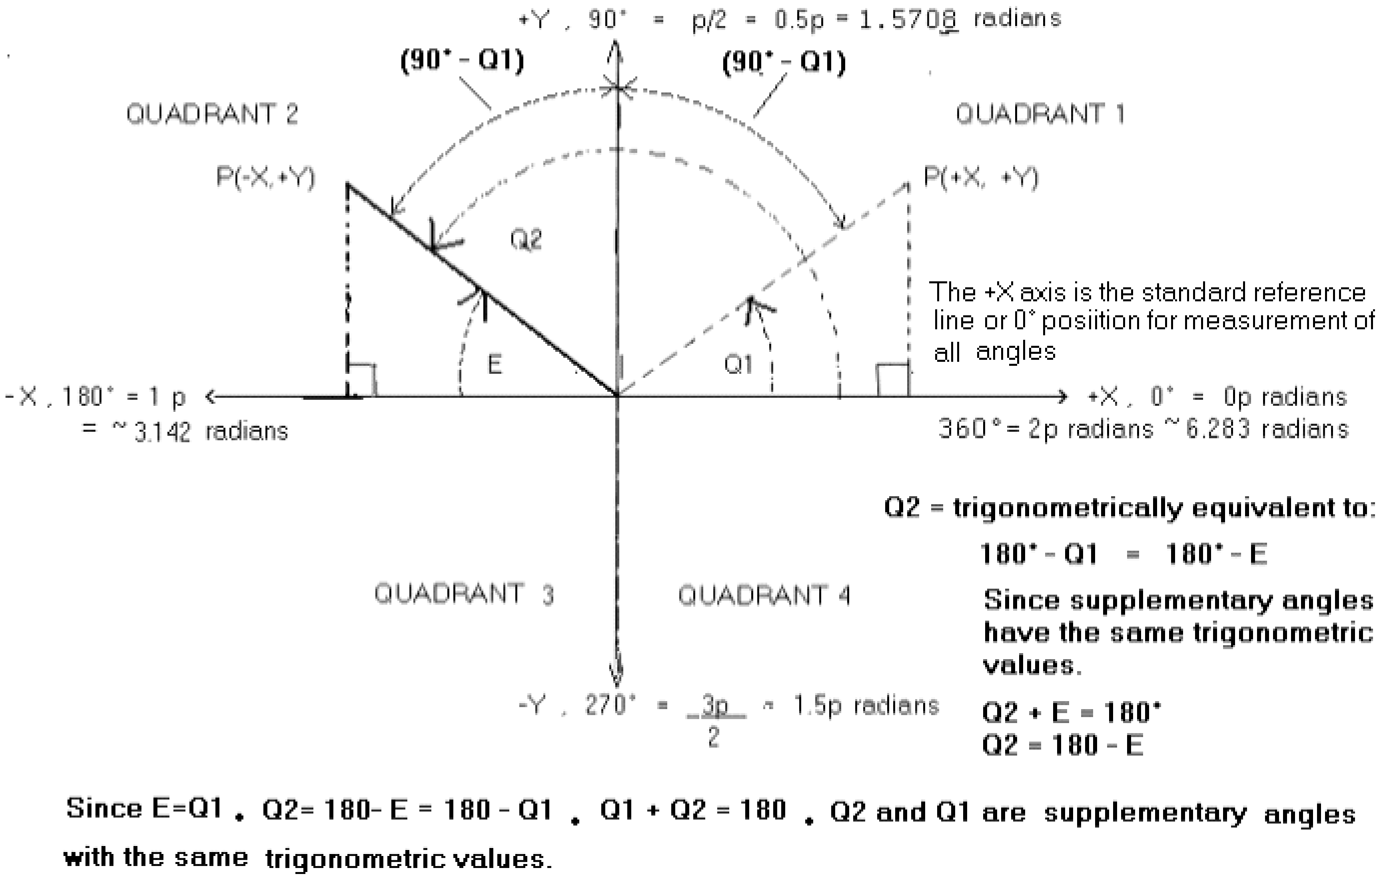
In the full range of angles from 0° to 360°, the trigonometric values will cycle or repeat within 90° (but not necessarily every 90, due to the nature of the SIN values or waveform, as will be seen in a graph below) , hence they will repeat a total of four times. Therefore, the trigonometric values for angles in the range of angles from 0° to 90°, can simply be reused (as a reference) for the trigonometric values of all the remaining angles between 90° and 360°.

In this discussion, Qn is used indicate a quadrant of the rectangular coordinate measuring system, where (n) will have a value of 1 to 4. A quadrant angle is an angle measured in reference to the x-axis, 0° reference line or angle. If the ending or terminal side of that angle is in a specific quadrant, the angle is associated and indicated as an angle of, or in that quadrant. For example, a quadrant 2 angle would be indicated or expressed as a Q2 ¢, "a quadrant two angle", or simply as Q2.

Quadrant	Angles	
1	0° to 90°	: Q1
2	>90° to 180°	: Q2
3	>180° to 270°	: Q3
4	>270° to 360°	: Q4

Below is a method to find a trigonometrically equivalent (E) or corresponding acute angle that is less than or equal to 90° when given an angle greater than a right-angle (90°). Angles greater than 90° are often called obtuse (wide, large) angles, and angles less than or equal to 90° are often called acute (narrow, thin) angles. As shown below, these obtuse angles greater than 90° have their "ending (after rotating)" side within another quadrant (quarter) other than the first quadrant of a circle or a rectangular co-ordinate measuring system. By creating a right triangle with the side adjacent to the angle on the horizontal or (x) axis of the quadrant in which the angles ending side is in, and the hypotenuse side of that angle created from the ending side of the (obtuse) quadrant angle, a trigonometrically equivalent or corresponding acute angle is created. The trigonometric functions of this corresponding acute (< 90°) angle are equal to that of the given obtuse (> 90°) angle.

When using a calculator to find the angle given a trigonometric value, care must be taken since it may return (ie. the output, indicated or displayed) the trigonometrically equivalent or corresponding acute angle (ie., an angle less than or equal to 90°, hence it would also be trigonometrically equivalent to a first quadrant angle) of which you must then convert to the proper angle if needed. In the figure shown below, the angle in question is a second quadrant angle, (Q2), since it is an angle between 90° and 180°. [FIG 198]



The +X axis is the standard reference line or 0° posiition for measurement of all angles

Q2 = trigonometrically equivalent to:

180° - Q1 = 180° - E

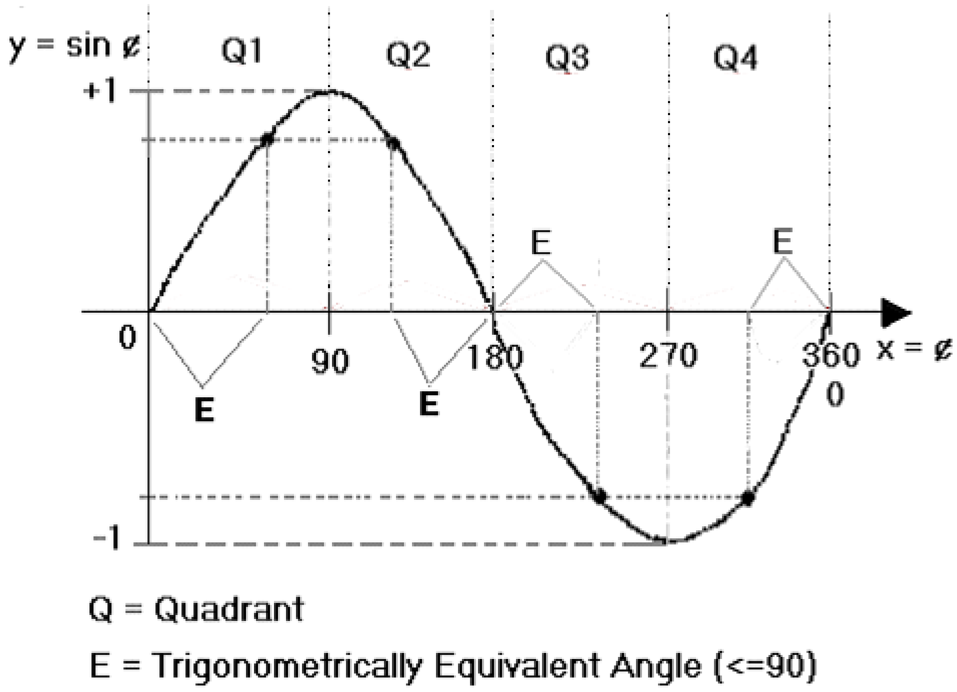
Since supplementary angles have the same trigonometric values.

Q2 + E = 180°
Q2 = 180 - E

Since E=Q1 , Q2= 180- E = 180 - Q1 , Q1 + Q2 = 180 , Q2 and Q1 are supplementary angles with the same trigonometric values.

Using the ending or terminal side of this angle and the X-axis of the quadrant in which it is in, the trigonometrically equivalent or corresponding acute angle (E) is shown. Clearly, this angle (E) is equal to 180° less the value of the quadrant angle (Q2) since they are supplementary (sum to 180°) angles. Notice the ("mirror image") identical triangle (with the same side lengths) created in the first quadrant, and its trigonometric values will be equivalent to those of any other trigonometrically equivalent (E) or corresponding acute (<=90°) angle in any quadrant, except perhaps for the mathematical signs (+,-) of those trigonometric values.

Below is a graph-plotting of the SIN of the angle waveform with respect or in reference to the (linear) angle values along the (x) or horizontal axis. It shows that after the first quadrant (Q1) of and from 0 to 90 degrees which defines the acute trigonometric equivalent reference angle (E), that the trigonometric values will essentially repeat in the other quadrants (Q2, Q3 and Q4). It could be said that the other trigonometric values (here, for SIN ¢) for angles greater than 90 degrees are essentially like "mirror images" since they will have the same (side lengths, and trigonometric) values. That is, angles greater than 90 degrees have a corresponding trigonometrically equivalent (E) angle in the 0 to 90 degree range, and which has the same trigonometric (absolute) values. In short, supplementary angles which sum to 180° have the same trigonometric values. [FIG 199]



Clearly, each trigonometric value (here in this example, SIN ¢ was used) indicated as points on the curve, will occur 4 times in the range of 0 to 360 degrees. Each occurrence will be in one of the 4 quadrants where each quadrant has a range of (360°/4) = 90 degrees.

From 0°, as the angle increases, the corresponding SIN ¢ values will increase up to an absolute value of 1 at the peaks (of the curve or waveform at 90° and 270°), and then decrease in the exact reverse (or mirror-like) manner from this value of 1 to the troughs (of the curve or waveform at 0°=360° and 180°) and have a value of 0.

Another way to state the above graph is that within 0° to 360°, 4 angle values will have the same SIN value as that of an angle (between 0° and 90°, in Q1) that has that same SIN value. This SIN value will occur 4 times during 360°. Notice that the corresponding SIN values are mirror images and symmetrical at and about the 90° mark, and the 270° mark (which is 180° more from 90°). As seen in the image, clearly these angles and their equivalent sine values are not generally separated equally by 90° (ie., not complementary angle values). Take note of the first point indicated, that the amount of angle from here up to 90° is equivalent to its complementary angle (an angle and its complementary angle sum to 90°). 90° plus this same complementary angle value is the corresponding trigonometric angle of the second point and angle with the same trigonometric values. Point 1 and point 2 are equidistant (or "symmetrical") from the 90° mark where SIN 90°=1. For example, they could both be 20° from the 90° mark, when point 1 corresponds to 70°, and point 2 corresponds to 90° + (complementary angle to Q1) = 90°+ (90° - Q1) = 90 + (90° - 70°) = 90° + 20° = 110°. SIN 70° = SIN 110°. The SIN values will decrease on each side of this peak till 0° or 180° is reached where SIN 0°= 0. The sine of 89° is the same as the sine of 91°. The sine of 70° is the same as the sine of 110°. The sine of 1° is the same as the sine of 179°.

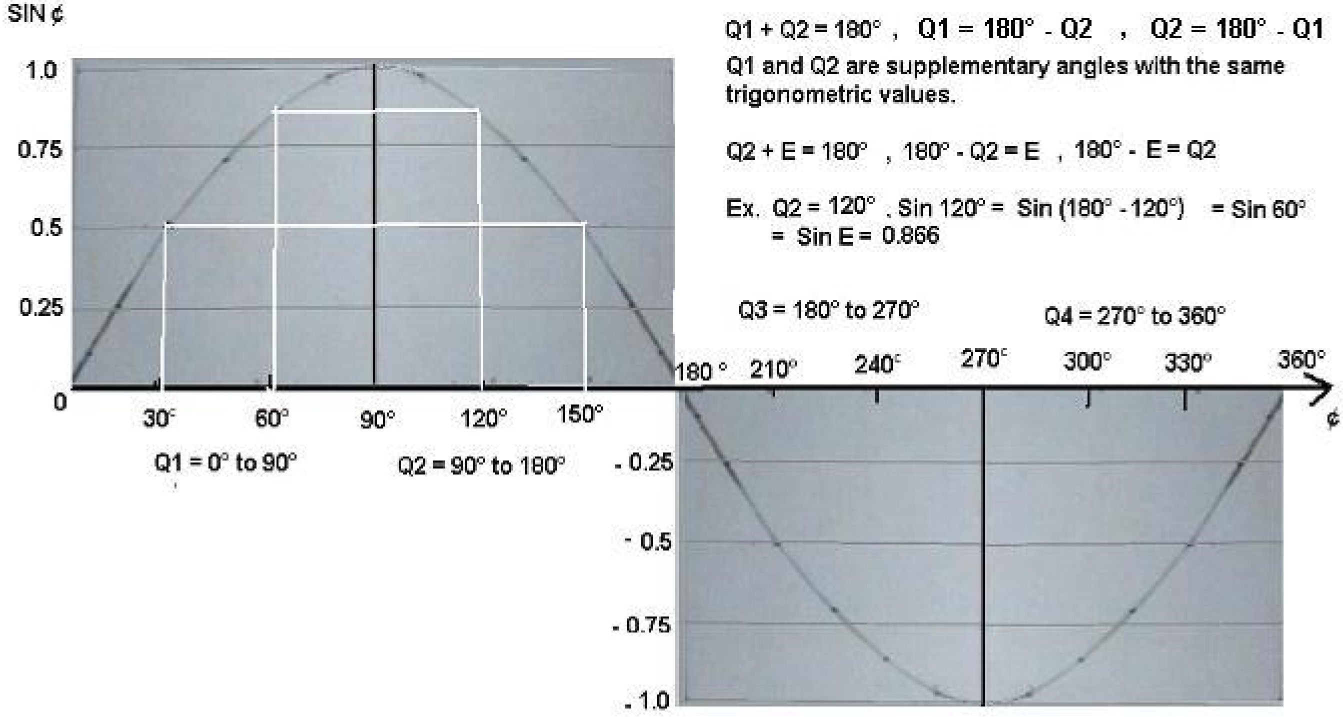
Each point, or angle and its corresponding SIN value on the SIN curve, has an angular distance from the peak (ie. high values, where the SIN values are 1) that is a value equal to the complementary angle of the first quadrant angle = Q1 = trigonometrically equivalent angle (E). Just the same, it could be said that each point (angle and its corresponding SIN value) has an angular distance from or to the "troughs" (ie. low values, where SIN values are 0), and this value is equal to the first quadrant angle = Q1 = trigonometrically equivalent reference angle (E).

Observe the following as an example, and it will be verified in an example below after a discussion. The following 4 points (with coordinates: (x=¢ , y=sin ¢)), with each having the same absolute "y" = sin ¢ coordinate-location value, are indicated on the graph above:

Q1 Q2 Q3 Q4 : showing which quadrant the angle is within.
sin 50° = sin 130° = sin 230° = sin 310° Q1, Q2, Q3, and Q4 all have the same trigonometrically equivalent (E) corresponding angle of Q1 = 50°
Each has the same SIN value of SIN 50° = about 0.766

Notice for example that SIN values are negative in the third and fourth quadrant, this is because the y coordinate values of points in the third and fourth quadrant are negative in sign, and SIN ¢ = opp/adj = y/x. As previously shown, when the radius line was considered as 1 or 100%, SIN ¢ = y/x = y/1 = y. The SIN values in Q2 are a mirror image of the SIN values in Q1. Except for the sign, the SIN values in Q3 are the same as the SIN values in Q1. The SIN values in Q3 are a mirror image of those in Q1. As seen in the above graph, it is an error to think that angles must have a separation of 90° to have similar trigonometric values. For angles to have the same trigonometric values, they will have the same trigonometrically equivalent (E) acute (<90°) angle.

Though not drawn to "linear scale" on the vertical axis, here is sine-like graph that can help illustrate the trigonometric equivalences of angles that are symmetrical in their amount of degrees or angle value from 90°: [FIG 200]



Q1 + Q2 = 180° , Q1 = 180° - Q2 , Q2 = 180° - Q1

Q1 and Q2 are supplementary angles with the same trigonometric values.

Q2 + E = 180° , 180° - Q2 = E , 180° - E = Q2

Ex. Q2 = 120° . Sin 120° = Sin (180° - 120°) = Sin 60°
= Sin E = 0.866

If you were to switch the corresponding angle values shown, the graph would resemble the standard rectangular coordinate system with the angles measured from the positive (x) reference (0°) axis.

Here is a method to calculate the trigonometrically equivalent angle given any angle, or angle in any quadrant:

For an angle that is less than or equal to 90°, it is in the first quadrant and the trigonometrically equivalent (E) angle (<90°) is obviously equal in value to that angle:

E = Q1 : trigonometrically equivalent angle for an angle in the first quadrant

For an angle that is greater than 90° and less than or equal to 180°, it is in the second quadrant, and its trigonometrically equivalent angle sum to 180° :

180° = Q2 + E : supplementary angles sum to 180°, therefore supplementary angles have equivalent trig. values
E = 180° - Q2 : trigonometrically equivalent (E) angle for an angle in the second quadrant,
Q2 = 180° - E

For an angle that is greater than 180° and less than or equal to 270°, it is in the third quadrant and is equal to 180° plus its' trigonometrically equivalent angle:

Q3 = 180° + E mathematically:
E = Q3 - 180° : trigonometrically equivalent angle for an angle in the third quadrant

As a special note: A triangle can not contain a single angle equal to or greater than 180° since the interior sum of all three angles within a triangle is always 180°.

For an angle that is greater than 270° and less than or equal to 360°, it is in the fourth quadrant and is equal to 360° less its trigonometrically equivalent angle.

360° = Q4 + E
Q4 = 360° - E
E = 360° - Q4 : trigonometrically equivalent angle for an angle in the fourth quadrant

Because of the facts stated above, the trigonometric (absolute) values of two corresponding supplementary angles (that sum to 180°) are the same value.

Ex. SIN 10° = 0.173648177

The supplementary angle of 10° is (180° - 10°) = 170°

SIN 170° = SIN (180° - 170°) = SIN 10° = 0.173648177

Ex. Q1 Q2 Q3 Q4 : Qn = "Quadrant angles"
sin 50° = sin (180° - 50°) = sin (180° + 50°) = sin (360° - 50°)
sin 50° = sin 130° = sin 230° = sin 310° = about 0.766 : absolute value

Note above, that for this example, Q1 and Q2 are supplementary angles. Q1 and Q3 are separated by 180°. Q3 and Q4 are separated by 180°

Here is a helpful chart to express these values:

Quadrant	Angles		Trigonometrically Equivalent (E) Angle
1	0° to 90°	: Q1	E = Q1
2	>90° to 180°	: Q2	E = 180° - Q2
3	>180° to 270°	: Q3	E = Q3 - 180°
4	>270° to 360°	: Q4	E = 360° - Q4

Ex. Find SIN 135° = SIN 2.35619449 (rads)

The angle is a second quadrant angle since 135° is between 90° and 180°. Its' corresponding acute angle is:

E = 180° - Q2 : E = acute (<=90°), trigonometrically equivalent angle
E = 180° - 135°
E = 45° : Therefore, 45° is trigonometrically equivalent to 135°, and vice-versa. 45° is also the supplementary angle to (180° - 45°) = 135° :

SIN 135° = SIN 45° = SIN 0.785398163 (rads) = 0.707106781

Likewise: | COS 135° | = | COS 45° | : same values, but using absolute (or "signless") values here
| TAN 135° | = | TAN 45° |

The absolute value symbols are needed due to the fact that cosine and tangent values are negative in sign in the second quadrant and positive in the first quadrant. Even though the numerical signs may differ, the angles trigonometric (absolute) values are equivalent. The trigonometric (ratio of side lengths of an angle) values were initially defined for right triangles which has side lengths all being sign-less in value, hence essentially positive in value. It may then seem somewhat odd to then assign a (pos. or neg.) sign to these trigonometric values. The sign is now due to the fact that the axis of the rectangular coordinate system is signed in value, therefore lengths and values will be signed, hence assigning a direction to those lengths:

QUADRANT 1 (0° to 90°)

$$\text{COS ¢E} = \frac{\text{opp.}}{\text{adj.}} = \frac{Y}{X} = \frac{\text{pos. value}}{\text{pos. value}} = \text{pos. value}$$

COS Q1 ¢ will be positive.

QUADRANT 2 (90° to 180°)

$$\text{COS ¢E} = \frac{\text{opp.}}{\text{adj.}} = \frac{Y}{X} = \frac{\text{pos. value}}{\text{neg. value}} = \text{neg. value}$$

COS Q2 ¢ will be negative.

Ex. Here of a Q2 angle:

COS 135° = - (COS 180° - 135°) = - (COS 45°) :after affixing the proper sign to the result, as defined above
COS 135° = - (0.707106781)
COS 135° = - 0.707106781

Sinusoidal Oscillations

Many things in nature and science (such as "ac", alternating (back and forth movement or flow, with the measurement values then having an opposite polarity, hence positive and negative) voltage and current electricity) are said have a sinusoidal or sinusoidal-like quality about them because they do something repetitively of which can be mathematically expressed with a sinusoidal equation and curve or waveform that is repetitious. As indicated, a good example of this is with the voltage and current output of an electricity generator. When its rotating coil of wire effectively becomes perpendicular to the magnetic field of a magnet, then maximum voltage is induced (ie., produced) which causes a corresponding maximum current to be produced. The output voltage and-or current will have a sinusoidal (sine) waveform or shape with respect to the rotation angle and-or time. The actual amount of voltage produced depends of several factors such as the number of turns of wire to make the coil, and the speed of the rotation of that coil and-or magnet (field), and the magnetic field strength of which also includes how close the coil and magnet can become so as to have maximum electricity generation effect.

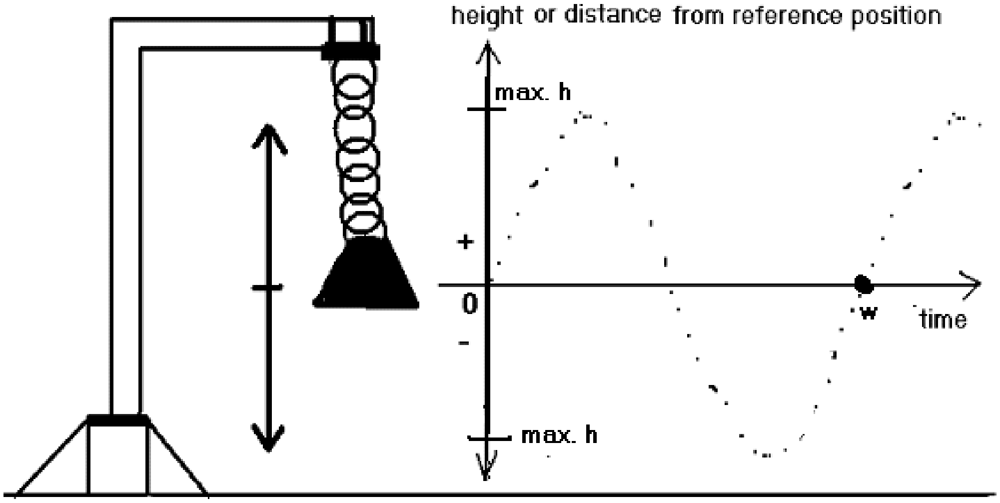
Besides the word "sinusoidal", other common words for repetitious behavior are "vibrate", "oscillate", "cyclic", and "periodic" (repeating over the same time period). All of these words are essentially a form and meaning of the word "repetition" (repeating).

Below is a mechanical oscillation system. A weight is suspended by a spring. If this string is either stretched or compressed, storing that input energy, and then released, its movement and corresponding position will be sinusoidal (sine like). Note that for the weight to change direction, it must first slow down and then actually stop for an instant of time, before changing direction. The weight will repeatedly accelerate and decelerate. Its speed or velocity will change, hence on the graph, the slope of the curve is changing and has a value of 0 when the weight stops and changes direction. Because of some (fractional, small) losses (such as due to friction) of energy during each cycle in this system, the maximum height or "amplitude" value will also decrease or decay in value as time increases.

The length or amount of time taken for this system to complete one cycle of this repetitious motion is called the wavelength (as shown in the image below between 0 and w on the time-line axis). The reciprocal of this wavelength value is the number of repetitions per second, and is usually called the frequency (of repetitions or cycles) and having units of (cycles/second) = hertz. Frequency is "how often" something occurs during some length or period of time. The faster something vibrates, repeats or oscillates, the less time taken for each one of those cycles or waveforms to complete, and therefore frequency and wavelength (time) are mathematically inversely related.

Ex. For a frequency of 1000 hertz or cycles per second. A 1000cps = 1000hz signal has a wavelength of 1/(1000 c/1s) = 0.001s/c = 0.001 seconds per cycle = 1 millisecond per cycle, or simply 1 millisecond.

In the figure below, the motion, particularly the height of the vibrating or oscillating object held by the spring will be sinusoidal in nature. When the spring stretches or compresses, it stores energy and the object will decelerate and loose kinetic energy and the object will eventually be at its maximum, positive or negative height or distance from its rest position where no energy was applied to it. If there is no energy to replace any energy losses in this system, such as due to mechanical friction and the resulting heat, then the oscillations will decrease in height until they eventually stop. This is sometimes called as the oscillations and the amplitude being dampened over time. [FIG 201]



Since the height waveform corresponds to, and can be mathematically represented as a SIN waveform with respect to time, we can therefore associate the maximum (100%=1) height (also called the amplitude of the vibration, waveform, change or movement) with the maximum value of the SIN ¢ value which is 1 and = 100% = 1.0 as a relative or fractional value. During the period of time equal to the wavelength, we can calculate the corresponding height at any instant or point in time. The SIN value will simply be the fraction of, and factor to the maximum height value. Since this graph is in relation to time rather than the angle as required for the SIN ¢ trigonometric function, we can convert this specific time value to its specific and corresponding angle or (relative, fractional) part of 360°. The time length of 1 complete wavelength or cycle will correspond to 360°. The ratio of the specific time during that wavelength or period of time to the entire wavelength (ie., time duration of the complete cycle or wave) will give us what specific fraction or portion of the wavelength is being considered and therefore, what specific fraction of a full cycle, rotation, or 360°, and hence what specific angle corresponds to that specific time value:

Letting max. value = maximum value = amplitude of the waveform:

y = SIN ¢ = (max. value)(fraction of max. value) = (max. height)(SIN ¢) , and: ¢ in relation or respect to time is:
y = (max. height) SIN ((fraction of 1 cycle or 360°, being considered) (360°)) : max. height = max. amplitude

T = period time = total time of 1 cycle of the waveform , and or the rotation of something
Ts = period = 1 / frequency = 1 / F = 1 / (cycles / second) = 1 / (c/s) = seconds / 1 cycle
F = 1 / T = 1 / period : note that frequency and time are reciprocals: FT = 1 , (c/s) (s/c) = 1

$$\text{height} = (\text{maximum height}) \times \text{SIN} \left(\left(\frac{\text{time}}{T}\right)\left(\frac{360°}{1}\right)\right)$$

: wavelength = distance = vT , T = period = 1 / frequency
: *

Extra: wavelength = distance the (energy) wave will travel through a material after 1 cycle is completed and-or the time of 1 period has elapsed (completed).

wavelength = distance = vt = vT = v / frequency = v / f

If the frequency increases, the wavelength will decrease. This in an inverse mathematical relationship. When frequency (F) increases, the period (T) time will decreases, and the wavelength will decreases.

Extra: 1 revolution = 1 cycle = 360° = 2(pi) radians : 2(pi) = 2(3.14159265..) =~ 6.2818

Note that: T = 1/F = seconds / cycle = s / **rev**olution = s / **rot**ation

(Also considering the above formula, *):

height = current or instantaneous value = SIN ((t / T) 360°));
height = value = (max. amplitude) SIN ((t) (1 / T) 360°)) = (max. amplitude) SIN ((time)(F) 360°));

Or since: 360° = 2(pi) = about 6.28 radians , and some rearranging of the factors:

value = (max. amplitude) SIN (2 (pi) F t)

The value of: (2(pi)F) is sometimes called the "angular velocity" per unit of time, and is given a symbol that looks like: W
Angular velocity is the amount of rotation per second , letting W = angular velocity , W = angle / time = ¢ / t

value = amplitude SIN (W t) , if t = T, the angle = 360° , and:

W = "angular velocity" or "angular speed" = "rotational speed" = $\frac{\text{revs}}{t} = \frac{\text{cycles}}{t}$ = frequency of rotation = F

$W = \frac{360^\circ}{T} = 2(pi) (1/T) = 2(pi) F$: here we see that F is essentially a multiplier to the angle, cycles or revs, and determines and is needed to express the actual angular or rotational velocity. With this equation, the units of W are rps (rotations per second) since the units of frequency are cycles per second of time, and that 360°= 2(pi) radians of rotation is being done each second of time. If you multiply the (rps) value by 60, you will have the equivalent value of revolutions per minute (rpm). 60 sec. = 1 min.

W = angle / time = ¢ / t = (s / r) / t = s / (r t) = (distance / t) / r = v / r : v = linear and=or= tangential velocity
: s = arc length , ¢ rads = s / r , s = ¢r = r ¢

W = change in rotation or angle / change in time : angular or rotational velocity

v = change in distance / change in time = r W = ds / dt = r d¢ / dt = r W = W r , Extra: r = v / W

From: arc length = s = ¢ r , and where the angle is in radians, r = radius

A full 360° rotation has an arc length of: s = C = Circumference = 2 (pi) (r) , then

W = ¢ / t = (s / r) / t = s / (r t) = C / (r t) = 2 (pi) (r) / (r t) = $\frac{2\,(pi)}{t}$ =~ $\frac{6.28 \text{ radians}}{t}$: for a full orbit here, t = P = period of orbit

A body in rotation, and even if not having translational or linear motion (with its corresponding KE value) and-or velocity, still has kinetic energy and it is proportional to its mass, the square of the angular or rotational velocity (W), and the square of the average radius (r) of all the points of that mass: **KE = mv^2 / 2 = m (W r)^2 / 2 = m W^2 r^2 / 2**

In terms of torque: Pw = energy / time = J / s = (Torque)(rotational velocity) = (T nm)(rotational velocity) = T W

Considering an angle velocity of W = 1 rotation or 1 revolution per second = 2 (pi) radians / s:
P = (Torque)(angular velocity) = T W = T (¢ / s) , If we let the rotational velocity expressed with units of revolutions per second = revs / s = rps , then ¢ = 2 (pi) / 1 rev , W = (n rps) 2 (pi) radians / s
If given a rpm value, we can divide that value by 60 so as to find the corresponding rps:
P = T W = T (rpm) / 60 = T (2 (pi) rps) / s

Extra: Consider: C = 2 (pi) radius = 2 (pi) r = a linear length , and: C / r = 2 (pi) r / r = 2 (pi) , and that

360° = 2 (pi) radians = an angle of 2 (pi) =~ 6.28

AN EQUATION FOR THE APPARENT TILT OF THE EARTH

The apparent tilt and-or angle of the Earth with respect to the Sun or solar plane is sinusoidal in nature. The Sun or solar plane is essentially the imaginary disk or plane created between the Earth and the Sun as Earth revolves (orbits, travels, moves, goes) around the Sun. Because of the orbit of Earth about the Sun being a slight ellipse shape, and not exactly circular, the apparent tilt of the Earth with respect to the Sun throughout the year is actually not exactly sinusoidal in nature, but it is close enough to be considered and analyzed as such in terms of practicality.

Earth's axis is tilted, and it does not change in value. Earth's axis does not change in value, but actually remains constant at about 66.5° with respect to the Solar Plane in the direction of the Sun. The true north to south line, axis or pole line, constantly points (direction) to (nearly) the star called Polaris or the "pole star" that is directly overhead at the north polar axis. With respect to the perpendicular (90°) to this solar plane, the axis is therefore often noted as constantly being: (90° - 66.5°) = 23.5° tilted form it. What is tilting throughout the year then? It is the angle between the Earth's standardized, geographical equator line and the solar plane - say toward the direction of the Sun, that changes throughout the year. As the Earth orbits the Sun throughout the year, in the summer time of the northern hemisphere, it is tilted toward the Sun during the day, and the equator line and-or region of the Earth is tilted below the solar plane by a maximum of 23.5°, and in the winter time, it is tilted above the solar plane by a maximum of 23.5°. This apparent axis tilt of the Earth throughout the year is generally said as what actually causes the climate seasons of the year.

Throughout the yearly orbit of Earth about the Sun, the eastward to westward path of the Sun will change slightly every day. The Sun will rise and set in a slightly different location and time every day. The Sun also has an effective or apparent angle with respect to the local horizon throughout the day as Earth revolves on its axis from eastward to westward. The tilt of the Earth, such as at the equator, with respect to the solar plane (or "ecliptic") is at 0° on March 21 and Sept 21 during the year.

Earth's axial tilt with respect to the solar plane, and for every day of the year is about $23.4\underline{4}$° as of the year 2020AD. We can express this value in a formula to find the tilt of the Earth at a specific day number from March 21 which can be considered as day number 0 for this yearly or 365 day cycle, hence the sinusoidal wave's wavelength is 365 days (365.25 to be more exact).

Lets begin this analysis with a simple liner equation expressing the mathematical relationship between two variables.

$y = x$: a linear equation, if x is multiplied by a value (m):
$y = mx$: y will be a multiple of the values of x

If m increases from 0 to a maximum value, y will also vary from 0 to this maximum value = amplitude:
If x is an angle:

y = m ¢

If m is set as a constant or maximum value, and the angle increases from 0, y will also increase from a value of 0. Here, y would be equal to a multiple of the angle.

If the angle is made to cycle or repeat from 0 up to a maximum value, y will also cycle or repeat from a value of 0 to some maximum value determined by both factors of (m) and the and the maximum angle value.

If the angle cycles from 0 up to a maximum value, and then descends from this maximum value to back to 0, the corresponding y values will also repeat or cycle in the same manner, and this can be mathematically represented using sine values with respect to, or of, the angle values, and these sine values also vary in the same cyclic manner from 0 up to a maximum value of 1, and then from 1 back down to 0. In short, these sin values then become as a relative or fractional value of the maximum value of the (specific) sine waveform (with a maximum amplitude, and having a certain wavelength and-or frequency):

y = (max. value) sin ¢ : for the initial discussion about the (apparent) tilt of the Earth throughout the year, we can use these corresponding values in this equation:

tilt angle = (maximum tilt ¢) x (sin ¢) : sin ¢ yields values 0 to 1, hence the seasonal, apparent tilt angle will be less than or equal to the maximum tilt angle. The tilt angle value will be a sinusoidal curve of values, and whose maximum value or amplitude is 23.5°

At a certain day number of the year, this represents a certain fractional portion of the 1 year or wavelength of the complete cycle, and-or it represents the same fractional portion of a complete 360° rotation. This (simpler) formula below considers the (average) orbit of Earth as a circle, but it is actually slightly elliptical. Applying these facts to the above formula:

tilt angle = 23.4$\underline{4}$° x SIN (day number from March 21 (360°/365.25)) : apparent tilt of the Earth throughout the year. A basic equation. 360° / 365.25 days is a constant of: ~ 0.985626283° / 1 day when averaged, however, the rate of tilt actually changes in a sinusoidal manner.

tilt angle = 23.4$\underline{4}$° x SIN (day number from March 21 x 0.985626283) : averaged, circular orbit, apparent tilt angle for Earth

The apparent tilt of the Earth (axis, pole or equator, reference position) with respect to the solar plane (which is considered the 0° reference angle and position) will be 23.5 degrees, max. "tilt" forward or toward the Sun during the daytime in the summer (at about June 21) for the northern hemisphere, and 23.5 degrees, max. "tilt" back away from the 0° reference position, solar plane or Sun during the daytime in the winter (at Dec 21, which is 6 months or half the yearly cycle past Jun 21). This angle is usually expressed as -23.5 since the (apparent) tilt is in the opposite direction from the 0° solar plane or reference angle. When the Earth (apparently or effectively) tilts away from the Sun, the northern hemisphere of the Earth will experience winter, and the southern hemisphere will experience summer.

The total tilt is then the amount of angle between these two angles: 23.5 - (-23.5) = 23.5 + 23.5 = 47°.

The tilt of the Earth is actually an apparent tilt, or illusion, since the imaginary line extending from Earths daily axis of rotation about itself always extends or "points to" the "north star" which is also called Polaris which is many "light years" (time of light travel) away.. The axis of the Earth is constantly tilted 23.5 degrees with respect to the solar plane (or "ecliptic"), but due to the orbit of Earth around the Sun throughout the year, it will have the effect that the one pole get closer to the Sun and the other pole gets farther away, hence creating the weather changes or seasons throughout the year.

The maximum apparent "height" that the Sun will appear above the horizon (0° reference line) at the observers local noon (true 12:00 pm) will be 90° less the latitude ("lateral" or side location, measured in degrees from the equator plane which is the imaginary line between north and south on the Earth) of the observer plus the current tilt angle. You can find **the latitude of your location** from some maps, or you can measure the angle between your local horizon and the north star (Polaris). The reference latitude at the equator is considered as 0°, and latitude is the angle created from the point at the center of the Earth to a location on the surface of the Earth. When the equator is located at the solar plane during the year, a person at the north pole of the Earth will see Polaris, the North Star, nearly directly overhead, and the angle between the horizon line and the line to Polaris is 90°, and this is the latitude at Earths north pole (axis). A person at the Equator will see Polaris as being at the horizon, and the angle between the horizon and Polaris will be 0°, and which is the latitude at the equator. The word "latitude" is based on the word lateral and slats (ie., side lateral, location), like the horizontal side shingles on houses that go from the ground level area to the top area of the house. In relationship to Earth, latitude is your location between north and south, and a line of latitude extends around the earth in the east and-or west directions.

Longitude is how far east or west a point on Earth is. The word "longitude" is based on the word "long". In relationship to Earth, longitude is your location eastward and-or westward, and a longitude line actually extends from the north pole to the south pole.

Greenwich, a city that is about 5 miles east of London, England along the Thames River. Greenwich has an astronomical observatory at a location that was standardized as the 0° reference position of longitude. This longitude line is called the **Prime Meridian** and goes in a northern and southern direction from the north pole to the south pole. This line is also the reference meridian and-or time zone of the world.

The time of an event anyplace or location in the world can be expressed in terms of the time at this reference longitude, and it is called: Greenwich Mean Time (GMT, mean=average) and-or Universal Coordinated Time (UTC or UT1), and loosely as "World Time" Each of the 24 (longitudinal) and hourly "time zones" is (in theory) approximately 360°/24 time zones = 15°/ timezone. Each longitude line separated by an angle of 15° can be said as being 1 hour and-or 1 timezone apart. For each and every location along the same longitude line, the true local time will be the same and the Sunlight will be directly overhead at the same time of noon which is 12PM. 15° of Earth's rotation and-or longitude separation corresponds to 1 hour = 60 minutes of time. 5° or Earth's rotation and-or longitude separation will correspond to 20 minutes. For 1 minute, setting up a equivalent fraction and-or proportion equation:

15°/60min as = x°/1min , x° = (15°)(1min) / 60min = 0.25° , therefore 1 min is to 0.25° , and
1s is to $0.004166\underline{7}°$, 4 min is to °1

OR: 15° / 1hr = 15° / 60 min = 0.25° / min = 0.25° / 60s = $0.004166\underline{7}°$ / 1s
The Moon appears from an observer on Earth to be 0.5° wide in diameter , and it will appear to move this diameter length in 2 minutes.

United States decided to keep large areas of the country's population and schedules at the same time, and made 4 time-zones that have roughly a north to south imaginary boundary line separating them. The 4 times-zones in the continental United States are the Eastern, Central, Mountain and Pacific time-zones. Starting from the Eastern boarder of the United States with its Eastern time-zone, and going in a westward in direction, each other time zone is an hour behind its eastern neighbor time-zone. Juneau, SE Alaska, USA is GMT-8. Hawaii Islands, USA is GMT-10. North-east Canada is also in what is called the Atlandic time-zone, and this is +1 hour ahead of the Eastern time-zone.

Many countries have adopted a concept called **Daylight Savings Time (DST)** where all clocks are set an hour ahead (ex. from 2AM to 3AM) later during some months so as to effectively or apparently have another hour of daylight each day - particularly in early (AM) waking and start of work hours during the winter months when the northern hemisphere of Earth is effectively tilted away from the solar plane and receives less daylight hours. When not in the months when DST is applied, it is called **Standard Time** which is the normal time according or in reference to GMT. DST in the USA is currently from 2AM on the second Sunday in March, to 2AM on the first Sunday in November, and on that day in March, the time is moved ahead one hour to normal true time. In the winter months in locations where DST is considered, the Sun will then appear to rise an hour earlier in clock time, and it will therefore, likewise set an hour earlier. The concepts of DST are naturally somewhat confusing to many, and is even debated by people.

Without considering the time-zones of the United States, New York City is 4 hours behind in time than that of the GMT. Since 15° about the Earth corresponds to 1 hour of time, New York City being -74° is 74°/15° =~ 4.93 hours from Greenwich city in England, and this may be expressed as GMT-4. 4.93 hours is nearly 5 hours, but is still only within the -4 to -5 hour longitude lines from GMT and its hourly longitude lines. If it is 1pm in New York City, the GMT is 4 hours ahead and that time is (1pm + 4hours) = 5pm such as in Greenwich England and all locations north and south in that hourly time zone or region bounded by longitude lines separated by 15° apart about the Earth.

Total Minutes = (hours)(60min/hour) + (remaining minutes of an hour) and:

Longitude Degrees from Greenwich = (Total Minutes)(0.25°/min)

There is an article in the Extra's section at the end of this book, and which is about calculating your local noon time from your known longitude.

How To Find Your Local Longitude. At noon time which is 12PM and where the Sun is the highest angle in the sky, calculate the difference from the Greenwich mean time at the prime (ie., reference, initial) meridian which is considered at the 0° longitude reference line. If the Sun is not shining that day, if your clock was set to the true local time, you could then find the difference that way. For each hour = 60 min. difference between the two time values, there is a 15° change (increase or decrease) in longitude from Greenwich. To calculate the total number of minutes, multiply the hours value by 60, and add any remaining minutes of an hour to that value.

Ex. If the Sun is at its highest angle in the sky for the day, and-or as indicated as 12pm = noon on a sundial, and it is known to be 5hr:30min "world time " in Greenwich England, your local longitude from Greenwich is:

Local longitude = (total hours)(15°/1hr)

First, converting the fraction (here minutes) of an hour to hours: 60 min / 1hr = 30 min / x hr , xhr = 0.5hr

5:30 = 5hr:30m = 5hr + 30 min = 5hr + 0.5 hr = 5.5hr

Local longitude = (total hours)(15°/1hr) = (5.5hr)(15°/hr) = 82.5° West of Greenwich

Approximate Latitude And Longitude Of Some Selected Cities And Areas

The longitude of a location is its (eastward (+, ahead in time) or westward (-, lower in time) angle from the Greenwich, England longitude line which is considered as the reference longitudinal line having a value of 0°. This location is also the accepted reference time for the world.

The latitude of a location is its central angle from the equator line. The location of a point or place on Earth has coordinates that are the latitude and longitude of that point:

A point (p) and-or location on the surface of Earth's sphere = p(latitude° , longitude°).

City	Latitude	Longitude	: close, approximate values
Greenwich , England	51.5°N	0°	: the reference (eastward and westward) longitude angle location, coordinate and world time value
New York City , USA	40.7°N	74°W	: N = north of the equator , W = west of Greenwich or: -40.7° lat, and -74° lon.
Kansas City , Missouri, USA	39.1°N	94.58°W	: central USA
Los Angeles , California, USA	30.05°N	118.2°W	
Anchorage , Alaska, USA	61.22°N	150°W	
Chicago , Illinois, USA	41.86°N	87.64°W	
Moscow , Russia	55.7°N	37.6°E	
Beijing , China	39.9°N	116.4°E	
Tokyo , Japan	35.7°N	139.8°E	
Sao Luis , Brazil	2.53°S	44.26°W	
Mecca , Saudi-Arabia	21.39°N	39.86°E	
Capetown , South Africa	33.9°S	18.4°E	: S = south of the equator, (-) sign also means south of equator or west of Greenwich 33.9°S , 18.4°E = -33.9° Lat, -18.4 Lon.

Nagercoil , India's	8.18°N	77.4°E	: India's most southern city:
Rome , Italy	41.9°N	12.5°E	
Honolulu , Hawaii, USA	21.31°N	157.86°W	: near the middle of the Pacific Ocean
Easter Island	27.11°S	109.35°W	: in Pacific ocean, 2180 miles west of Caldera, Chili
Miami , Florida, USA	25.76°N	80.2°W	
Jerusalem , Israel	31.77°N	35.2°E	
Cairo , Egypt	30.06°N	31.25°E	
Perth , Australia	31.95°S	115.86°E	
Mexico City , Mexico	19.43°N	99.13°W	: capital city of Mexico
Brasilia , Brazil	15.79°S	47.88°W	: capital city of Brazil
Ushuaia , Chili	54.8°S	68.3°W	: In Patagonia, South America Region, Chili's most southern city. relatively close to Antarctica
Georgetown Island or Ascension Island	7.93°S	14.41°W	: In middle of south Atlantic ocean, and between Angola, Africa and central Brazil. Northwest of Tristan Island
Tristan Island	37.11°S	12.28°W	: In middle of the south Atlantic ocean, and between Capetown, South Africa , and Southern Brazil
Mt. Everest , Nepal	27.98°N	86.93°E	: Highest mountain on Earth, in Himalayas Mts, north of India
Manila , Philippines	14.6°S	120.98°W	
Quito , Ecuador	0.18°S	78.47°W	: "ecuador" is a Spanish word for "equator"
Hithadhoo , Maldives	0.61°S	73.1°E	
Islamabad , Pakistan	33.74°N	73.08°E	
Montreal , Canada	45.51°N	73.59°W	
Quebec , Canada	46.81°N	71.21°W	
London , England	51.51°N	0.118°W	: very close to Greenwich, England, and GMT=**GMT+0**=UTC+0
Dublin , Ireland	53.35°N	6.266°W	
Stockholm , Sweden	59.33°N	18.06°E	
Gibraltar , Spain	36.14°N	5.354W	: southern extended tip of Spain, a peninsula, a Britain Territory
Accra , Ghana , Africa	5.615°N	0.206°W	: in north-west Africa along the Atlantic ocean to the south
Kathmandu , Nepal	27.7°N	85.3°E	
New Delhi , India	28.61°N	77.22°E	
Horta , Azores Islands	38.66°N	28.07°W	: approximately in the central, north atlantic ocean. These 9 islands are autonomouse territories of Portugal.
Arctic Circle	66.5°N		: or= (90° - 66.5°) = 23.5° south of the north geographical pole
Tropic Of Cancer	23.5°N		: more accurately as 23.44°N , north of equator
Tropic Of Capricorn	23.5°S		: more accurately as 23.44°S , south of equator
North Pole	90°N		
South Pole	90°S		
Equator	0° N and 0° S		: the reference of latitude, halfway between Earth's poles

A **magnetic compass** is a lightweight, horizontally balanced needle (thin, lite-weight, narrow, "pointer") made of iron that can freely rotate till the needle points in the direction of the north magnetic pole of the Earth, hence indicating which direction is (roughly) north, and also indirectly indicating the other directions of south, east and west. This compass functions on the basic principle that iron or steel is attracted to a magnet and-or can also be influenced by the north to south magnetic field lines. The magnetic pole of the Earth moves and varies by a few miles or degrees or up to 20 miles a year since Earths molten iron core is moving slightly due to various forces such as the gravity of the Moon that orbits around the Earth, and the change in the Sun's gravity throughout Earth's elliptical orbit about the Sun.. In short, the geographical (true) north pole of the Earth is generally not at the same geographical location or direction as Earth's north magnetic pole (and magnetic compass direction), and is only a close approximation.

As of the year 2020, the coordinates of Earths north magnetic pole are about: 164° E longitude and 87° N latitude. The coordinates of Earth's south magnetic pole are about 136° E longitude and 64° S latitude.

If you are seeking to travel in a certain direction, the true north (geographical, not magnetic) pole direction can be found by locating the North-Star, also called Polaris (the pole or polar star), and traveling along the surface of the Earth in that direction. The angle between true north and magnetic north is an error or (magnetic) offset angle of the compass in terms of direction, and the value of this angle depends on where you are locate on Earths surface. This angle could be 0° and up to 15°. If the direction of a compass and magnetic north is compared to that of the direction to the North-star, this error angle can be found and recorded for your local area, and so as traveling in a (true) geographical direction is then more accurate when using a compass. It is also useful for various astronomical and yearly events such as the directions of sunrise and sunset locations. Each city, park and or other locations should have a permanently installed, fixed direction pointer as a decorative and functional device. Due to that the magnetic pole of Earth can change in location, and thereby direction, every few years, and that locations with a high amount of ferrous (ex. iron ore) can also cause a compass to point in the wrong direction, a **solar compass** was invented in 1831 by James Clark Ross Ross was the first to find the location of Earth's north magnetic pole, and during an expedition in the arctic region. This solar compass will find true or geographical north by observing the true east sunrise and-or sunset in the west. If you do not have a solar compass, the direction of the North Star, Polaris, at night-time can be used, and-or by knowing the eastward to westward apparent path of the Sun across the sky during the daytime.

As the Earth rotates on its polar axis, at every new hour, the Sun will be overhead in the next westward time zone as the Earth rotates in the eastward direction. Some "shortwave, AM" radio stations continuously broadcast the current UTC. The military sometimes calls GMT as "Zulu Time" ("zero meridian time"). The first westward time zone from Greenwich is sometimes noted as having a time of: -1 GMT, meaning "an hour behind" (in Earths rotation eastward and-or also is used for sunrise or sunset times in reference to GMT time), and the first eastward time zone from the Prime Meridian is sometime noted as having a time of: +1 GMT, meaning "an hour ahead" than the time at the Prime Meridian time zone. In reference to GMT, Paris, France is GMT+2. New York City, USA is GMT-5 in the summer months.

Time zones are based on an angle, and are not based on some fixed distance. The maximum distance of a 15° time zone is nonetheless at the equator where an angle represents a much longer (circular, east-west direction) arc than locations near Earths poles. At the equator, the Earths arc, disk or circumference is about 25000 miles which corresponds to 360°. Using proportions or equivalent fractions: 1° is to x miles, as 360° is to 25000 miles, and we find 1° corresponds to about 70 miles (at the equator line only), and 15° corresponds to about (70miles)(15) = 1047 miles.

During the equinox days where the length of day and night are equivalent to 12 hours each at any location on Earth, locations that are 70 miles apart eastward and westward will have a solar shadow that is 1° in difference, and this can be measured on a fine (ie., precision) scaled solar clock or sundial. For locations north and south of the equator, this distance corresponding to 1° will get less and less toward the poles. Using a proportions or an equivalent fraction equation for linear relationships: 70 miles is to 1°, as is X miles or the circumference of the Earth is to 360°, and we find X equal to about: (360)(70mi) = 25200 mi.

Each season is defined as one-quarter (1/4) of a year, or 365.25 days/4 = $91.3\underline{1}$ days = roughly 90 days ~ 3 months:

Time Of Year Date	Season	Days From March 21	Tilt	
March 21 to June 21	"spring"	0 to 90	0° to +23.5°	:March 21 is an equinox day
June 21 to September 21	"summer"	90 to 180	+23.5 to 0°	
September 21 to December 21	"fall"	180 to 270	0° to -23.5°	:September 21 is an equinox day
December 21 to March 21	"winter"	270 to 360	-23.5 to 0°	

As was previously indicated, the tilt of the Earth throughout the year is nearly, or not exactly, sinusoidal. This is due to that the orbit of Earth around the Sun is not exactly circular and is rather slightly elliptical or "egg shaped". The Sun is therefore not at the geometric center of either an ideal circular orbit or its actual elliptical orbit, but is offset slightly some distance from the center point of its elliptical orbit. During the northern hemispheres winter season and a slightly elliptical orbit, Earth is actually slightly closer (about 3 million miles closer than the average of 93 million miles) to the Sun and the increased gravity is causing it to orbit the Sun slightly faster, and during the summer, Earth is slightly farther from the Sun and the lessened gravity is causing it to orbit the Sun slightly slower. This has the effect of changing the (apparent) tilt angle slightly faster (than a yearly average or rate) than expected in the winter, and slightly slower than (the average) expected in the summer. Note that the time of each Earth day or rotation about is axis is still the same time of about 24 hours, and rather the Suns position or (angle of) elevation in the sky is slightly different (more or less) than expected, and this should be considered for (more accurate) Sundial clocks so as to make a correction to the time physically displayed, as a shadow line, and so as to still use the standard, yearly, 24 hour time system. You can look into the topic of: "Equation Of Time" which is the understanding and calculation to account for this apparent "error" or difference from what (ie., average) was to be expected. At the extreme error points, the maximum difference between true solar noon where the Sun is at the highest angle (with respect to your local horizon) overhead and where it will be in the sky throughout the day, and localized (due to time zones, so everyone in a zone has the same time; hour and minute, to avoid confusion) noon time on the clock, will be "off" (in error) by about +- about 15 minutes. Since 1 hour or 60 minutes corresponds to an apparent 15 degrees of Sun movement, the maximum time error of 15 minutes will correspond to an apparent 3.75 degrees of maximum angle error from its commonly expected "average position".

Because of the apparent tilt of the Earth throughout the year, the locations of the sunrise and sunset along the horizon will change in the same (nearly) sinusoidal periodic manner and cycle. The locations of the moonrise and moonset will also be affected in a similar manner. The Moon also has a constant, 5° inclined (or "tilted") orbit about the Earth, and therefore it goes above and below the solar plane during its orbit around the Earth. This is a visible, total apparent change of 10° during its orbit, and this is the apparent diameter of 20 moons since it appears at about 0.5° in diameter or wide to an observer on Earth. The apparent tilt of the Earth throughout the year will also make the Moon's angle above the horizon appear to change. The total apparent tilt of the Earth throughout the year is about 23.5° + 23.5° = 47°.

As the Earth tilts throughout the year, the apparent location of the Sun up in the sky as seen at the same location on Earth and time every day will have a locus or path that has the shape of a "figure eight = 8" throughout the year. As the northern hemisphere of Earth tilts southward and toward the Sun in the summertime, the Sun will appear to travel and set in a slightly more northern direction and results in the Sun setting in a north-west direction along the horizon, and is actually 23.5° northward or clockwise from true west on about July 21. Likewise, in the winter, the Sun will set in the south-western direction along the horizon, and is actually 23.5° southward or counter-clockwise from true west on about December 21. This process and annual (yearly) apparent path of the Sun as seen at the same time of day, such as local noon or 12pm or 0pm on a 24hour time system, is known as the **Analemma** of the Sun. Because the orbit of Earth is closer to the Sun in the Winter and traveling faster, and then farther from the Sun in the Summer, one end of this figure eight (or somewhat sinusoidal or elliptical in shape) position or path up in the sky will be longer than the other.

Equation of a sine wave at particular frequency:

The general meaning of the word frequency is how frequent something is or how often it occurs, such as in the number of times or occurrences per unit of time such as a second.

Since some of these concepts below were also discussed in the previous topic, you may wish to review it so as to possibly have a greater understanding of these concepts.

For something that is spinning, such as a point on the circumference of a rotating wheel, or a periodic wave (such as a sine wave) that is repeated over and over, what is the basic formula for the height or amplitude (ie. max height) of that waveform?

For 1 revolution, the angle is 2(pi) radians =360°.

y = sin (¢) = sin (x) , : Here the amplitude is 1: y = 1 sin (x), but if the maximum amplitude is no longer 1, but some other multiplying or magnifying factor value, then it must be included in the equation as a multiplier to sin (¢):

y = height = amplitude = (maximum amplitude) sin (¢)

For something rotating in a periodic manner, it will have a certain number of rotations per second, and this is the same as cycles per second (cps =hertz = hz) or frequency (f). The time (t) duration or (time) period of each cycle is: time = (1/frequency). Frequency of the cycles and the time of each cycle are inversely related, and are in fact, mathematical reciprocals of each other:

$\text{Fhz} = \frac{1}{\text{Ts}}$ and $\text{Ts} = \frac{1}{\text{Fhz}}$ and: (F)(T) = 1 , Ex. $1000\text{hz} = \frac{1}{0.001\text{s}}$

For example, the higher the frequency, the lower the time value or period of each cycle.

The amount of angle that has happened after a time value while rotating depends both on the frequency of the cycles and the time elapsed from 0° which is considered as the starting or reference position and angle. From the above "reciprocal equation":

(frequency)(time elapsed during the cycle) = 1 = (cycles / second)(seconds) ,
the result is a fraction or relative value of the complete rotation (2p rads = 6.28 radians = 360°) or cycle in question.

y = (max. amplitude) sin (¢) : general sin equation, and (y) is with respect to the value of the angle

y = (max. amplitude) sin ((2pi) f t) : (2)(pi) = a complete rotation or (radian) angle of 360°. (2)(pi) radians = 360°. (2)(pi)(f) = total degrees of rotation per second which is sometimes called the angular velocity, and multiplying by (t) we can find both the angle or degrees rotated and-or the amplitude at a certain value of time.

y =~ (max. amplitude) sin (6.28 f t) : f = frequency in cycles per second = hertz (hz) , t = time in seconds

CONVERSIONS OF AN ANGLE'S TRIGONOMETRIC VALUES

Each trigonometric value has a corresponding angle (<=90°) associated with it, and therefore, that trigonometric value corresponds to that angles other corresponding trigonometric values. Each angle (<=90°) has a corresponding SIN, COS and TAN value. Given just one value, you can calculate the other two values. Most of the conversion equations or formulas below can be derived from the trigonometric **identity** ("identical", a mathematical relationship of trigonometric values which will hold true for any and all values of the angle) of:

$\text{SIN}^2 ¢ + \text{COS}^2 ¢ = 1$: this is sometimes called the "Pythagorean Trigonometric Identity"

The equation above can be derived by observing the drawing, given previously in this book, of approximating the trigonometric values graphically, and using the Pythagorean Theorem with it. Some of the identities derived below were previously given.

From: $h^2 = r^2 = x^2 + y^2 = 1 = (\text{SIN } ¢)^2 + (\text{COS } ¢)^2$: when r = radius line = 1, or hypotenuse line = 1

$\text{SIN } ¢ = \sqrt{1 - \text{COS}^2 ¢}$

$\text{COS } ¢ = \sqrt{1 - \text{SIN}^2 ¢}$

And from $\text{TAN } ¢ = \frac{\text{SIN } ¢}{\text{COS } ¢}$: also $\text{COS } ¢ = \text{SIN } ¢ / \text{TAN } ¢$ and $\text{SIN } ¢ = \text{COS } ¢ \ \text{TAN } ¢$

$\text{TAN } ¢ = \frac{\text{SIN } ¢}{\sqrt{1 - \text{SIN}^2 ¢}} = \frac{\sqrt{1 - \text{COS}^2 ¢}}{\text{COS } ¢}$: calculating TAN ¢ using either the SIN or COS of the angle

Here is the trigonometric identity for cofunctions of complementary angles:

Given an angle (¢< 90°) its complementary angle is (90° - ¢). The trigonometric cofunctions of these angles have the same value:

$\text{SIN } ¢ = \text{COS } (90° - ¢)$ also: $\text{TAN } ¢ = \text{COTAN}(90° - ¢)$

$\text{COS } ¢ = \text{SIN } (90° - ¢)$ Ex. $\text{COS } 60° = \text{SIN } (90° - 60°) = \text{SIN } 30°$

$\text{TAN } ¢ = \frac{\text{SIN } ¢}{\text{COS } ¢} = \frac{\text{SIN } ¢}{\text{SIN } (90° - ¢)}$: calculating TAN ¢ using the SIN values of two angles

Here is how to solve for either sin ¢ or cos ¢ using tan ¢.

From: $1 = \sin^2 ¢ + \cos^2 ¢$ since $\tan ¢ = \sin ¢/\cos ¢$, $\sin ¢ = \cos ¢ \tan ¢$:

$1 = \cos^2 ¢ \tan^2 ¢ + \cos^2 ¢$ factoring out $\cos^2 ¢$:

$1 = \cos^2 ¢ \, (1 + \tan^2 ¢)$ solving for $\cos^2 ¢$:

$\cos^2 ¢ = \frac{1}{1 + \tan^2 ¢}$ solving for cos ¢ by taking the square-root of both sides:

$\cos ¢ = \sqrt{\frac{1}{1 + \tan^2 ¢}} = \frac{1}{\sqrt{1 + \tan^2 ¢}}$

Since $\sin ¢ = \tan ¢ \cos ¢$ and substituting the above expression for cos ¢ :

$$\sin \text{¢} = (\tan \text{¢}) \quad (\cos \text{¢})$$

$$\sin \text{¢} = (\tan \text{¢}) \left(\frac{1}{\sqrt{1 + \tan^2 \text{¢}}} \right)$$

$$\sin \text{¢} = \frac{\tan \text{¢}}{\sqrt{1 + \tan^2 \text{¢}}}$$

Also, $(\sin \text{¢}) (\cos \text{¢}) = \dfrac{\tan \text{¢}}{(1 + \tan^2 \text{¢})^{0.5}} \; \dfrac{1}{(1 + \tan^2 \text{¢})^{0.5}} = \dfrac{\tan}{1 + \tan^2 \text{¢}}$

Here are some identities (ie., trigonometric equivalences) of the complementary angles (A and B) of a right triangle :

From $c^2 = a^2 + b^2$ and $\mathrm{SIN}\,A = \dfrac{a}{c}$ and $\mathrm{SIN}\,B = \dfrac{b}{c}$, $c = b / \mathrm{SIN}\,B = a / \mathrm{SIN}\,A$, algebraically:

$a = c\,\mathrm{SIN}\,A$ squaring both sides of the equation:
$a^2 = (c\,\mathrm{SIN}\,A)^2$
$a^2 = c^2\,(\mathrm{SIN}\,A)^2$

$b = c\,\mathrm{SIN}\,B$ squaring both sides of the equation:
$b^2 = (c\,\mathrm{SIN}\,B)^2$
$b^2 = c^2\,(\mathrm{SIN}\,B)^2$

$c^2 = a^2 + b^2$ using algebraic substitution:
$c^2 = c^2\,\mathrm{SIN}^2 A + c^2\,\mathrm{SIN}^2 B$ since c^2 is a common factor to both terms:
$c^2 = c^2\,(\mathrm{SIN}^2 A + \mathrm{SIN}^2 B)$ dividing both sides by c^2 and canceling:

$1 = \mathrm{SIN}^2 A + \mathrm{SIN}^2 B$ therefore:

$\mathrm{SIN}\,A = \sqrt{1 - \mathrm{SIN}^2 B}$: B = (90° - A), B is the complementary angle to A, and:

$\mathrm{SIN}\,B = \sqrt{1 - \mathrm{SIN}^2 A}$: A = (90° - B), A is the complementary angle to B:

Substituting $a = (c\,\mathrm{COS}\,B)$ and $b = (c\,\mathrm{COS}\,A)$ into the initial derivation above, it can also be shown that:

$\mathrm{COS}\,A = \sqrt{1 - \mathrm{COS}^2 B}$: A and B are complementary angles, and :

$\mathrm{COS}\,B = \sqrt{1 - \mathrm{COS}^2 A}$: A and B are complementary angles

As an alternate derivation, consider that we already know:

$\mathrm{SIN}\,B = \mathrm{COS}\,A$ squaring both sides:
$\mathrm{SIN}^2 B = \mathrm{COS}^2 A$ using substitution into the following:

$\mathrm{SIN}^2 \text{¢} + \mathrm{COS}^2 \text{¢} = 1$: Pythagorean-like relationship of SIN and COS, using angle A:
$\mathrm{SIN}^2 A + \mathrm{COS}^2 A = 1$ substituting for $\mathrm{COS}^2 A$:
$\mathrm{SIN}^2 A + \mathrm{SIN}^2 B = 1$: Pythagorean-like relationship of complementary angles ,
(and with the same trigonometric function; here it's SIN)

SIN A = √1 - SIN^2 B = √1 - SIN^2 (90° - A) = \/ 1 - COS^2 A

Ex. The sine of 70° can be calculated using the sine of its complementary angle of 20° :

SIN 70° = \/ 1 - SIN^2 20° : 90° - 70° = 20°

As mentioned previously, the smaller the angle, the fewer the terms that need to be calculated for a given precision using the SIN ¢ series. 20° is a much smaller angle than 70°

From SIN^2 A + COS^2 B = 1 : where A and B are complementary angles

The angles above can also be supplementary to each other since if ¢ > 90° (a second quadrant angle):

SIN ¢ = SIN (180° - ¢) and: COS ¢ = COS (180° - ¢)

Ex. (SIN 160°)^2 + (COS 20°)^2 = (SIN 20°)^2 + (COS 20°)^2 = 1

This leads to a general conclusion that the COS^2 of an angle of a triangle, plus the SIN^2 of the sum of the other two angles (which sum to a supplementary angle of the third angle) of that triangle equals 1.

SIN^2 (¢1 + ¢2) + COS^2 ¢3 = 1 : Trigonometric Identity Of All Three Angles Of A Triangle

Since COS ¢ = \/ 1 - SIN^2 ¢ , after substituting this into the above equation and simplifying:

SIN^2 (¢1 + ¢2) = SIN^2 ¢3 taking the square root of both sides and switching sides:

SIN ¢3 = SIN (¢1 + ¢2) : Trigonometric Identity Of All Three Angles Of A Triangle

Consider that since ¢3 and the sum of (¢1 + ¢2) are supplementary angles which have the same trigonometric values.

Likewise:

COS^2 (¢1 + ¢2) + SIN^2 ¢3 = 1 : Trigonometric Identity Of All Three Angles

COS^2 (¢1 + ¢2) = COS^2 ¢3 taking the square root of both sides:

COS ¢3 = COS (¢1 + ¢2) : Trigonometric Identity Of All Three Angles Of A Triangle
(use absolute (positive sign) trigonometric values)

TAN ¢3 = SIN (¢1 + ¢2) / COS (¢1 + ¢2) : Trigonometric Identity Of All Three Angles Of A Triangle,
Angle ¢3 is supplementary to (¢1 + ¢2).

Extra: Given a circle, From: sin ¢ = opp. / hyp. = y / r and cos ¢ = adj. / hyp. = x / r

y = r sin ¢ and x = r cos ¢ r = \/ x^2 + y^2
r = y / sin ¢ and r = x / cos ¢ , hence: y / sin ¢ = x / cos ¢ , y / x = sin ¢ / cos ¢
x / y = cos ¢ / sin ¢
x = r cos ¢ = y / sin ¢ cos ¢ = y cos ¢ / sin ¢ = y / tan ¢ : when r is not initially known
y = r sin ¢ = x / cos ¢ sin ¢ = x sin ¢ / cos ¢ = x tan ¢ : when r is not initially known
y / x = tan ¢ = opp. / adj.

From the above derivations, is can also be shown that: 1 = (cos ¢ / sin ¢) (y / x) , hence a constant equal to 1
Also: y cos ¢ = x sin ¢ = r

Double And Half Angle Trigonometric Identities

These trigonometric identities are commonly known today in the mathematics community and they were progressively derived during a span of about two-thousand years starting from the Babylonian, Egyptian, Greek, Indian, Asian, Arab, and European-Western and other mathematicians who took mathematics to new heights. The derivations are typically built upon the other more basic trigonometric identities mentioned in this book. These identities were commonly used to make trigonometric tables and still can be used if you prefer not to calculate them by other means such as the series methods. These equations presented here for are only for basic familiarity purposes if you happen to encounter them or other similar types of equations. These equations are not required for further use in this book and may be skipped over for now and viewed at another time.

$\sin(2x) = 2\sin x\cos x = \frac{2\tan x}{1 + \tan^2 x}$: sine of twice the angle , x = the angle

$\cos(2x) = \cos^2 x - \sin^2 x = 2\cos^2 x - 1 = 1 - 2\sin^2 x = \frac{1 - \tan^2 x}{1 + \tan^2 x}$

Note that, from: $2\cos^2 x - 1 = 1 - 2\sin^2 x$, we have the "Pythagorean-like trigonometric identity" :
$\sin^2 x + \cos^2 x = 1 = (\sin x)^2 + (\cos x)^2$

$\tan(2x) = \frac{2\tan x}{1 - \tan^2 x}$

Note that from: $\tan x = \sin x / \cos x$, therefore,
$\tan(2x) = \sin(2x) / \cos(2x)$ and $\tan(x/2) = \sin(x/2) / \cos(x/2)$

$\cos(x/2) = \pm\sqrt{(1 + \cos x) / 2}$: This can be derived from solving for : $\cos(2x) = 2\cos^2 x - 1$ and considering that if $(2x)$ is the angle, then (x) is half the angle. Therefore: $\cos x = 2\cos^2(x/2) - 1$. Solving for $\cos(x/2) = \cos$ (half angle), we have this identity shown. $(x/2)$ represents the half an angle value.

$\sin(x/2) = \pm\sqrt{(1 - \cos x) / 2}$: Credited to (Claudius) Ptolemy of Alexandria

Ex. Find Sin 0.5°

If we let $x = 0.5°$, then twice the angle is: $2x = 2(0.5°) = 1°$, and half the angle is: $(2x)/2 = 1°/2 = 0.5°$:

$\text{Sin } 1° = 0.017452406$

$\text{Cos } 1° = \text{SIN } 89° = 0.999847695$

$\text{Sin } 0.5° = \text{SIN }(1°/2) = \sqrt{(1 - 0.999847695) / 2} = 0.008726535$

If we solve the last formula given for the cosine of the angle of which is actually twice of that specific angle value of $(x/2)$ on the left side, we can derive the above equation for: $\cos(2x) = 1 - 2\sin^2 x$

From: $\sin^2 x + \cos^2 x = 1$, $\sin^2 x = 1 - \cos^2 x$, and substituting this value into: $\cos(2x) = 1 - 2\sin^2 x$, we have another identity as shown above for: $\cos(2x) = 2\cos^2 x - 1$. If we solve this last equation for $\cos^x$ we have:

$\cos x = \sqrt{(\cos(2x) + 1) / 2}$, and since the angle on the left hand side is half of that on the right hand side, we have the above half-angle identity for $\cos(x/2)$.

$\tan x = \dfrac{2 (\tan x/2)}{1 - (\tan x/2)^2}$: from tan (2x) = ¢ identity , and using ¢ = (x/2). Similar to the identity for: tan 2x

$\tan (x + y) = \dfrac{\tan x + \tan y}{1 - \tan x \tan y}$: if y=x, tan (x + y) = tan (x + x) = tan(2x) and the formula is shown above.

Using the above identity, if you have a table of tangent values of angles from 0° to 45°, you can use it to solve for the tangent values of angles from 45° to 90°:

If x = 45°: $\tan (45° + y) = \dfrac{\tan 45° + \tan y}{1 - \tan 45° + \tan y} = \dfrac{1 + \tan y}{1 - 1 + \tan y} = \dfrac{1 + \tan y}{\tan y}$, here, y° /=/ 0°

$\tan (x - y) = \dfrac{\tan x - \tan y}{1 + \tan x \tan y}$, $\tan(45° - y) = \dfrac{1 - \tan y}{1 + \tan y}$ Ex: tan(30°) = tan(45° - 15°) , here, use: y=15° in the formula.

FINDING THE ANGLE GIVEN A TRIGONOMETRIC VALUE

The formula for the series expansion of ARCSIN X is given below and its derivation can be found in the appendix. This is one of the possible formulas to keep near a basic "home-use", 4 function calculator. There are similar formulas for ARCCOS X and ARCTAN X but they are not presented right here since it is easier to work with, and possibly remember only one formula. A series for ARCCOS X and ARCTAN X can be found in the appendix.

$$\text{ARC SIN } X = X + \sum_{n=1}^{n=\infty} \frac{(1)\ldots(2n-1)}{(2)\ldots(2n)} \cdot \frac{X^{(2n+1)}}{(2n+1)}$$

: ARC SIN Series expansion of the function SIN x. This expansion, and some others, were developed by **Colin Maclaurin** when he used a (Brook) Taylor series with the functions derivatives evaluated at x=0.

The angle calculated by this series is a radian angle. Notice that some initial factors (on the left) are indicated along with the common expression for those factors. This indicates that all the previously calculated factors of:

$\frac{(2n-1)}{(2n)}$ up to and including this terms value are to be also included in each new term.

n is an integer (regular counting number) from 1 to infinity (∞) for this series: 1, 2, 3, 4, 5, 6, 7, . . .

Expanding the first eight terms of the series:

$$\text{ARCSIN } X = X^1 + \frac{(1)X^3}{(2)(3)} + \frac{(1)(3)X^5}{(2)(4)(5)} + \frac{(1)(3)(5)X^7}{(2)(4)(6)(7)} +$$

$$+ \frac{(1)(3)(5)(7)X^9}{(2)(4)(6)(8)(9)} + \frac{(1)(3)(5)(7)(9)X^{11}}{(2)(4)(6)(8)(10)(11)} + \frac{(1)(3)(5)(7)(9)(11)X^{13}}{(2)(4)(6)(8)(10)(12)(13)} +$$

$$+ \frac{(1)(3)(5)(7)(9)(11)(13)X^{15}}{(2)(4)(6)(8)(10)(12)(14)(15)} + \frac{(1)(3)(5)(7)(9)(11)(13)(15)X^{17}}{(2)(4)(6)(8)(10)(12)(14)(16)(17)} + \ldots$$

Notice the pattern of which can be memorized as: The coefficients of X start with one in the numerator and increase by one alternately in every numerator and denominator until it equals the exponent of X that increases by 2 for each term.

As a memory aid, the general format for each term can be memorized as:

$$\frac{(\text{products of odd series up to } n-2)\ X^n}{(\text{products of even series up to } n-1)\ \ n}$$

: where the exponent of X is the odd series: 1, 3, 5, 7, 9, . . . You can view the topic of: Products Of First Terms Of The Odd and Even Series for some formulas that could be used to find and-or express these indicated products.

Simplifying most of the terms given above:

$$\text{ARCSIN } X = X + \frac{X^3}{6} + \frac{3X^5}{40} + \frac{15X^7}{336} + \frac{105X^9}{3{,}456} + \frac{945X^{11}}{42{,}240} + \frac{10{,}395X^{13}}{599{,}040} + \frac{135{,}135\,X^{15}}{9{,}676{,}800} + \ldots$$

The smaller the sine value (generally due to a smaller trigonometrically equivalent reference angle (<=90°)), the faster (ie. fewer terms needed to be evaluated) the sum of the terms converges to a given value since the value of each next term is more rapidly approaching a value of 0. Hence, for a given precision (essentially, the number of correct significant digits), the smaller the angle, the fewer number of terms that need to be evaluated. Remember that a power of a fraction ($X<1$) is actually a fraction of a fraction and so on which results in a very small value. To give you an idea of the results using only the 8 terms given above: when $x=1$ (the sine value of 90° angle), precision (ie., lowest decimal numerical weight) correct (ie., accuracy) to the 1st or 2nd decimal place (ie. weight) is achieved, when $x=0.5$, a precision correct to the 5th or 6th decimal place is achieved, and when $x=0.1$, a precision correct to the 16th or 17th decimal place is achieved. One method to increase accuracy without utilizing more terms when X is greater than say about 0.5 is to convert the angles sine value to its (lower) corresponding cosine value and then use the ARCCOS X series.

Ex. Given SIN ¢ = 0.425, find ¢.

$$\text{ARCSIN } 0.425 = 0.425 + \frac{(0.425)^3}{6} + \frac{3(0.425)^5}{40} + \frac{15(0.425)^7}{336} +$$

$$+ \frac{105(0.425)^9}{3{,}456} + \frac{945(0.425)^{11}}{42{,}240} + \frac{10{,}395(0.425)^{13}}{599{,}040}$$

$$+ \frac{135{,}135(0{,}425)^{15}}{9{,}676{,}800} + \ldots$$

$$\text{ARCSIN } 0.425 = 0.425000000 + 0.01279427 + 0.001039934 + 0.000111808 + 0.000013744 + 0.000001828 + 0.000000256 + 0.000000037$$

ARCSIN 0.425 = about 0.438961877 radians which is about 25.15066292°.

Checking by using a calculator:

ARCSIN 0.425 = 0.438961885 (radians) = 25.15066341°. : If a few more terms were utilized, the result shown above would match this correct value.

When the sine value given is high, here is a method that utilizes the complementary angle's sine value which is a lower value to use in the series, and where fewer terms are then required for a certain precision:

$90° = A + B$: sum of the complementary angles A and B

$A = 90° - B$ which can be expressed as:

$\text{ARCSIN (SIN A)} = 90° - \text{ARCSIN (SIN B)}$: note, A = ARCSIN(SIN A) and B = ARCSIN (SIN B)

Since: $\text{SIN B} = \sqrt{1 - \text{SIN}^2\text{ A}}$: as shown previously, therefore:

$\text{ARCSIN (SIN A)} = 90° - \text{ARCSIN}\left(\sqrt{1 - \text{SIN}^2\text{ A}}\right)$: here, optionally using degree angles as indicated with the 90° angle value.

Ex. Evaluate ARCSIN 0.93969262

Let SIN A = 0.93969262

$\text{SIN B} = \sqrt{1 - 0.93969262^2} = 0.342020143$

B = ARCSIN (SIN B) = ARCSIN 0.342020143 = 0.349067219 rads = 20° Therefore,

A = ARCSIN (SIN A) = ARCSIN 0.93969262 = A = 90° - B = 90° - 20° = 70°

If you want to use all radian angles instead of degree angles:

Since 90° = 1.570796327 rads:

$1.570796327 = A + B$: here, A and B are complementary angles with units of radians, that sum to 1.570$\underline{8}$ radians mathematically:

$A = 1.570796327 - B$
$B = 1.570796327 - A$

Modifying the general formula so as to correspond to radian angles:

$\text{ARCSIN}\ (\text{SIN}\ A) = 1.570796327 - \text{ARCSIN}\ (\sqrt{1 - \text{SIN}^2 A})$: using radian angles

If given an angles COS or TAN value and you want to use the ARC SIN series, convert the given value to the angles corresponding SIN value.

Ex. Given COS ¢ = 0.82 find the angle.

First convert the value given to the (same) angles corresponding SIN value.

$\text{SIN}\ ¢ = \sqrt{1 - \text{COS}^2\ ¢}$

$\text{SIN}\ ¢ = \sqrt{1 - (0.82)^2}$

$\text{SIN}\ ¢ = 0.57236352$

Placing this SIN ¢ value into the ARC SIN expansion, we find that the angle is 34.91520625°.

Hence: ARCCOS 0.82 = ARCSIN 0.57236352 = 34.91520625°

Ex. Given TAN ¢ = 1.732 find the angle.

First convert the value given to the corresponding SIN value of the (same) angle.

$$\text{SIN}\ ¢ = \frac{\text{TAN}\ ¢}{\sqrt{1 + \text{TAN}^2\ ¢}} = \frac{1.732}{\sqrt{1 + (1.732)^2}} = \frac{1.732}{1.999956} = 0.866019052$$

Placing this SIN value into the ARCSIN series, we find that the angle is about 60°.

Hence: ARCTAN 1.732 = ARCSIN 0.866 = 60°

Here are some other trigonometric identity methods to evaluate ARCSIN X:

From: $\text{COS}\ ¢ = \sqrt{1 - \text{SIN}^2\ ¢}$ and letting:

$\text{ARCSIN}\ X = ¢ = \text{ARCCOS}\ (\text{COS}\ ¢)$: their trigonometric results is the same angle, therefore:

$\text{ARCSIN}\ X = \text{ARCCOS}\ \sqrt{1 - \text{SIN}^2\ ¢}$ Since $X = \text{SIN}\ ¢$:

$\text{ARCSIN}\ X = \text{ARCCOS}\ \sqrt{1 - X^2}$: $X = \text{SIN}\ ¢$

From: $\text{TAN}\ ¢ = \dfrac{\text{SIN}\ ¢}{\sqrt{1 - \text{SIN}^2\ ¢}}$ and letting:

ARCSIN X = ¢ = ARCTAN (TAN ¢) therefore:

$$\text{ARCSIN } X = \text{ARCTAN}\left(\frac{\text{SIN } \text{¢}}{\sqrt{1 - \text{SIN}^2 \text{¢}}}\right)$$

Since X = SIN ¢ :

$$\text{ARCSIN } X = \text{ARCTAN}\left(\frac{X}{\sqrt{1 - X^2}}\right)$$

: X = SIN ¢

Some methods for evaluating ARCCOS and ARCTAN will be given further ahead.

EPSILON (e)

The symbol (e) represents a constant that is an irrational value, like pi=3.14159...is, and is approximately 2.718281828. This value is used to represent the limiting (ie. maximum) factor value of constantly (ie. infinitely) compounded growth (growth with respect to the current size, or "growth upon (previous) growth - which includes any growth due to interest growth") over a (one) period of predetermined time. It is mathematically defined to be a very natural number and is frequently used when representing growth or decay (loss) processes in nature, therefore, the constant (e) is often found in many mathematical formulas. You could say that (e) and (pi) are natural constants. (e) is equivalent to the expression below, and **a derivation of (e) is given in the appendix section of this book**.

$$e = \left(\frac{1}{1} + \frac{1}{n}\right)^n = \text{about } 2.71828 \text{ as } n \dashrightarrow \infty$$

: (n -->∞) means: "as n approaches infinity". Remember, infinity has no specific value or end, and therefore, it cannot be mathematically represented, but only "approached", or approximated for practical purposes. In a way, infinity is an irrational value. Infinity is a concept and general description for a non-ending or unending process. "As n approaches infinity" could be thought of as: "as (n) gets (unendingly) higher in value". (e) is also called Euler's (pronounced as "Oiler's") Number.

Mathematically, combining the fractions:

$$e = \left(\frac{n+1}{n}\right)^n = \frac{(n+1)^n}{n^n} \qquad : \sim 2.71828 \text{ as } n \dashrightarrow \infty$$

As (n) approaches infinity, the entire base of this indicated power approaches: 1.0000....1 which is practically 1. It is as if the added 1 in the numerator becomes less and less meaningful as (n) increases, and it is a mathematical fact when you consider that 1 part of an increasing number of total parts, becomes less of a portion or fraction of the whole part or entire parts. The result will always be slightly over 1 as (n) becomes high n value:

For example, consider these fractions where (n) increases in value:

$$\frac{(n+1)}{n}\ ,\ \frac{8}{7} = 1.142857143\ ,\ \frac{15}{14} \sim 1.071428571\ ,\ \frac{1500}{1499} = 1.000667111\ ,\ \frac{999999}{999998} = 1.000001$$

Also, using the mathematically equivalent form of the base value:

$$\left(\frac{1}{1} + \frac{1}{n}\right)\ ,\ \left(\frac{1}{1} + \frac{1}{1499}\right) = 1 + 0.000667111\ ,\ \left(\frac{1}{1} + \frac{1}{999999}\right) = 1 + 0.000001 = 1.000001$$

Raising this value to a very high power (such as with an exponent that is high value of (n)):

$$(1.0000...1)^{\infty} = e \sim 2.71828...$$

Now it will be shown in a simple manner where this value of 2.71... , and not some other value, comes from.

If we let $x = \frac{1}{n}$, and substituting this value into the above power of a binomial, and expanding the indicated power:

$$\left(\frac{1}{1} + \frac{1}{n}\right)^n = (1 + x)^n$$

also notice that since $x = 1/n$, $n = 1/x$, hence: $(1+x)^n = (1+x)^{(1/x)} = x\sqrt{1+x}$
:when n is high, as n ----> infinity, x---->0, and the result approaches 2.71828.... = e

$(1 + x)^1 = 1 + 1x$: $n=1$

$(1 + x)^2 = (1+x)^1(1+x)^1 = 1 + 2x + x^2$: $n=2$

$(1 + x)^3 = (1+x)^2(1+x)^1 = 1 + 3x + 3x^2 + x^3$: $n=3$

$(1 + x)^4 = (1+x)^3(1+x)^1 = 1 + 4x + 6x^2 + 4x^3 + 1x^4$: $n=4$

We observe a pattern that the second terms numerical coefficient for (x) is equal to the value of (n). So if (n) is some high value, as indicated below, the first two terms would be for example:

$(1 + x)^{50} = 1 + 50x + \ldots$: when $n=50$

$(1 + x)^{999999} = 1 + 999999x + \ldots$:when $n=999999$

Since $x=1/n$, $x = 1/999999 = 0.000001$, (x) approaches an infinitely small value as (n) approaches infinity. The second term in this series (for e) is always equal to 1 regardless of the value of (n). For example if (n) = 999999, (x)= 1/n = 1/999999 = 0.000001. The product of (n) and (x) is always 1, and this is so since (n) and x) are reciprocals.

$999999 (0.000001) = 1$

The value of the first two terms is always: $1 + 1 = 2$

The remaining (infinite number of) terms will sum up to 0.71828... for a total of: $2 + 0.7182\ldots = 2.71828\ldots = e$

The remaining terms will get smaller and smaller in value. This is due to the increasing power of (x) in the terms. Given a value less than 1, the higher the indicated power (ie., the exponent) it is raised to, the smaller the resulting power value. From basic multiplication of decimals, a fraction of a fraction, or a power (>1) of a fraction, will result in a smaller value.

From $x = \frac{(1)}{(n)}$

$x^2 = \left(\frac{1}{(n)}\right)^2 = \frac{1}{n^2} > x^3 = \left(\frac{1}{(n)}\right)^3 = \frac{1}{n^3}$: $n > 1$

Also, a quotient is inversely related to the divisor. The higher the divisor, the smaller the quotient.

Whereas (e) is used to represent a naturally or "continuously" growing or increasing value,

e^{-1} or= $\frac{1}{e}$ is frequently used when representing a naturally or "continuously" decaying value.

(e) and-or (e^{-1}) is sometimes used in some electronic formulas, such as for capacitors (essentially electric charge holders, potential energy), to express the natural like changes and values of voltages and-or currents (minute, nearly infinitesimally small, electrons having an electric charge).

Using a relative value of 1 = 100%, if this value of 1 grows compoundedly with an infinite (nearly endless, continuous, unbroken) number of growing steps over 1 period of time, it will grow to a maximum or limit of (e) = 2.718... The time it takes for the value of 1 to grow to (e) is the period time of the given situation. If then given an initial value of 5 and it had naturally compounded growth during the same time period, that value of 5 will grow to: $5e = (5)(2.71828) =\sim 13.\underline{6}$ at the end of one period of time. If the initial was 13.6 and naturally decays compoundedly during the same amount of time, it would become a value of: $13.6 / e^1 = 13.6 / 2.71828 = 5$

A negative power, such as a negative power of e, of can be calculated by using the reciprocal of the corresponding positive power:

$$b^{-x} = \frac{1}{b^x}$$ If the base of the power is (e):

$$e^{-x} = \frac{1}{e^x} \approx \frac{1}{2.7182818^x}$$

$$e^{-2} = (e^{-1})^2 = \left(\frac{1}{2.7182818}\right)^2 = 0.367879441^2 = 0.135335283$$

And generalizing the above**, we can solve for a negative power of a base, here (e), using the same indicated power (here, x) of the reciprocal of that base.**

Since $(1/e) = (1/2.718281828) = 0.367879441 = e^{-1}$ and raising each side to the (x) power, and switching sides:

$(e^{-1})^x = 0.367879441^x$ after using the power to a power rule on the left side:

$\mathbf{e^{-x} = 0.367879441^x}$ and $\mathbf{e^x = 2.718281828^x}$

$\mathbf{b^{-x} = (1/b)^x}$ and-or $\mathbf{b^{-x} = \frac{1}{b^x} = (b^{-1})^x = (1/b)^x}$ **: A negative power of a base is equal to the same positive power of the reciprocal of that base.**

As discussed previously in this book, (e) is the base for natural logarithms. Fortunately, a series for calculating powers of (e) has been developed. It will provide great computational use. This series for (e) is shown next, and its derivation is shown in the appendix.

SERIES FOR POWERS OF (e)

$$e^x = \sum_{n=0}^{n=\infty} \frac{x^n}{n!} \quad : \; 0! = 1 \text{ and } x^0 = 1$$

Expanding the terms of this series:

$$e^x = 1 + x^1 + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \frac{x^5}{5!} + \frac{x^6}{6!} + \frac{x^7}{7!} + \dots$$

: a derivation of this is shown in the appendix section

Simplifying the factorials:

$$e^x = 1 + x^1 + \frac{x^2}{2} + \frac{x^3}{6} + \frac{x^4}{24} + \frac{x^5}{120} + \frac{x^6}{720} + \frac{x^7}{5{,}040} + \frac{x^8}{40{,}320} + \frac{x^9}{362{,}880} + \frac{x^{10}}{3{,}628{,}880} + \dots$$

When the value of x is less than or equal to 1, the series rapidly converges toward 0. The smaller x is, fewer terms need to be evaluated for a given accuracy (ie., number of correct significant digits) of the power of e. To give you a general idea of the results of using the 11 terms given above, when x=1, you can expect precision (decimal place or position) correct (accuracy) to the 6th decimal digit, when x=0.5, you can expect precision correct to the 9th digit, and when x=0.1, you can expect a precision correct to the 16th digit.

When x is greater than 1, rather than use more terms for a greater precision and accuracy, you can factor (e^x) to where each exponent of (e) is less than or equal to one. The result is that of repeated multiplication. For example:

$e^2 = (e^1)(e^1)$ or perhaps:

$e^2 = (e^{0.5})^4 = (e^{0.5})(e^{0.5})(e^{0.5})(e^{0.5})$: that is, use the series to evaluate $e^{0.5}$, and then raise that value to the 4th power. You can an use multiplication to do this.

Here are some useful powers of (e):

$e^1 = 2.71828182845904\ldots$

$e^{0.5} = \sqrt{e} = 1.64872127070012\ldots$

$e^2 = e^1 e^1 = 7.38905609893064\ldots$

$e^{-1} = \frac{1}{e^1} = 0.3678794411714\ldots$

$e^{-2} = \frac{1}{e^2} = \frac{1}{e^1}\,\frac{1}{e^1} = 0.135335283\ldots$

$e^{10} = 22{,}026.46579481\ldots$

Ex. e^3.74 = e^(2 + 1.74)
e^3.74 = (e^2)(e^1.74)
e^3.74 = (e^2)(e^1)(e^0.74)
e^3.74 = (7.389056098)(2.718281828)(2.095935514)
e^3.74 = 42.09799016

Ex. e^-1.47 = (e^-2)(e^0.53) : from -2 + x = -1.47 , therefore x = 2 + (-1.47) = 2 - 1.47 = 0.53
e^-1.47 = (0.135335283)(1.698932309)
e^-1.47 = 1/e^1.47 = 0.229925485**...**

Ex. Evaluate e^21

N = e^21 = (e^20)(e^1)
N = (e^10)^2 (e^1)
N = (22,026.46579)^2 (2.718281828)
N = (485165195.4)(2.718281828) : Using a 10-digit calculator
N = 1,318,815,734

Ex. Evaluate 5^2.3 using a power of (e). To do this, lets first convert the base of 5, to its equivalent power of (e):

Let 5 = (e^x) raising each side to the 2.3 power: 5^2.3 = (e^x)^2.3

Given: 5 = e^x let's solve for the necessary and proper exponent of (e) by taking the logarithm of both sides:

ln 5 = ln e^x using the log of an indicated power rule, and this can be expressed as:
ln 5 = x ln e dividing both sides by ln e:

$x = \frac{\ln 5}{\ln e}$ = ln 5 = 1.609437912 therefore:

5^2.3 = (e^1.609437912)^2.3 using the power to a power rule; multiply the exponents:

5^2.3 = e^3.701707199 = ~ 40.5164

For any power of the same base, here 5, the expression to evaluate would then have the form of:

5^x = (e^1.609437912)^x = e^(1.609437912 x) : using a power of (e) to evaluate any indicated power of 5.

Using the above expressions, a general formula for evaluating any indicated power of a value by using a power of (e), is:

First we would arrive at:

b^x = (e^(ln b))^x which can be expressed using the power to a power rule as:

b^x = e^(x ln b) : **A GENERAL FORMULA FOR EVALUATING ANY INDICATED POWER OF A NUMBER WITH A POWER OF (e)**.
Since indicated roots can be expressed as an indicated power of a number, this same formula can be used to solve for roots.
Consider this derivation also:

b^a = e^x , therefore: ln b^a = ln e^x therefore:
a ln b = x ln e , therefore: a ln b = x therefore, substituting this value of (x) in e^x, we have:

b^a = e^(a ln b) Ex. 5^2 = e^(2 ln 5)

Find: $\sqrt{2}$ converting this root or radical expression to its corresponding exponential notation:

$\sqrt{2}$ = 2^(1/2) = 2^0.5 Using a power of (e) to solve this:

$\sqrt{2}$ = b^x = 2^0.5 = e^(x ln b) = e^(0.5 ln 2)

$\sqrt{2}$ = e^((0.5)(0.69314718)) = e^0.34657359

$\sqrt{2}$ = 1.414213562

EVALUATING POWERS OF (e) USING A SMALL TABLE OF CONSTANTS

Besides using the series for (e) to directly calculate or solve powers of (e), you can use the method described below which utilizes multiplication of powers of (e) that have already been solved for. This book has strived to promote using formulas instead of using tables. The small table below with only 100 entries can effectively replace a table with thousands of entries. Tables may still be necessary for various reasons, and therefore, some are given in the appendix section of this book, and they are still very useful for checking formula calculations when a calculator is unavailable.

Ex. Find e^0.35

Factoring this into powers of (e) where the exponent of each factor corresponds to each different decimal number and position of the given exponent:

e^0.35 = e^0.3 e^0.05 Now factoring these exponents into a power of a power:
Ex: e^0.3 = (e^1)^0.3 = (e^(1/10)^(0.3 x 10) = (e^0.1)^3

e^0.35 = (e^0.1)^3 (e^0.01)^5 : essentially repeated multiplication, ex: (e^0.1)^3 = (e^0.1)(e^0.1)(e^0.1)

You must calculate at least one of the powers of (e), usually (e^0.1), by using the series for powers of e, or use a table to find the corresponding value.

e^0.1 = 1.105170918076

Or, if you don't want to use the series for (e), you can calculate the value of (e^1) based on its definition and take its' tenth root to get the value of e^0.1.

$\sqrt[10]{e}$ = e^1/10 = e^0.1

Likewise, e^0.01 can be calculated using the series, or it can be "derived" by taking the tenth root of e^0.1:

e^0.01 = e^(0.1/10) = (e^0.1)^(1/10) = $\sqrt[10]{e^{0.1}}$

e^0.1 = 1.105170918076
e^0.01 = 1.010050167084
e^0.001 = 1.001000500167
e^0.0001 = 1.000100005
e^0.00001 = 1.00001000005
e^0.000001 = 1.000001000001 : notice as the exponent approaches 0, the value of the power approaches 1

Rather than perform repeated multiplication of the above constants, you can make a small, but powerful table of all the integer powers, from 1 to 9, of these constants . For example:

x	e^x	e^0.x	e^0.0x	e^0.00x	e^0.000x
0	1.000000000000000	1.000000000000000	1.000000000000000	1.000000000000000	1.000000000000000
1	2.718281828459045	1.105170918075648	1.010050167084168	1.001000500166708	1.000100005000167
2	7.38905609893065	1.22140275816017	1.020201340026756	1.002002001334	1.000200020001334
3	20.08553692318767	1.349858807576003	1.030454533953517	1.003004504503377	1.0003000450045
4	54.59815003314424	1.49182469764127	1.040810774192388	1.004008010677342	1.000400080010668
5	148.4131591025766	1.648721270700128	1.051271096376024	1.005012520859401	1.000500125020836
6	403.4287934927351	1.822118800390509	1.06183654654536	1.006018036054065	1.000600180036005
7	1096.633158428459	2.013752707470477	1.072508181254217	1.007024557266849	1.000700245057177
8	2980.957987041728	2.225540928492468	1.083287067674959	1.008032085504274	1.00080032008535
9	8103.083927575384	2.45960311115695	1.09417428370521	1.009040621773868	1.000900405121527

x	e^0.0000x	e^0.00000x	e^0.000000x	e^0.0000000x	e^0.00000000x
0	1.000000000000000	1.0000000000000	1.000000000000000	1.000000000000000	1.000000000
1	1.00001000005	1.0000010000005	1.000000100000005	1.00000001	1.000000001
2	1.000020000200001	1.000002000002	1.00000020000002	1.00000002	1.000000002
3	1.000030000450005	1.0000030000045	1.000000300000045	1.000000030000001	1.000000003
4	1.000040000800011	1.000004000008	1.00000040000008	1.000000040000001	1.000000004
5	1.000050001250021	1.0000050000125	1.000000500000125	1.000000050000001	1.000000005
6	1.000060001800036	1.000006000018	1.00000060000018	1.000000060000002	1.000000006
7	1.000070002450057	1.0000070000245	1.000000700000245	1.000000070000003	1.000000007
8	1.000080003200085	1.000008000032	1.00000080000032	1.000000080000003	1.000000008
9	1.000090004050122	1.0000090000405	1.000000900000405	1.000000090000004	1.000000009

e^0.35 = e^0.3 e^0.05 : e^x factored to indicated powers that have one digit greater than 0. For using the table, this can be expressed as:

e^0.35 = e^((0.1)3) e^((0.01)5)

In the table above, use:

(e^0.x) where x = 0.1 , and choose the corresponding row 3 which is the 3rd multiple of e^0.1
(e^0.0x) where x = 0.01 , and choose the corresponding row 5 which is the 5th multiple of e^0.01

e^0.35 = (1.349858808)(1.051271096)
e^0.35 = 1.419067549

If the indicated power of (e) is negative, the same method can be used if you place it into a form with a positive exponent and then take its reciprocal:

$$e^{-0.35} = \frac{1}{e^{0.35}} = \frac{1}{1.419067549} = 0.704688089$$

By using a reverse type of manner to that described above you can solve for the (indicated exponent) power of (e) that will be equal to the power value presented. In essence, you will be solving for a logarithm (an exponent), and here, with this table with powers of (e), it will be a natural logarithm. To find the next digit of the logarithm, divide the remainder (ie.

remaining factor) of the number by the highest corresponding power of (e) in the table that corresponds to that digit position. This process is also discussed further ahead in the topic of: CALCULATING LOGARITHMS USING A SMALL TABLE OF CONSTANTS .

Ex. Solve for x (the exponent), given e^x = 5 from the table above.

First note: e^(x.xx...) = (e^x)(e^0.x)(e^0.0x) . . . :(Note, x is used here only as a position indicator for the number being found, that is, after the first x is found, x will be recalculated for each new positional value)

Another, perhaps **clearer**, way to express this concept is:

e^(a.bcd...) = e^(a + 0.b + 0.0c...) = (e^a)(e^0.b)(e^0.0c) . . .

The basic process is to factor the number, here in this example it is 5, into factors that are powers of e:

5 = e^(x.xx...) = (e^x)(e^0.x)(e^0.0x) . . . : the last expression is the individual factors of 5

If you divide 5 by one of these factors, you will have the remaining value of the other factors, clearly, for example, after dividing both sides of the equation by (e^x), we have the total value of the remaining factors:

$$\frac{5}{e^x} = (e^{0.x})(e^{0.0x}) \ldots$$

After finding the value of (5/e^x), (ie. dividing the factor and value of e^x out of 5), we keep dividing each successive remaining quotient (here, of the initial given value of 5) by each successive total remaining factor value:

Starting with 5:

Looking at the table we see that e to the power of x that is nearest to 5 (without exceeding it) is 1.

e^1 = 2.718281828 Solving for how much of the 5 is left to continue factoring, we factor it by each new value:

5 / 2.718281828 = 1.839397205

Looking at the table we see that e to the power of 0.x that is nearest to 1.839397205 (without exceeding it) it is 0.6. Factoring to find what value is left of the 5 for the new factor to consider:

1.839397205 / 1.822118800 = 1.0094687843

Looking at the table we see that e to the power of 0.0x that is nearest to 1.0094687843 (without exceeding it) is 0, which means that 0 will be in that position of the exponent. e^0.00 = e^0 = 1, and multiplying by 1 will not change the result.

What we have up to this point in the process is: (e^1)(e^0.6)(e^0.00) = e^1.60

Factoring what is left of the 5 for the new factor to consider is the same value we had previously. We are to find the closest value to it for the position: e^0.00x , and its value is: e^0.009 .

What we have up to this point in the process is: 5 = (e^1)(e^0.6)(e^0.00)(e^0.009) = e^(1 + 0.6 + 0.00 + 0.009) = = e^1.609 :

Hence x is approximately 1.609 , and e^1.609 = about 5 : note also that 1.609 = ln 5 = $\log_e 5$

The table of powers of (e) can also be used to find the natural logarithm (base e) of a number.

The above concepts are powerful, and can even be applied to powers of any other base, for example, powers of ten = = 10^x as shown here:

Evaluating Powers Of 10 Using A Small Table Of Constants

Ex. 10^0.752 = 10^(0.7 + 0.05 + 0.002) =
= (10^0.7) (10^0.05) (10^0.002) , Converting these exponents to integers we have:
= (10^0.1)^7 (10^0.01)^5 (10^0.001)^2

10^0.1 = 1.258925411794
10^0.01 = 1.023292992281
10^0.001 = 1.002305238078
10^0.0001 = 1.000230285021

Again, rather than perform repeated multiplication, a small table is presented here:

x	10^x	10^0.x	10^0.0x	10^0.00x	10^0.000x
0	1.000000000000000	1.000000000000000	1.000000000000000	1.00000000000000	1.000000000000000
1	10.00000000000000	1.258925411794167	1.023292992280754	1.0023052380779	1.000230285020825
2	100.0000000000000	1.584893192461114	1.0471285480509	1.004615790278395	1.00046062307284
3	1000.000000000000	1.99526231496888	1.071519305237606	1.006931668851804	1.000691014168259
4	10000.00000000000	2.51188643150958	1.096478196143185	1.009252886076685	1.000921458319296
5	100000.0000000000	3.162277660168379	1.122018454301963	1.011579454259899	1.001151955538169
6	1000000.000000000	3.981071705534972	1.148153621496883	1.01391138573668	1.001382505837099
7	10000000.00000000	5.011872336272722	1.17489755493953	1.016248692870696	1.001613109228309
8	100000000.0000000	6.309573444801933	1.202264434617413	1.018591388054117	1.001843765724026
9	1000000000.000000	7.943282347242816	1.230268770812382	1.02093948370768	1.002074475336479

x	10^0.0000x	10^0.00000x	10^0.000000x	10^0.0000000x	10^0.00000000x
0	1.000000000000000	1.000000000000000	1.000000000000000	1.00000000000000	1.000000000000000
1	1.000023026116027	1.000002302587744	1.000000230258536	1.000000023025851	1.000000002302585
2	1.000046052762256	1.00000460518079	1.000000460517125	1.000000046051703	1.00000000460517
3	1.000069079938699	1.000006907779138	1.000000690775767	1.000000069077555	1.000000006907755
4	1.000092107645368	1.000009210382787	1.000000921034461	1.000000092103408	1.000000009210341
5	1.000115135882277	1.000011512991739	1.000001151293209	1.000000115129261	1.000000011512926
6	1.000138164649436	1.000013815605993	1.00000138155201	1.000000138155115	1.000000013815511
7	1.000161193946858	1.000016118225548	1.000001611810864	1.00000016118097	1.000000016118096
8	1.000184223774555	1.000018420850406	1.000001842069771	1.000000184206825	1.000000018420681
9	1.00020725413254	1.000020723480565	1.000002072328731	1.00000020723268	1.000000020723266

Ex. 10^1.79 = (10^1) (10^0.7) (10^0.09)
10^1.79 = (10) (5.011872336) (1.230268771)
10^1.79 = 61.65950019

Ex, 10^-3.7 = 10^(-4 + 0.3) =
10^-3.7 = (10^0.3)(10^-4)
10^-3.7 = (1.995262315)(10^-4) By observation; moving the decimal point 4 places leftward:

10^-3.7 = 0.0001995262315

We can also solve the above example as: 10^-3.7 = 1/10^3.7 = 1/((10^3)(10^0.7))

This table for powers of 10 can also be used to find the common (base 10) logarithms. For example, in a previous example we calculated:

10^1.79 = 61.65950019 , hence $\text{Log}_{10}\ 61.65950019 = 1.79$

NATURAL LOGARITHMS

Natural logarithms are logarithms where the base is the ("natural") constant of (e) = 2.71828**... ,** and which has been discussed previously in this book. Several series for natural logarithms have been developed and most are similar, and they are of great and necessary computational aid, especially before the age of electronic calculators. The following discussion about logarithms is fairly extensive, and the reader may skip over most of the material till some other time as long as they have a basic understanding of what a logarithm is.

Here is a simple explanation of what a logarithm, and specifically what a natural logarithm means:

N = e^x : e^x will calculate the growth (numerical) factor that a value will effectively have after continuously (with infinitely compounded growth) growing after x periods of time, where after each 1 period of time, it grows by a factor of e^1 = about 2.718 times more.

With x=2, e^2 = (e^1)(e^1) , a value will grow by a factor of (e^1) twice, There will be two periods of natural or infinitely compounded growth. After the first period it will grow by a factor of (e^1) and produce a resulting growth, say growth1, and then after another period of this type of growth, the growth1 value will also grow by a factor of (e^1) resulting in the value of growth2. The initial value will grow or increase by the factor of: (e^1)(e^1) = e^2 times more.

Time: 0 , period 1 of growth , period 2 of growth
Value: value , value (e^1) = value2 , value2(e^1) = value3 by substitution:

value3 = value2(e^1) = (value1(e^1))(e^1) = value1(e^2)

After 2 periods of infinitely compounded growth, value 1 will grow by a factor of (e^2). In general, after x periods of infinitely compounded growth, an initial starting value will grow by a factor of (e^x).

ending value = initial value (e^x) : after x periods of infinitely compounded growth

x = Ln (N) : will solve for how many periods of time (ie. the exponent x, in e^x) it will take a value to grow continuously (with infinitely compounded growth) so as to be equal to the value of N.

If you know the starting value of growth (c), it will grow to N after x periods of infinitely compounded growth:

N = c e^x : after x periods of growth. If you divide both sides by (c) we can still find the number of time periods of infinitely compounded growth for (c) so as to be equal to N. Note, (c) can equal 1 also, and then the equation is simply: N = 1 e^x = e^x, but you you understand that 1 is now the starting value that the natural growth will be applied to.

$\frac{N}{c}$ = e^x = (1)e^x solving for x, by taking the natural logarithm (ln) of both sides:

$\ln (N/c) = \ln e^x = x \ln_e e = x (1) = x$

x = ln (N/c)

Ex. 36.945 = 5e^x

We see that 5 is the initial value that will undergo continuous or natural growth, and that this value of 5 has, or will, grow to 36.954 after some time (ie., some number of time periods) of growth. We can find the number of time periods of growth by solving for x:

$x = \ln (36.945 / 5)$
$x = \ln 7.345 = 2$: after a time length of 2 periods of natural growth, a value of 5 will "grow" to 36.945

The most common series for natural logarithm calculations is presented below and it is easy to remember. The derivation of this series can be found in the APPENDIX section of this book.

First, a simple equation must first be solved since the series is for the solution of LN (1 + x), where (1 + x) must be <=2, therefore (x) must be <=1 since (1+1)=2. Checking:

$1 + x \le 2$ solving for x by transposing (+1):
$1 + x - 1 \le 2 - 1$ combining:
$x \le 1$: x must be less than or equal to 1

Even though (x) must be less than or equal to 1 for the series to converge to a specific value, the series actually evaluates the natural logarithms of values between 0 and 2. The terms will get smaller and smaller in absolute value. Though 2 is a limited or low value, there are mathematical methods so as to use the series for any general value.

Ex. When evaluating LN N given N = 0.5, what should (x) be for use in this natural logarithm series?

Equating LN (1+x) = LN N : N <=2 since N=0.5
LN (1+x) = LN 0.5

Therefore, $1 + x = 0.5$
$x = 0.5 - 1$: note, the general formula for x is then: $x = (N - 1)$
$x = -0.5$

Here is the series for the natural logarithm of a number (N):

$$\text{LN } N = \text{LN } (1+x) = \sum_{n=1}^{n=\infty} (-1)^{(n+1)} \cdot \frac{x^n}{n} \qquad : N \le 2 \text{ , } x \le 1 \quad : x=N-1$$

: A NATURAL LOGARITHM SERIES
(Credited to Nicolaus Mercator)

Expanding some initial terms:

$$\text{LN } N = \text{LN } (1+x) = \frac{x^1}{1} - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \frac{x^5}{5} - \frac{x^6}{6} + \;.\;.\;. \qquad : N \le 2 \text{ , } x \le 1 \quad x=N-1$$

Generally, for an accuracy of (n) significant digits when N is about 0.7 (then x is about: (0.7 - 1) = -0.3), use 2n terms. The smaller (x) is in absolute value, fewer terms need to be evaluated for a given precision. If you create a computer program or algorithm (method(s), step(s) or procedure(s) to solve a problem such as the series shown) to perform or calculate this expression, a large amount of terms can easily be evaluated, and-or the program can be made to stop immediately when the difference between successive terms is at some acceptable level (ie., close to 0.0), and the value of all further terms is considered negligible and need not be calculated. For example, when the difference is less than or equal to 0.000,001 (ie., a millionth), there will be at least 6 accurate decimal digits or "places" in the result.

Here are the corresponding values of (x) for ln 0.7 and ln 1.3:

ln 0.7 = ln (1 - 0.3) use x = 0.7 - 1 = - 0.3
ln 1.3 = ln (1 + 0.3) use x = 1.3 - 1 = + 0.3 : note that this has the same absolute value as when N=0.7

Here are the corresponding values of (x) for ln 0.2 and ln 1.8:

ln 0.2 = ln (1 - 0.8) : x = 0.2 - 1 = - 0.8
ln 1.8 = ln (1 + 0,8) : x = 1.8 - 1 = 0.8 ; the same in absolute value as above

By observing the two results above, the closer the value of N is to 1, as the first instance is, the smaller the absolute value of (x). When N is less than 1, (x) will be negative and all terms of the series, and the resulting sum, will be negative in sign. Logarithms of values between 0 and 1 are negative in value.

The natural logarithm of 2 can be useful when calculating some natural logarithms by first factoring the number and taking the sum of their logarithms so as to find the actual logarithm. Other methods will be presented below for calculating any natural logarithm.

ln 2 = 0.6931471805599451. . .

Ex. $\ln 5 = \ln\left(\frac{10}{2}\right) = \ln 10 - \ln 2 = 2.302585093 - 0.693147181 = 1.609437912$

Here's another example that shows what to do when the value (ie.,N, the number of the logarithm) is greater than or equal to 2 when trying to find its logarithm with the series:

Ex. Evaluate ln 21

ln 21 = ln (10^2)(0.21) : expressing the number (here 21) in scientific notation
ln 21 = ln (10^2) + ln (0.21)
ln 21 = 2 ln 10 + ln 0.21
ln 21 = 2 (2.302585093) + ln 0.21 : the important point to remember (or at least have available) here is that (ln 10) is always equal to the constant of 2.302585092994..., and that the natural logarithm to be found is in the required range (0<N<2) for the logarithm series formula given.

ln 21 = 4.605170186 + (-1.560647748)
ln 21 = 4.605170186 - 1.560647748
ln 21 = 3.044522438

Or if you want slightly better accuracy using the same number of terms, you can use a different logarithm factor that is a higher power of 10, for example, here is a small reference table that is very useful:

ln 10 = 2.302585092994)
ln 100 = ln 10^2 = 2 ln 10 = 2 (2.302585092994) = 4.605170185988
ln 1,000 = ln 10^3 = 3 ln 10 = 3 (2.302585092994) = 6.907755278982
ln 10,000 = ln 10^4 = 4 ln 10 = 9.210340371976
ln 100,000 = ln 10^5 = 5 ln 10 = 11.51292546497
ln 1,000,000 = ln 10^6 = 6 ln 10 = 13.81551055796

Ex. Using the last example: ln 21

ln 21 = ln (10^3)(0.021)
ln 21 = ln 1000 + ln 0.021
ln 21 = $6.9077\underline{6}$ + ln 0.021 = $3.0445\underline{3}$: in the series for LN N, use x = (N - 1) = (0.021 - 1) = -0.979

There are other methods to evaluate the logarithm of a value greater than 2, but the method above is perhaps the one to use since the number of the logarithm to be found can be placed into a value not only less than 2, but less than 1. Below are some examples of some other methods to use to solve a logarithm. Some people may say something like: "Why bother with these methods when we have calculators to do this". The answer is why bother with learning any math at all then? This book tries to show some of the "in and outs", or "nuts and bolts" of mathematics so that you may have more of a grasp of these topics, and so as to apply in some way.

Ex. Evaluate ln 5 (other than the method shown above that uses the basic log rules)

Taking the third root of 5, we get: $\sqrt[3]{5}$ = 1.709975947

Therefore: 1.709975947^3 = 5

Actually, any root could have been taken as long as the final logarithm to be evaluated (using the series) has N, the number, less than or equal to 2.

hence: ln 5 = ln 1.709975947^3
ln 5 = ln (1.709975947) (1.709975947) (1.709975947)
ln 5 = ln 1.709975947 + ln 1.709975947 + ln 1.709975947
ln 5 = 3 ln 1.709975947
ln 5 = 3 (0.536479304)
ln 5 = 1.609437912

Another method is to factor the number for factors less than 2 as required for the series given, and then sum the logarithms of each of the factors for the resulting logarithm:

ln 5 = ln (3 x 1.666666667) : after factoring 5
ln 5 = ln (3) (1.666666667) factoring 3:
ln 5 = ln (1.7) (1.764705882) (1.666666667)
ln 5 = ln 1.7 + ln 1.764705882 + ln 1.666666667

Below is a method that uses a special factorization of N. The result is very similar to that of first placing the number into scientific notation.

Ex. ln 11

ln 11 = ln (10 + 1) : since we already know ln 10. Factoring 10 from each term:

ln 11 = ln 10 $\left(1 + \frac{1}{10} \right)$

ln 11 = ln 10 (1 + 0.1)

ln 11 = ln 10 (1.1) : here N is basically 11 factored by 10. Using the log product rule:
(11 / 10) = 1.1, hence 11 = (10)(1.1) = N

ln 11 = ln 10 + ln 1.1

Ex. $\ln 9$

$\ln 9 = \ln (10 - 1)$: since we already know $\ln 10$. Factoring 10 from each term:

$\ln 9 = \ln 10 \left(1 - \frac{1}{10} \right)$

$\ln 9 = \ln 10 (1 - 0.1)$

$\ln 9 = \ln 10 (0.9)$ using the log product rule:

$\ln 9 = \ln 10 + \ln 0.9$: Note, since $\ln 10$ is obviously greater than $\ln 9$, there must be something to reduce this, and this value is the negative value of logarithms of values less than 1, such as $\ln 0.9$ shown.

A perhaps simpler method to get the same results as above is to factor the number by the highest positional product (ie., the weight of that digit position, times the digit value) of that number. For example:

$\ln 537$

$\frac{537}{500} = 1.074$, hence: $537 = (500)(1.074)$ using substitution:

$\ln 537$
$\ln (500)(1.074)$
$\ln (5)(100)(1.074)$
$\ln 5 + \ln 100 + \ln 1.074$

If 5 is factored, you would have to evaluate the logarithm of another number, hence with this type of factorization method, it is handy to have the logarithms of the first 9 integers available:

$\ln 1 = 0$
$\ln 2 = 0.693147180559$
$\ln 3 = 1.098612288668$
$\ln 4 = 1.386294361119$
$\ln 5 = 1.609437912434$
$\ln 6 = 1.791759469228$
$\ln 7 = 1.945910149055$
$\ln 8 = 2.079441541679$
$\ln 9 = 2.197224577336$

$\ln 10 = 2.302585092994$
$\ln 100 = 4.6051701859881$: same as $\ln 10^2 = 2 \ln 10$
$\ln 1{,}000 = 6.907755278982$: same as $\ln 10^3 = 3 \ln 10$
$\ln 10{,}000 = 9.210340371976$: same as $\ln 10^4 = 4 \ln 10$

Here is another method to evaluate logarithms:

$\ln \left(\frac{1}{x} \right) = \ln \left(\frac{1x^0}{x^1} \right) = \ln \left(\frac{1 x^{0-1}}{1} \right) = \ln 1x^{-1} = -1 \ln x$

$\ln \left(\frac{1}{x}\right) = -\ln x$

or by multiplying each side by -1, and then switching sides:

$\ln x = -\ln \left(\frac{1}{x}\right)$: "LOG RECIPROCAL FORMULA"
: The log of a number is equal to the negative of the log of its reciprocal.

Also notice that the larger (x) is, the lower N = (1/x) is. On the right hand side, when N is less than 1 (when x is greater than 1) we see that (since its equal to ln x on the left hand side) the logarithm of N actually gets higher in value, though with a negative sign, as N approaches 0 (when x gets very large, approaching infinity). In short, logarithms between 0 and 1 are negative in sign. Since log 1 = 0, it is not difficult to imagine that when the number is less than 1, that the log will be less than 0, or negative in value.

Using the log quotient rule as a check:

$\log \frac{1}{x} = \log 1 - \log x = 0 - \log x = -\log x$, multiplying by (-1) and switching sides:

$\log x = -\log \frac{1}{x}$: checks

Ex. Find ln 52

$\ln 52 = -\ln \left(\frac{1}{52}\right)$

ln 52 = - ln 0.019230769
ln 52 = - (- 3.951243719)
ln 52 = + 3.951243719

Here are some examples of using logarithms to evaluate expressions:

Ex. Evaluate 3.25^1.3 : find the 1.3 indicated power value of 3.25

Let N = 3.25^1.3

From: N = e^(x ln b) : derived in the discussion about calculating powers (N=b^x) with logarithms.
b is the base of the power (here, it's 3.25):

N = e^(1.3 ln 3.25) = e^((1.3)(ln 2 + ln 1.625)) : after factoring 3.25 for factors <= 2
N = e^((1.3)(1.178654996))
N = e^1.532251495
N = 4.628586339

Ex. Evaluate $\sqrt[2.3]{5}$

Let N = $\sqrt[2.3]{5}$

From: N = e^((ln b) / x) : derived in the discussion about calculating roots with logarithms.
b = radicand (or base in 5^(1/2.3) = $\sqrt[2.3]{5}$)

N = e^((ln 5) / 2.3)
N = e^(1.609437912 / 2.3)
N = e^0.699755614
N = 2.013260635

Ex. Show that N^x = e^(x ln N) : a good way to calculate powers of N using the series for powers of e.

Taking the log of both sides:

ln N^x = ln e^(x ln N) Using the log rules:

x ln N = (x ln N) ln e since ln e = 1:

x ln N = x ln N : since the results are the same, the values were the same and therefore equal

Ex. Given 10^x = e^1 solve for x.

Taking the natural logarithm of both sides:

ln e^1 = ln 10^x using the log rules:
1 ln e = x ln 10
1 = x ln 10 solving for x and switching sides:

$x = \frac{1}{\ln 10}$: = about 0.4342944819
: ln 10 = about 2.302585093

Ex. Given 10^x = e^2 solve for x.

Taking the natural logarithm of both sides:

ln e^2 = ln 10^x using the log rules:

2 ln e = x ln 10

2 = x ln 10 solving for x and switching sides:

$x = \frac{2}{\ln 10}$: = approximately (2) (0.4342944819) = 0.8685889638
Or: two times the reciprocal of ln 10

Ex. Given 10^3 = e^x solve for x:

Taking the natural logarithm of both sides:

ln e^x = ln 10^3
x ln e = 3 ln 10
x = 3 ln 10 : about 3 (2.302585093) = 6.90775527898
Or: three times (ln 10)

Above, we found that 10^0.4342944819 = e^1. If we want to find the value of the second power of (e), we can raise each side to the second power or any other indicated power of (e) in question, and so as to also have its equivalent power of 10, and perhaps to express that power of (e) as a power of 10:

(e^1)^x = (10^0.4342944819)^x , with powers to a power, distribute the exponent:

e^x = 10^(0.4342944819 x) If we want to find the value of the second power of (e), set x=2:
For reference: **10^x = e^(2.302585093 x)** :
The coefficients of (x) in each equation are reciprocals, and this will be verified later in this book.

e^2 = 10^((0.4342944819)(2)) = 10^0.868588962 =~ 7.389056068

A method to calculate a logarithm is to factor the number into a power of (e) and a remaining factor that is less than (2) for the series. Due to that many more terms are required for a given accuracy for values greater than 1 for the logarithm series, it is best that this remaining factor be less than or equal to 1.

$$\frac{N}{e^x} = \text{(remaining factor)}$$: (remaining factor) = (remaining factor of N) = quotient

N = (power of e) (remaining factor) = (e^x) (remaining factor)

ln N = ln ((e^x) (remaining factor))
ln N = ln e^x + ln (remaining factor)
ln N = x + ln (remaining factor)

N can be divided by a constant that is powers of (e), or by repeated division by e^1 (= 2.718281828...) and counting the number of these divisions which is equivalent to the power of (e):

$$\frac{N}{e^1} = Q1 = \text{quotient}$$: if this quotient or remaining factor of N is >1, keep dividing by e^1:

$$\frac{Q1}{e^1} = Q2$$ This is equivalent as dividing N by e^1 repeatedly, which is the same as dividing N by the next integer power of (e) as shown here:

$$\frac{Q1}{e^1} = \frac{\;\frac{N}{e^1}\;}{e^1} = \frac{N}{e^2}$$

Ex. Find or calculate: ln 5

5 / e^2 = 0.676676416 therefore: 5 = (e^2)(0.676676416) , taking the ln of both sides of this equation:

ln 5 = ln ((e^2) (0.676676416))
ln 5 = ln e^2 + ln 0.676676416
ln 5 = 2 + (-0.390562087)
ln 5 = 1.609437913

CALCULATING LOGARITHMS USING A SMALL TABLE OF CONSTANTS

In general, this is the reverse process of finding powers of (e) using a table of constants as shown previously in this book.

Ex. Find x = ln 3.2

The general working method, or formula in relation to the table (shown previously) is:

(Note, (x) below represents a place holder or digit position in the number, and is not a regular variable):

ln N = ln(e^x.xxxx...) : or perhaps for more clarity as: ln (e^a.bcde...)
ln N = ln(e^x.0 e^0.x e^0.0x e^0.00x e^0.000x . . .)
ln N = ln(e^x.0) + ln(e^0.x) + ln(e^0.0x) + ln(e^0.00x) + ln(e^0.000x) + . . .
ln N = x + 0.x + 0.0x + 0.00x + 0.000x + . . .

Here is a helpful description of this process:

ln N = ln N factoring N:
ln N = ln (factor1)(factor2) factoring factor2 into factor3 and factor4:
ln N = ln (factor1)(factor3)(factor4) factoring factor4 into factor5 and factor6:
ln N = ln (factor1)(factor3)(factor5)(factor6) : and so on, the factorization can continue with the "remaining factor"

ln N = ln (factor1)(factor3)(factor5)(factor6) = ln factor1 + ln factor2 + ln factor3 + ln factor4 + ln factor5 + . . .

Using the table, when x=2 , e^x = e^2 and this value is larger than the given value of 3.2 , so therefore, x=1 is where to start the factorization process:

$$\frac{3.2}{e^1} = \frac{3.2}{2.718281828} = 1.177214212$$

: factoring 3.2, here by using a power of (e)
Therefore:

ln 3.2 = ln ((2.718281828)(1.177214212)) : ln N = ln (factors of N)
ln 3.2 = ln (2.718281828) + ln (1.177214212)
ln 3.2 = ln (e^1) + ln(e^0.?) : now we are to find the value of the exponent in e^0.x

From the table for the e^0.x constants, e^0.2 is larger than the new value of "N" we are considering, specifically the remaining factor of: (1.177214212) that we are now comparing powers of (e) to, so use e^0.1 to factor this new "N" factor in question:

$$\frac{1.177214212}{e^{0.1}} = \frac{1.177214212}{1.105170918} = 1.065187468$$

Now we have these factors of N=3.2::

ln 3.2 = ln (2.718281828) + ln (1.177214212) continuing the factorization process:
ln 3.2 = ln (2.718281828) + ln (1.105170918) + ln(1.065187468) expressing these factors as a power of (e):
ln 3.2 = ln(e^1) + ln(e^0.1) + ln(e^0.0?) A ln results in the indicated power (ie. exponent):
ln 3.2 = 1.0 + 0.1 + ?

From the table, the greatest value of (x) for e^0.0x is 6 for the new "N" (1.065187468), hence the updated (more correct) logarithm is:

ln 3.2 = ln(e^1) + ln(e^0.1) + ln(e^0.06) + . . .
ln 3.2 = 1.0 + 0.1 + 0.06 + . . .
ln 3.2 = 1.16 + ? + . . .

Continuing this process by factoring the latest factors, we have:

ln 3.2 = 1.0 + 0.1 + 0.06 + 0.003 + 0.0001 + . . .
ln 3.2 = 1.1631 + . . .

Don't forget, you can also solve for this as:

$$\ln 3.2 = -\ln \frac{1}{3.2} = -\ln 0.3125$$: here, N<1, see below.

Note that when N=1, ln N = ln 1 = 0, and give any other value (such as 0.3125) of N that is less than 1 and between 0 and 1, the result will be negative (<0) in value. However, using the table that was created for positive powers of (e) would be a bit difficult to use for negative powers of (e), so here is a similar table with negative exponents that can be utilized when N is less than 1.0. Actually, each value in this table below is the reciprocal of its corresponding value in the table of positive powers of (e) given previously. To avoid accessing both tables, just keep factoring N and adding in each new digit, where each new digit corresponds to the equivalent or next higher value of N.

For example, when finding ln 0.3125, the first sum to be added in to the exponent of (e) is -1 (not -2) which corresponds to 0.367879441, which is the closest higher value. Therefore, 0.3125 factors to 0.367879441 and 0.849463071, then continue the process with this "new" N, specifically the remaining factor(s) of N.

The basic reason that the next highest value is chosen is that factoring (ie. dividing) by using the next lower value will yield a factor >1, and hence the other table must also be utilized for this "new" N.

6	0.9999400017999639	0.999994000018	0.9999994000001801	0.9999999400000017	0.999999994
7	0.9999300024499429	0.9999930000245	0.999999300000245	0.9999999300000024	0.9999999929999999
8	0.9999200031999146	0.9999920000319998	0.9999992000003201	0.9999999200000032	0.9999999920000001
9	0.9999100040498785	0.9999910000404998	0.9999991000004049	0.999999910000004	0.999999991

Here is an example of using the above table to calculate negative powers of (e):

Ex. Evaluate e^-5.03

e^-5.03 = e^(-5 (+) -0.0 (+) -0.03) = e^-5 e^-0.0 e^-0.03
e^-5.03 = (0.006737946)(1.0)(0.970445533)
e^-5.03 = 0.006538809

You could always calculate the result using the table for positive powers of (e) when (e) is first expressed with a positive exponent as:

$$e^{-5.03} = \frac{1}{e^{5.03}} = (\text{value})$$

, and since (value) is the reciprocal of the actual result, we simply take the reciprocal of (value):

$$e^{-5.03} = \frac{1}{(\text{value})} = \frac{1}{152.933} = 0.006538811$$

CALCULATING POWERS BY CONVERTING THE BASE OF THE POWER TO (e)

By converting a base of a power to (e) we can solve powers, common antilogs (essentially powers of the common base of 10), and roots since we have a series for e^x. For this power of (e) to represent a given value correctly, the exponent of (e) must be determined or set to its correct or corresponding value.

Given N, what is the exponent of (e) required so that e^a = N ?

From e^a = N from the definition of logarithms:

a = $\log_e$ N = loge N = ln N : remember that a log value is essentially an exponent value

N = e^a raising each side to some indicated power expressed with the exponent of x:

(N)^x = (e^a)^x using the power to a power rule:

N^x = e^(ax)

This also shows that e^a is a constant or specific value (equivalent to N which is a constant value) when calculating all the power values (indicated with a exponent of x) of a given value of base N.

Ex. For calculating anti-logarithms (essentially calculating a power of a value) with a base of 10 (the common anti-logarithm base):

e^a = 10 therefore, according to the log definition:

a = ln 10 = 2.302585093 therefore:

e^2.302585093 = 10 raising each side to the (x) indicated power:

10^x = e^(2.302585093 x) : This is an equation or "formula" for calculating all powers of 10, or all common anti-logarithms, using a power of (e).

For reference, shown previously in this book was:
e^x = 10^(0.4342944819 x)
Note that the multipliers to the indicated power of (x) in the
two equations reciprocals, and this can be verified as:
When (x) = 1 for either equation we have:
10 = e^2.302585093 and e = 10^0.4342944819
Taking the ln for the left equation, and the log of the right equation:
ln 10 = 2.302585093 and log e = 0.4342944819 , mathematically:
(ln 10)(log e) = (2.302585093)(0.4342944819) = 1 : the product of reciprocals is 1
This also shows that: (ln 10) and (log e) are reciprocals:
(ln 10) = 1 / (log e) and (log e) = 1 / (ln 10)

Here is a derivation of a general formula for this concept :

N = b^x taking the (natural) logarithm of both sides:
ln N = ln b^x
ln N = x ln b hence by the log definition:
N = e^(x ln b)

N = b^x = e^(x ln b) : A GENERAL FORMULA TO EVALUATE ANY INDICATED POWER USING A POWER OF (e)

Ex. If the base of the power is: b=10:

N = 10^x = e^(x ln 10) = x e^((x)(2.302585093) = e^(2.302585093 x) : as just shown above

Using almost the same derivation as above, a formula can be derived for evaluating powers of any number via powers of 10. Evaluated powers of 10 are often found in common antilogarithm tables:

N = b^x taking the (common) logarithm of both sides:
log N = log b^x : USING base 10 so as the result is a power of 10
log N = x log b hence by the definition of logarithms:
N = 10^(x log b) which can be expressed as:
N = b^x = 10^(x log b) :A formula to evaluate any power via a power of 10.

Ex. 30^2 = 10^(2 log 30) = 10^((2)(1.4771$\underline{2}$)) = 10^2.9542$\underline{4}$ = 900 : for comparison, 10^3 = 1000

If the base of an indicated power is (e) and you want to calculate or express that power value using powers of 10, and using the formula above:

N = b^x = e^x = 10^(x log e) = 10^(0.4342944819033 x) : POWERS OF (e) VIA POWERS OF 10

Ex. e^1 = 10^(0.4342944819033 (1)) = 10^(0.4342944819033) = 2.718281828**...**

Here is a more general or algebraic method for calculating any power using any base:

N = b^x taking the log (using any base) of both sides:
Log N = Log b^x : this can be expressed as:
Log N = x Log b from the definition of logarithms:

N = b^x = logbase^(x $\log_{\text{logbase}}$ b) : A GENERAL FORMULA FOR CALCULATING ANY POWER BY USING A DIFFERENT BASE.
b = base of the given power, x = exponent or indicated power,
use a common logbase for calculations, N=power value

Ex. N=5^2 , calculate this power using a power of (e) and then a power of (10):

N = 5^2 = e^(2 $\ln_e$ 5) : here, base (e) was used as expected for a natural logarithm

Or by using any other base for the logarithms, such as base 10:

N = 5^2 = 10^(2 $\log_{10}$ 5) : e^(2 $\ln_e$ 5) = 10^(2 $\log_{10}$ 5) : both equal b^x = 5^2

N = 25

EQUATING POWERS

Here is a general formula for equating powers. A preliminary discussion of this was already mentioned during the topic of: SOLVING FOR AN EXPONENT USING LOGARITHMS.

N1^x1 = N2^x2 Taking logs (with any base you choose) of both sides:

log N1^x1 = log N2^x2 From the log of an indicated power rule:

x1 log N1 = x2 log N2 Solving for the exponent variable x2:

$$x2 = \frac{x1 \log N1}{\log N2}$$

: **GENERAL FORMULA FOR EQUATING POWERS: N1^x1 = N2^x2**
(Finding The Proper Exponent Of The Base)
Use the same base for both of the logarithms.

Ex. What is the equivalent of 7^2 using a base (or power value of) of 2 ?

N1^x1 = N2^x2

7^2 = 2^x2

$$x2 = \frac{x1 \log N1}{\log N2} = \frac{2 \log 7}{\log 2} \qquad \text{or by using a base of (e):} \quad \frac{2 \ln 7}{\ln 2}$$

x2 = 5.614709844

Hence, 2^5.6147049844 = 7^2 :

Ex. Write a formula for expressing all powers of 7 in terms of a power of (e).

7^x = e^x2 Hence, we need to find the exponent x2 in terms of (a function of) x.

$$x2 = \frac{x \ln 7}{\ln e}$$

With natural logarithms (have base e), the denominator becomes a value of 1.

x2 = x ln 7 Substituting this value of x2 into e^x2 above, we have:

7^x = e^(x ln 7) : or= e^(ln 7^x), now evaluating the constant of: ln 7 we have:

7^x = e^(1.945910149 x) : e^1.945910149 = 7 , 7^x = (e^(1.945910149))^x = e^(1.945910149 x)

Using the above example, it is not to difficult to realize that when the exponent of (e) is a natural logarithm, that the resultant value is equal to the number of that logarithm. This is easily verified below:

N2 = ln N1 Hence the antilog notation to solve for N1 is:

e^N2 = e^(ln N1) = N1

For example: $e^{(\ln_e 7)} = e^{1.945910149} = 7$

Hence: $7^x = (e^{\ln 7})^x = e^{(x \ln 7)}$: using the power to a power rule of multiplying exponents

The same can also be said whenever the base of the power and the base of the logarithm are the same:

$N2 = \log N1$: Choose any base (b) for the logarithm. By the log definition:

$b^{N2} = b^{(\log_b N1)} = N1$

For example: $10^{\log 100} = 10^2 = 100$: same as first taking a log on N, and then taking the antilog of that exponent that equals the log of N.

CALCULATING ROOTS USING (e)

When solving for a root of a value using the constant (e), first place the radical into its equivalent exponential form (ie. an indicated power form), and then equate it to a power of (e).

Ex. $\sqrt{10} = 10^{(1/2)} = 10^{0.5}$

$$
\begin{aligned}
\text{from: } 10^x &= e^{(2.302585093\, x)} \\
10^{0.5} &= e^{(2.302585093(0.5))} \\
10^{0.5} &= e^{1.151292546} \\
10^{0.5} &= 3.16227766
\end{aligned}
$$

$\sqrt{10} = 3.16227766$: the square root of a value calculated by its equivalent power value of (e)

Ex. $\sqrt[3]{7}$

$\ln 7 = 1.945910149$, hence $e^{1.945910149} = 7$, therefore, raising each side to the same indicated power:

$7^x = (e^{1.945910149})^x = e^{(1.945910149x)}$: any power of 7 converted to a power of (e).

$\sqrt[3]{7} = 7^{(1/3)} = 7^{0.333333333...}$

$$
\begin{aligned}
7^{0.333333333} = \sqrt[3]{7} &= e^{(1.945910149(0.333333333))} \\
\sqrt[3]{7} &= e^{0.648636715} \\
\sqrt[3]{7} &= 1.912931181
\end{aligned}
$$

Here is another general formula for calculating square-roots using (e):

Find $\sqrt{N}$

Let $\sqrt{N} = e^x$: converting the radical to its equivalent exponential form:

$N^{0.5} = e^x$ taking the natural logarithm of both sides of the equation:

$\text{LN } N^{0.5} = \text{LN } e^x$ using the log exponential rule:

$0.5\ \mathrm{LN}\ N = x\ \mathrm{LN}\ e$
$0.5\ \mathrm{LN}\ N = x$ substitution this value for (x) in a previous equation:

$\sqrt{N} = e^x = e^{(0.5\ \mathrm{LN}\ N)}$ (or= $e^{((\mathrm{LN}\ N)/2)}$) : **A SQUARE ROOT FORMULA (Using a power of e)**

Ex. $\sqrt{2} = e^{(0.5 \ln 2)} = e^{(0.5 (0.69314718))} = e^{0.34657359} = 1.414213562$

Ex. Solve $\sqrt[5]{76}$

$\text{root} = \sqrt[5]{76}$ placing this radical into its equivalent exponential form:
$\text{root} = 76^{(1/5)}$ taking the logarithm of both sides, using any base consistently:
$\text{Log root} = \text{Log } 76^{(1/5)}$

$\text{Log root} = \frac{(1)\ \text{Log } 76}{(5)}$ by the definition of logarithms:

$\text{root} = b^{((\log_b 76)/5)}$ if the base is (e):

$\text{root} = e^{((\ln 76)/5)} = 2.377730992$ and in general:

$r = \sqrt[i]{N} = b^{((\log_b N)/i)}$: **A GENERAL FORMULA FOR ANY INDICATED ROOT**
r=root, N=radicand, i=index, b=base of choice for the calculations

If you are using (e) for the base, perhaps to use the assistance of a "look-up" (ie., to match corresponding values) or reference table:

$r = e^{(\ln N / i)}$: **FINDING ROOTS USING (e)**
r=root, N=radicand, i=index

It is best that N be small when using the series for evaluating powers of (e). Here is an example of how to do this:

$\sqrt{47}$: expressing the radicand using a scientific notation (or power of 10) form:

$\sqrt{(0.0047)(10^4)}$

$\sqrt{10000}\ \sqrt{0.0047}$

$100\ e^{(0.5\ \mathrm{LN}\ 0.0047)}$

$\sqrt{47} = 6.8556546$

Here is a related equation that can be useful:

$\mathrm{LN}\ AB = N$: here AB is the product of A and B. By the definition of logarithms:
(or simply raising (e) to the (equivalent) value of both sides:)
$e^N = e^{(\mathrm{LN}\ AB)} = AB$ switching sides:

$AB = e^{(\mathrm{LN}\ AB)}$ the log of an indicated product can be expressed as:
$AB = e^{(\mathrm{LN}\ A + \mathrm{LN}\ B)}$: A PRODUCT EXPRESSED AS A POWER OF (e) or:
$AB = e^{(\mathrm{LN}\ A)}\ e^{(\mathrm{LN}\ B)}$: A PRODUCT EXPRESSED AS POWERS OF (e)

A generalization of the above, using any base (b), can be expressed as:

let N = (factor1)(factor2)   : or as many factors used,

N = b^(logb ((factor1)(factor2))) = b^ ((logb factor1) + b^(logb factor2)) = b^(logb factor1) b^(logb factor2)

SOLVING A LOGARITHM USING ANOTHER BASE

Since a series for logarithms which have a base other than (e) have not been developed, the natural logarithm of the same number can be found and then adjusted so that it equals the actual logarithm in question by using the constant of proportionality (c) between the two logarithms. This constant between two log systems is often called a modulus.

Ex. What is the constant of proportionality between common logarithms (base 10) and natural logarithms (base e) ?

First choose a value for N. A value of 10 was chosen for N in the example given below since the common logarithm of 10 is easily found to be 1. Then divide the two logarithms to find the quotient which is the constant of proportionality (ratio, factor) between the systems (ie., with a different log base) of logarithms in question.

$$\frac{\log N}{\ln N} = c1 \qquad \text{or} \qquad \frac{\ln N}{\log N} = c2$$

Notice that c1 and c2 are algebraically reciprocals (c1 = 1/c2 and c2 = 1/c1), and that log N or ln are logarithms having a different base which can be found from either equation:

$$\log N = c1 \ln N = \frac{\ln N}{c2} \qquad \text{and} \qquad \ln N = c2 \log N = \frac{\log N}{c1}$$

$$\frac{\log 10}{\ln 10} = \frac{1}{2.302585093} = 0.4342944819033 = c1 = (1/c2)$$

$$\frac{\ln 10}{\log 10} = \frac{2.302585093}{1} = 2.302585092994 = c2 = (1/c1)$$

Expressing the above common and natural logarithms in a general or basic terms for any value:

log N = (0.4342944819033) ln N   : SOLVING COMMON LOGS USING NATURAL LOGS

ln N = (2.302585092994) log N   : SOLVING NATURAL LOGS USING COMMON LOGS

Both of the above equations have a linear equation form of : y = m x. A discussion and graph of this will be given at the end of this current discussion.

Ex. Find log 15 using the natural log base (e).

We already found that the constant of proportionality when evaluating a common log with a natural log is always:
(log N / ln N) = (0.4342944819033) :

log 15 = (0.4342944819033) ln 15

But remember, for the natural log series shown previously, (x) must be greater than 0 and less than 2: (0<x<2). A simple method to convert N to be within this range is by placing N into a scientific notation (SN) form.

log 15
log (10^1)(1.5)
log 10 + log 1. 5
1 + log 1.5
1 + (0.434294482) ln 1.5

or:

log 15
log (100)(0.15) or= log (10^2)(0.15)
log 100 + log 0.15
2 + log 0.15
2 + (0.434294482) ln 0.15

or:

log 15
(0.434294482) ln 15
(0.434294482) (ln (10^2)(0.15))
(0.434294482) (2 ln 10 + ln 0.15)
(0.434294482) ((2)(2.302585093) + ln 0.15)
(0.434294482) (4.605170186 + ln 0.15)

log 15 = 1.176091259

Ex. Find log 15. This method will find a new number (N) value by repeatedly dividing by (e), which is essentially dividing by a power of (e^1) = 2.302585093 :

$$\frac{N1}{e} = N2 , \quad \text{therefore,} \quad N1 = N2\, e\text{^}1$$

$$\frac{\frac{N1}{e}}{\frac{e}{1}} = \frac{N1}{e\text{^}2} = N2, \quad \text{therefore,} \quad N2 = N1e\text{^}2$$

By repeatedly dividing 15 by e^1=2.302585093, we find:

15 = 0.037181282 e^6

log 15 = log (0.037181282 e^6)
log 15 = (0.434294482) (ln (0.037181282 e^6))
log 15 = (0.434294482) (ln 0.037181282 + ln e^6)
log 15 = (0.434294482) (ln 0.037181282 + 6 ln e)
log 15 = (0.434294482) (ln 0.037181282 + 6)
log 15 = 1.176091259

There is nothing intuitive that there should be a constant between two systems of logarithms. We can try other examples to help verify that this value is repeated over and over (using the same bases (ex. 10 and e) of the logarithms) and therefore, it is most likely a constant, but the best method to prove that it is indeed a constant is to have an algebraic verification (whose variables generally represent any value):

Given: N = b2^x by the definition of logarithms:

$x = \log_{b2} N$ taking logs of both sides of the above equation using another base (b1):

$\log_{b1} N = \log_{b1} b2^x$ using the log power rule:

$\log_{b1} N = x \log_{b1} b2$ since $x = \log_{b2} N$:

$\log_{b1} N = \log_{b1} b2 \ \log_{b2} N$: **A GENERAL FORMULA OF EVALUATING LOGS WITH A DIFFERENT BASE**
Mathematically:

$\dfrac{\log_{b1} N}{\log_{b2} N} = \log_{b1} b2 = r$: (constant) ratio of logarithms of N using different bases
Here, the second equivalence can be thought of as:
$\log_{b1} b2 = \log_{\text{old base}} \text{new base}$

Since b1 and b2 are both constants, $\log_{b1} b2$ can only be a constant, and the ratio above is a constant value.

When a base of a log is set to a lower value, the value of this log expression will naturally be higher, therefore in order to equal the original log of the number, this higher value must be reduced. It gets reduced to a fraction of itself by multiplying it by a value less than 1 (ie., a fraction), and this will be the value of the constant.

Ex. Evaluate $\log_{10} 20$ using natural logs. Since base (e) is a lower value than base 10, the result will be a higher value than it would be using a base of 10. This higher value will be reduced by the constant known between the two bases. Using the above general formula:

$\log 20 = \log_{10} e \ \ln 20$

$\log 20 = 0.434294481 (2.995732274)$
$\log 20 = 1.301029996$

Using the above concepts we can also derive another formula for equating powers:

Given: $b1^x = N = b2^y$ Solving for y: By the definition of logarithms:

$x = \log_{b1} N$ and $y = \log_{b2} N$ from the concepts discussed above:

$\log_{b1} N = \log_{b1} b2 \ \log_{b2} N$ using algebraic substitution:

$x = \log_{b1} b2 \ y$ solving for y:

$y = \dfrac{x}{\log_{b1} b2} = \dfrac{x}{r}$ equating this to the previous derivation given in the **GENERAL FORMULA FOR EQUATING POWERS:**

$y = \dfrac{x \log b1}{\log b2} = x\,c$: use any, and the same consistent base for the logs
(c) is also a constant equal to the ratio (r) of the two logs of N.

(c) = (1/r).
$y = x\,c$ and $x = y/c$ and $(y/x) = c$ and $x/y = (1/c)$

Given $y = \log_b x$, and if you want to use your own base (for the logarithm) instead of base (b), here is what to do. It is a form of the "change of base" formula:

$y = \log_b x$: log_b = logb is an alternative notation for a log, here with base value of (b).

From the definition of logarithms:

$b^y = x$ taking logs of both sides with your choice of the base; perhaps you may want to use (e):
$\log b^y = \log x$
$y \log b = \log x$ solving for y:

$$y = \log_b x = \frac{\log x}{\log b} = \frac{\ln x}{\ln b}$$

: A method to evaluate a logarithm using a "change of base".
: The base used must be the same in the numerator and denominator.
As a basic verification, consider this example:

$$\frac{\log 5}{\log 3} = \frac{\ln 5}{\ln 3} = 1.4649\underline{7}$$

Ex. $7^y = 49$, find y.

$$y = \frac{\log 49}{\log 7} = \frac{\ln 49}{\ln 7} = 2$$

: the simple verification to this is shown above with $b^y = x$, and then taking the log of both sides and solving for (y).

Expressing the above or a more generalized formula:

$$\mathbf{b^x = N}$$

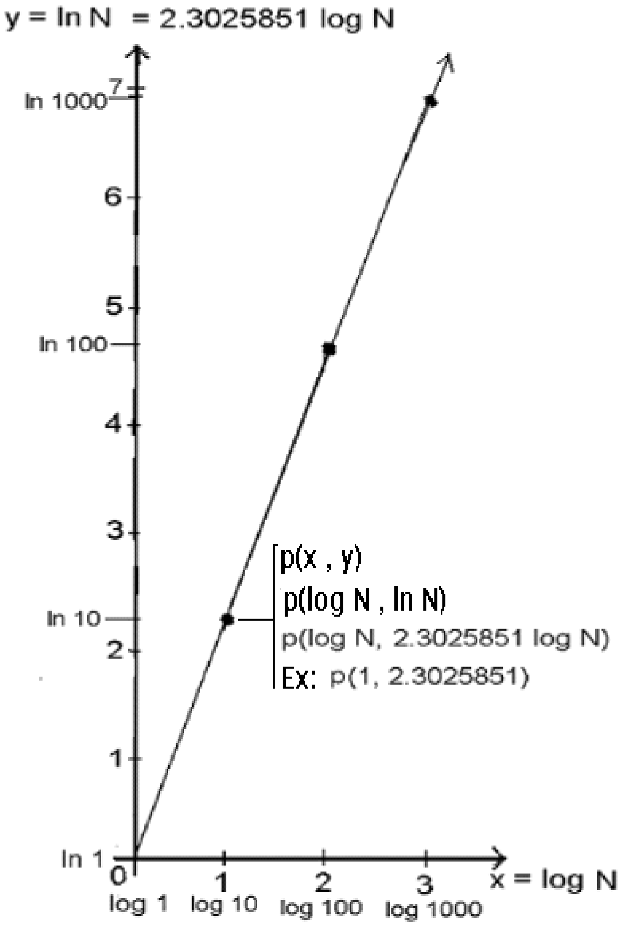
$$\mathbf{x = \frac{\ln N}{\ln b}}$$

: use any base of the logarithm consistently, that is, in both the numerator and denominator mathematically and considering if natural logarithms were optionally used:

$\ln N = x \ln b$ by the log definition: $\mathbf{N = e^{(x \ln b)} = b^x}$, the actual Number or power value , and:

$\ln b = \frac{\ln N}{x}$ by the log definition: $\mathbf{b = e^{((\ln N) / x)} = \sqrt[x]{N}}$

Here is a graph showing the linear, or constant mathematical relationship between two logarithms of the same value (here, N), where each logarithm has a different base. This graph specifically shows the mathematical relationship of, or between, ln N and log N, hence the mathematical relationship of, or between, base 10 and base (e) logarithms.
[FIG 202]



ln N = (2.302585092994) log N : The relationship between natural and common logarithms (or any other two logarithms having different bases) of N is a linear or constant mathematical relationship. You can also write an equation and make a graph of their mathematical relationships and the main difference in the graphs of the lines would be the value or steepness or slope of the line.

This has the form of a linear equation:

y = m x : where y = mx = ln N = (2.302585092994) log N , where m= 2.302585092994 and x = log N

The mathematical relationship between the log of a power of a value, and the indicated exponent is linear if N, the base of the indicated power, is a constant value:

y = log N^x = x log N = log N x : has the general linear equation form of: y = mx
We see that (y) is simply a multiple of the log of the base of the indicated power, and this multiple or factor is the value of (x).

Before moving on, here is a related thing to know about logarithms. It is somewhat surprising, and It may help fill in some gaps when trying to understand logarithms to the fullest.

$\log_{b1} b2$ and $\log_{b2} b1$ are reciprocals

Let's give some algebraic verification to this fact. From what we know about reciprocals, their product should equal 1.

$(\log_{b1} b2)\ (\log_{b2} b1) = 1$ this could be represented and expressed as this simplified form as their respective log value:

$x \quad y = 1$: $x = 1/y$ and $y = 1/x$, From the log definition:

$b1^x = b2$ and $b2^y = b1$ By substitution or replacement:

$b1^x = b2$

$(b2^y)^x = b2$

$b2^{(yx)} = b2^1$

Clearly, by observational matching or comparison of the exponents, we find that (x) and (y) are reciprocals:

$yx = 1$, and therefore, $x = 1/y$ and $y = 1/x$, and the logarithm expression that equal (x) and (y) are therefore, also reciprocals.

For another verification of the above:

$b1^x = b2$ taking the x root of both sides:

$\sqrt[x]{b1^x} = \sqrt[x]{b2}$ converting the radicals to their equivalent exponential form:

$b1^{(x/x)} = b2^{(1/x)}$

$b1 = b2^{(1/x)}$ Since $(y) = (1/x)$, by substitution:

$b2^y = b2^{(1/x)}$ Again, by observation of the exponents, $y = 1/x$, hence (x) and (y) are reciprocals. If we continue further:

$b2^y = \sqrt[x]{b2} = b2^{(1/x)}$: when (x) and (y) are reciprocals

Perhaps a simpler verification of what is expressed above would be:

$b1^x = b2$, according to the definition of a power or repeated multiplication of the same value a certain number of times that is equal to the exponent value, and then doing the reverse or inverse would be repeated division by that same base value a certain number of times equal to the same exponent. The quotient of this repeated division would be equal to the original base value. For example:

$2^3 = (2)(2)(2) = 8$ and: (1): $8/2 = 4$, (2): $4/2 = 2$, (3): $2/2 = 1$

This is 3 complete (ie., no remainder) divisions of 8 by 2.

2 is therefore the 3rd root of 8:

$\sqrt[3]{8} = 2$, and in general:

If b1^x = b2, then b1 = $\sqrt[x]{b2}$ = b2^(1/x) = b2^y : after assigning variable (y_ as being equal (1/x)

Ex. b1^5 = b2 then b2^(1/5) = $\sqrt[5]{b2}$

Ex. 100^0.5 = $\sqrt[2]{100}$: 0.5 and 2 are reciprocals of each other: 0.5 = 1/2 and 2 = 1/0.5

10 = 10 : checks

b1^x = b2 and b2^y = b1 : this condition is true when x and y are reciprocals

100^0.5 = 10 10^(1/0.5)=10^2 = 100

Here is the mathematical relationship between b1 and b2 expressed algebraically:

From: b1^x = b2 and b2^y = b1

Dividing both sides of the first equation by the same or equivalent value of b1:

$\frac{b1^{x}}{b1^{1}} = \frac{b2^{1}}{b2^{y}}$ by using the exponential rules:

b1^(x-1) = $\frac{1}{b2^{(y-1)}}$ or=:

b1^(x-1) = b2^(0 - (y-1)) = b2^(1-y) : The mathematical relationship between b1 and b2. As shown above, the relationship between (x) and (y) is that they are reciprocals and where: $x=\log_{b1} b2$ and $y=\log_{b2} b1$

Ex. Given $\log_{e} 10 = 2.302585093 = x$

We now know that the reciprocal of the above expression is:

$\log_{10} e = 0.434294481 = y$ checking: 2.302585093 = 1 / 0.434294481 , or= x = (1/y)

If we let b1=e and b2=10 their mathematical relationship is:

b1^(x-1) = b2^(1-y)

e^(2.3026 - 1) ~ 10^(1 - 0.4343)
e^1.3026 ~ 10^0.5657
3.6788 = 3.6788 : checks

Ex. This is a basic example: **$1.414213\underline{6}$ = 2^x** , by the log definition: x = log2 $1.414213\underline{6}$ = $\log_{2} 1.414213\underline{6}$

Taking logs of both sides: log $1.414213\underline{6}$ = log 2^x = x log 2 , therefore, after solving for x:

$x = \log_{2} 1.414213\underline{6} = \frac{\log 1.4142136}{\log 2} = \frac{\log \text{Number}}{\log \text{Base}}$: using any consistent base, say 10 or e, we find: x = 0.5

DIFFERENT BASES

Here, the logarithms (essentially the exponents) of two log expressions having different bases are set to be equal in value to (x). Since the bases are different, the number of one of the log expressions must of course be properly adjusted (by solving for it).

Equating two logarithms:

$x = \log_{b1} N1 = \log_{b2} N2$ therefore, according to the definition of logarithms:

$N1 = b1^x = b1^{(\log_{b2} N2)}$

$N2 = b2^x = b2^{(\log_{b1} N1)}$

Ex. Find the equivalent logarithm equation of $\log_{10} 100$ using a base of 5.

Expressing this in a mathematical equation form, solve:

$\log_{10} 100 = \log_5 N$ considering N as the second number or N2:

$N2 = b2^{(\log_{b1} N1)}$

$N2 = 5^{(\log_{10} 100)}$

$N2 = 5^2$

$N2 = 25$

Hence: $\log_{10} 100 = \log_5 25$

$2 = 2$: checks

EQUATING POWERS OF (e) AND NATURAL LOGARITHM EXPRESSIONS

Sometimes you may prefer to convert between expressions containing a power of (e) and a natural logarithm for various reasons. One reason for the conversion may be to use a series that you are more comfortable with. Below, the results are interesting and easy to remember, but the result is such that a series must be used twice.

Let $e^x = \ln N$

N can be solved simply by the definition of logarithms:

$N = e^{(e^x)}$: Note, this is not a "power to a power",
that is, it is not: $N = (e^e)^x = e^{(ex)}$

Ex. $e^2 = \ln N$ Solving for N:

$N = e^{e^x}$

$N = e^{e^2}$

$N = e^{7.389056099}$

$N = 1618.177992$ Hence:

$e^2 = \ln 1618.177992$: both sides are equal to $7.389056\underline{1}$

Solving for (x) given $e^x = \ln N$

Taking logarithms of both sides of the equation:

$\ln e^x = \ln(\ln N)$ Using the log exponential rule:

$x \ln e = \ln(\ln N)$ Dividing both sides by (ln e) to isolate (x):

$x = \dfrac{\ln(\ln N)}{\ln e}$ Since $(\ln e) = 1$:

$x = \ln(\ln N)$

Ex. $e^x = \ln 1.5$

$x = \ln(\ln 1.5)$
$x = \ln(0.405465108)$
$x = -0.902720455$

Hence $e^{-0.902720455} = \dfrac{1}{e^{0.902720455}} = \ln 1.5$: both sides equal 0.405465108

As like all other equations, if either expression is multiplied by some value (known, such as a constant, or unknown, such as a variable), simply multiply the other side of the equation by the same value so as to keep the expressions and-or values on both sides of the equations equivalent:

Given $e^x = \ln N$ Multiplying both sides by some constant (c):
$ce^x = c \ln N$: or= $\ln N^c$

Ex. Using the last example, and multiplying both sides by 3 we have:

$$3 e^x = 3 \ln 1.5$$

Still, $x = \ln (\ln N)$, this can be easily seen by ridding (in this case, dividing) both sides of the equation by the constant (3 in this example) when solving for (x), and we then have:

$$e^x = \ln 1.5$$
$$x = \ln (\ln 1.5)$$
$$x = -0.902720453$$ hence, after multiplying both sides by 3:

$$3 e^{-0.902720453} = 3 \ln 1.5$$

Checking: $3(0.405465108) = 3(0.405465108)$
$1.216395328 = 1.216395328$

If a multiplying constant is to play a part of the variable being solved for, the methods are almost identical to the original derivations shown:

Given $e^x = c \ln N$ taking the logarithm of both sides:

$$\ln e^x = \ln (c \ln N)$$
$$x \ln e = \ln (c \ln N)$$ since $\ln e = 1$:
$$x = \ln (c \ln N)$$ Hence, to find the value of (x), simply take the logarithm of the opposite side of the equation.

Given $\ln N = ce^x$ by the definition of logarithms:

$$N = e^{(ce^{x})}$$

Hence, the value of N is simply (e) raised to an indicated power equivalent to opposite side of the equation.

SOLVING FOR RECIPROCALS USING (e) AND NATURAL LOGARITHMS

Solving for reciprocals is easily done on a calculator or computer, otherwise, you must solve for it using "long" division or some other method. One reason to solve for a reciprocal is that division of a dividend (or numerator) value can effectively be performed by multiplying that dividend value to the reciprocal value of the divisor (or denominator). For example, multiplication is usually performed in les time (ie., "faster") than division in the realm of computers, and especially if many calculations by "pen and hand" have to be made which could essentially slow the performance or results. Even though it may be overly complex and the long way of doing things, it is still helpful to know how to manipulate equations of all sorts when needed and-or to express them in a certain way. Here is one possible method to solve for a reciprocal:

let $y = \frac{1}{x}$ taking the natural logarithm of both sides:

$\ln y = \ln \left(\frac{1}{x}\right)$ using the "log reciprocal rule":

$\ln y = -\ln x$ by the definition of logarithms:

$y = e^{(-\ln x)}$ and since $(1/x) = y$, we have:

$\frac{1}{x} = e^{(-\ln x)} = \frac{1}{e^{(\ln x)}}$: A RECIPROCAL FORMULA USING (e)

Ex. $\frac{1}{53} = e^{-\ln 53} = \frac{1}{e^{\ln 53}} = e^{-3.970291914} = 0.018867924$

Clearly, by taking the reciprocal of each fraction above, or by simply equating numerators and denominators visually, $e^{\ln x} = x$. That is, this power of (e) simply equals (x) since it is the general form of the natural antilog notation for the number (here it's x). Also, as a check:

If $x = \ln 53 = \log_e 53$, then $e^x = 53 = e^{\ln 53}$

LOGARITHMS OF SIMILAR DIGITS

An interesting note about common logarithms is that when the number (N) varies by some power of 10 (essentially the result of moving the decimal point through the number's digits), that the whole or integer portion (frequently called the "characteristic") of the logarithms of N will increase or decrease by an integer value, and the fractional portion (frequently called the "mantissa") of the logarithm will be the same. This concept can also be applied to creating and using a table of logarithms.

Ex. $\log 10.00 = 1.0$ $\log 100.0 = 2.0$ $\log 1000 = 3.0$: When the base is 10, and N increases by 10, the log increases or increments by 1.

Ex. $\log 1.50 = 0.176091$**...** $\log 15.0 = 1.176091...$ $\log 150 = 2.176091$**...**

As indicated, when N increases by a factor of 10^1 or 10, that its' logarithm is increased by 1. When N increases by a factor of 10^2 or 100, that its' logarithm is increased by 2. In general, given N, the logarithm of: N 10^x will be a value of (x) higher, or more specifically its logarithm is: x + (logarithm of N):

$$\log (10^x) N = x + \log N$$

This is easily verified using the log rules:

$\log (10^x)N$
$\log 10^x + \log N$
$x \log 10 + \log N$: $\log 10 = 1$
$x + \log N$: checks

Ex. Find log 15 with the aid of natural logarithms.

First of all, for the natural logarithm series given previously, N, the Number of which the ln is to be found, must be $0<N<2$.

$15 = 1.5(10^1)$

From : $\log (10^x)N = x + \log N$

$\log 15 = \log (10^1)(1.5) = 1 + \log 1.5$ checking using the log product rule:
$\log (10^1)(1.5) = \log 10^1 + \log 1.5 = (1) \log 10 + \log 1.5 = 1 + \log 1.5$

$\log 15 = 1 + \log 1.5 = 1 + (0.434294481) \ln 1.5 = 1.176091259$

Or perhaps:

$\log 15 = \log (10^2)(0.15) = 2 + \log 0.15$

$\log 15 = 2 + \log 0.15 = 2 + (0.434294481) \ln 0.15$

$\log 15 = 2 + (0.434294481)(- 1.897119985)$

$\log 15 = 1.176091259$

We see that when N is divided (ie., decreases) by a power of 10, (x) will be negative and the logarithm of N will therefore decrease by this value (the indicated power of 10).

Ex. Find log 1.5 : N = 1.5

$\log 1.5 = \log (10^{-1})\, 15 = \log \left(\frac{15}{10^1}\right)$: the right side shows the equivalent of N, and it's being divided by 10^1
From the log quotient rule, this is equal to: log 15 - log 10^1 = log 15 - 1

$\log 1.5 = \log (10^{-1})15 = \log 10^{-1} + \log 15 = -1 + \log 15$ or= $\log 15 - 1$

$\log 1.5 = -1 + 1.176091259$: (or: 1.176091259 -1)

$\log 1.5 = 0.176091259$

This concept can also be verified directly from the log "quotient rule":

$\log (N)(10^{-x}) = \log \left(\frac{N}{10^x}\right) = \log N - \log 10^x = \log N - x$: Since N was increased by a factor of 10^1, from 1.5 to 15, the logarithm will then need to be reduced by that same power of 10, which is 1 here.

CATENARY CURVE

Besides the basic curves shown previously in this book and the (somewhat similar equation) "bell curve" shown ahead in this book, there is a somewhat lesser known, but still an important curve to be mentioned. This curve is called the catenary curve. The word catenary is a derivative word from the Latin word for chain. A catenary curve is somewhat similar in shape to a parabola curve near its vertex or narrow part, and the formula for the shape of the catenary curve is based upon the upward pull or tension due to the downward pull of gravity upon a freely suspended (ie., no initial tension or force placed upon its ends and-or length) chain, thin flexible metal, or a rope. Because the single length of chain or rope is hung from the same height on two poles or rods, the curve will have two symmetrical sides. An inverted (ie. "up-side down") catenary curve is the strongest arch shape for a bridge, and if the "legs" of it are near vertical, then the weight of the bridge and anything on the bridge is then directed vertically into the ground that supports the bridge on the Earth's surface.

Since the value of (e) is used to mathematically express natural events, it is then of no surprise that the equation of the catenary curve includes this value of (e). The derivation (usually credited to Johann Heinrich Lambert) of the catenary equation is not presented below, but it is based on equations for the horizontal and vertical forces of gravity and tension acting upon the curve.

Though not usually important to a practical mathematician, a catenary curve is also the locus (all the locations or points of the (continuous) path to be traveled or traced out) of the focus point of a parabola curve that is made to "roll" along a line. A catenary curve is therefore related to a parabola curve or vice-versa.

Some examples of catenary curves are: a suspended chain link fence, a simple suspension bridge, a hammock or clothes line. The gigantic stainless steel Gateway ("gateway to the west") Arch in St. Louis, MO. was built to have the pleasing shape of an inverted catenary curve.

Consider a catenary curve made of a freely (ie., no horizontal forces applied to influence its shape) hanging length of chain links with its upper end links suspended or held in a firm position at the same height at both ends. The links at the "bottom" in the center of the curve do not have to support (hold up with tension (force)) any other links or weight applying a downward force, and therefore these links are practically parallel to the ground. As you then go up along the "sides" of the catenary curve, the links further up must (upwardly) support more and more (downward) weight, and therefore, this part of the curve or chain is nearing vertical due to the increasing weight pulling on it. This makes the sides of the catenary curve are slightly more narrow or closer together than that of a parabola.

A good thought experiment or actual experiment to help with the understanding of this catenary curve is to lay a length of rope on the ground or table, and then slowly pick the two ends up to the same height, and you will see the curve develop in shape, and with the center portion of it being "flat" or horizontal until a sufficient height is reached so as to have a complete curve shape, and this depends upon the height needed to raise the endpoints. The minimum possible height for the catenary curve is half the length of the rope. The rope can be longer than the distance between the poles, but it cannot be shorter because there would be no possible complete curve between the poles endpoints. Another thought experiment is to imagine a thin strip of material (paper, wood, plastic), perhaps 1 meter long and at least 1 cm wide. At its ends, it will not sag or curve downward due to gravity because its ends are essentially being pushed up by the poles and-or that the "surface tension (ie., a force)" is not allowing that area of the material to move downward and-or bend downward. Where the material and its weight is not supported, the material will begin to bend downward from each pole and it will be at its lowest in the center.

The basic equation of a catenary curve is:

$$y = \frac{e^x + e^{-x}}{2} \quad \text{or} = \frac{\frac{e^x}{1} + \frac{1}{e^x}}{2} \quad \text{or} = 0.5\,(e^x + e^{-x})$$

: this expression form is that of a number and its reciprocal, and here the number is a power of a value; here (e).

: this equation nearly has an exponential equation form.

When an exponent is negative (as in the above equation), it essentially means the reciprocal of that power, hence only one power value of (e) actually needs to be found for each instance (ie., of x) or use of this equation.

Note, as (x) approaches a value of infinity (and much lower for practical purposes of the curve), the reciprocal of e^x approaches a value of 0, and (y) approaches a value of: (e^x)/2. When x=0, y=1. This is also the minimum point of the catenary curve.

The denominator of 2 simply shifts the curve vertically downward by dividing each (y) value by 2, and even if this denominator was not present, the curve still has the same shape. This value of 2 is essentially due to that the derivation of this equation considered that each side supports half the weight (or force) of the chain or material used. That is, the (y) value corresponded to the force needed to supporting each side of the suspended chain at that value of (x).

The equation of this curve rather seems to be relative in nature for values between 0 and 1. Given the same length of chain or rope, and the same distance between the vertical supports, the height of the poles and the curve above the ground plays no actual role in the shape of the catenary curve. Even if the poles are at different heights, the curve is still a catenary curve, and that all catenary curves are similar, but are effectively, magnified versions of one another.

Hyperbolic Trigonometric Functions

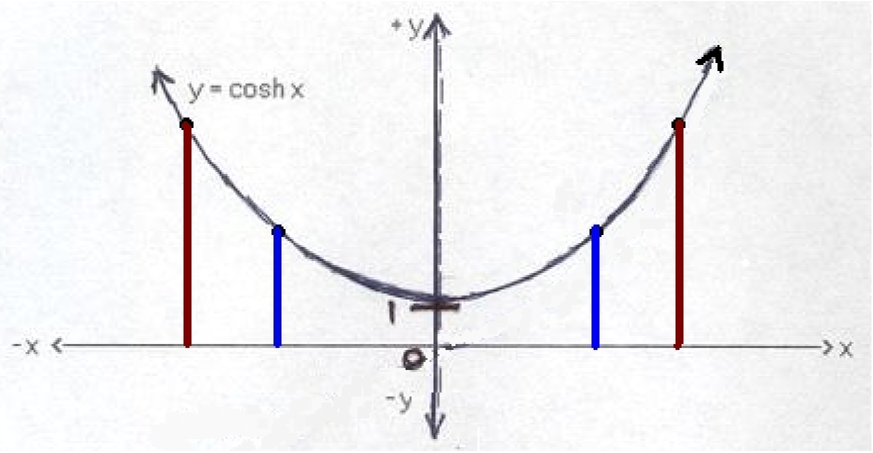
The right-hand side of the equation above is formally called the hyperbolic cosine (here, of x) function. The words hyperbolic cosine are often expressed or noted in the simple form of: cosh. Expressing this with an arbitrary numerical coefficient (a) for plotting on a graph:

$$y = a \cosh \left(\frac{x}{a}\right)$$

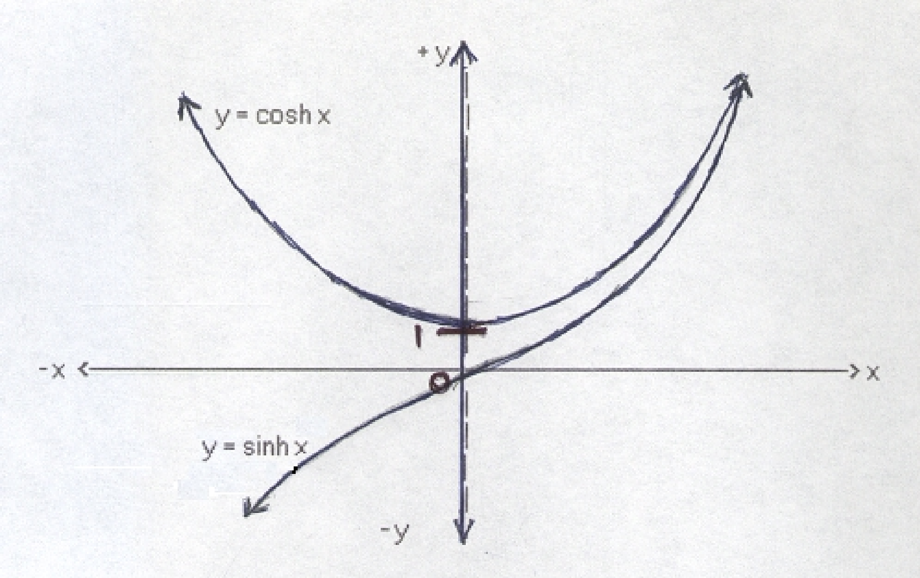
: a catenary curve, the greater (a) is, the "steeper" the sides of the curve
If a=1, the equation reduces to simply: y = cosh x. The lower (a) is, the more "narrow" the curve, and its sides do not expand or open wider as fast when (x) increases.

Remember, this equation is symmetrical (-x can be substituted for x without any problems) about the y-axis and in actual physical reproductions of the basic form of the defined catenary curve where both ends of the material used to construct the curve are suspended at the same height and under no pull, tension or force which would then distort, alter or "straighten" the natural catenary curve. The less the distance between the points of suspension given a fixed length of material, the "steeper" the sides of the catenary curve. The minimum distance possible between the points of suspension is practically 0, and the maximum distance is the length of the material used. Regardless of the material used to construct the curve, it has no effect on the basic equation of the catenary curve.

Given a constant length of rope being supported and creating a catenary curve, if the equidistant distance between the supports is shortened, the curve shape would still be the same as shown here: [FIG 203]



Here is the basic shape of a catenary curve, and it could be describe as having a shape between that of a circle and parabola: [FIG 203A]



The three common hyperbolic trigonometric functions are given below: [Note, these not actually trigonometric.]

$\sinh x = \frac{e^x - e^{-x}}{2}$: this somewhat resembles e^(sin x) which is periodic (repeats) every 2pi radians (about 6.28 radians), since (sin x) cycles through values from 0 to 1. Also: You may also look up Euler's Formulas for sin x.

$\cosh x = \frac{e^x + e^{-x}}{2}$: this is the curve (as seen in the above graph) of a commonly seen catenary curve

These functions are often preprogrammed into many scientific calculators, and have a corresponding input key (button), and therefore, some explanation is needed. These ("non-circular" or non-periodic) hyperbolic functions are somewhat similar in value to the trigonometric identities of the standard "circular" (values are periodic, or repeating) trigonometric functions of SIN, COS, and TAN described in the TRIGONOMETRY section of this book. For example:

(cosh x)^2 - (sinh x)^2 = 1 is similar to the familiar: (sin x)^2 + (cos x)^2 = 1 , and

sinh 0 = 0, cosh 0 = 1 is similar to the familiar: sin 0 = 0, cos 0 = 1

When (x) is small in value (around 10 or less), the hyperbolic functions defined above will make this simple hyperbolic equation shown below to be true by substituting (cosh x) for (x), and (sinh x) for (y) :

x^2 - y^2 = 1 : the std eq. of a hyperbola is : (x^2/a^2) - (y^2/b^2) = 1
For this equation of the catenary curve shown, a=1 and b=1.
Here: x = square-root (y2 + 1) and y = square-root (x^2 + 1)

This is why sinh and cosh are known as hyperbolic (trigonometric) functions. Notice on the graph that the greater (x) is, that (sinh x) becomes closer in value to (cosh x) and therefore, the above equation cannot be satisfied since their difference, being close to zero, does not equal 1.

When x is high, the second term (e^-x) in the numerator gets smaller (practically 0) and it has less and less effect on the curve), and sinh and cosh become closer to the same value of:

$\sinh x = \frac{e^x}{2} = 0.5\, e^x$: essentially this curve becomes that of the e^x curve

$\cosh x = \frac{e^x}{2} = 0.5\, e^x$

From: $(\cosh x)^2 - (\sinh x)^2 = 1$, we mathematically have:

$\cosh x = \sqrt{(\sinh x)^2 + 1}$

$\sinh x = \sqrt{(\cosh x)^2 - 1}$

For completeness, an alternate method to calculate sinh x and cosh x is a series method that is very similar to finding (sin x) and (cos x) with a series:

$$\sinh x = \sum_{n=0}^{n=\infty} \frac{x^{(2n+1)}}{(2n+1)!}$$

$$\cosh x = \sum_{n=0}^{n=\infty} \frac{x^{(2n)}}{(2n)!}$$

: this is very similar to the sinh expansion above, but here, 1 is not added to (2n).

(x) is a radian angle measurement. For both the (sinh x) and (cosh x) series above, you can expect about 8 decimal places of accuracy when (x) is near 1, and 8 terms are summed. The lower (x) is, the greater the accuracy for a given number of terms evaluated. Actually, the series for sinh x and cosh are almost identical to the (sin x) and (cos x) series, except that the terms of these hyperbolic series do not have the $(-1)^n$ factor that produces an alternating (signed terms) series, hence all the terms for sinh and cosh are formally defined as being positive in sign.

Ex. $\sinh 1 = 1.175201194$
Ex. $\cosh 1 = 1.543080635$

Since $\text{TAN } x = \frac{\text{SIN } x}{\text{COS } x}$, and applying the above hyperbolic expressions to this, tanh is defined as:

$$\tanh x = \frac{\sinh x}{\cosh x} = \frac{\frac{e^x - e^{-x}}{2}}{\frac{e^x + e^{-x}}{2}} = \frac{e^x - e^{-x}}{e^x + e^{-x}} = e^x - (1/e^x)\ /\ e^x + (1/e^x)$$

The greater (x) is, the values of sinh (x) and cosh (x) become nearer and nearer, e^{-x} becomes very small, and therefore, the value of tanh (x) approaches $e^x / e^x = 1$.

Below, some generalities about the cosh equation will discussed.

$$y = \cosh u = \frac{e^x + e^{-x}}{2}$$

Why is the denominator 2? Like a numerical coefficient, the denominator for this equation shifts the curve of: $(e^x + e^{-x})$ along the y-axis. To further simplify this analysis, we will let the denominator equal 1, and let $N = e^x$. It is clear to see that the equation reduces to that of a number plus the reciprocal of that number:

$y = e^x + e^{-x} = e^x + \frac{1}{e^x} = N + \frac{1}{N} = \frac{N^2 + 1}{N}$: the numerator shows that the catenary curve is related to a quadratic or parabola curve.

When (x) is negative in value, the terms effectively switch position, resulting in the same general equation:

$$y = e^{-x} + e^{-(-x)} = \frac{1}{e^x} + e^x = \frac{1}{N} + N$$

This simply indicates that the curve of this equation is symmetrical about the y-axis. It also indicates that (y) can never be negative in value (assuming N is always a positive value). When x=0, we will find the minimum value of (y):

$y = e^0 + \frac{1}{e^0} = 1 + 1 = 2$: though with the full equation above, the min. is this value divided by 2, hence: $2/2 = 1$

To verify this, first consider $y = 0$:

$0 = N + \frac{1}{N}$ Multiplying both sides by N to solve for N, we get: (Or by just combining fractions on the right hand side)

$0 = N^2 + 1$: a quadratic equation where a=1, x=N, b=0, and c=1. Solving for N^2:

$N^2 = -1$ taking the square root of both sides of this equation:

$N = \sqrt{-1}$: the solution is imaginary (non-real)

Now consider $y = 1$:

$1 = N + \frac{1}{N}$ After multiplying both sides by N to solve for N, we get:

$N = N^2 + 1$: Here, the solution(s) for N cannot be real since any value squared and added to 1 is always greater than that value. Continuing to solve for N:

$0 = N^2 - N + 1$: a quadratic equation where a=1, x=N, b=-1, and c=1

The result is imaginary since when a=1 and c=1, |b| must be greater than or equal to 2 to produce a positive radicand in the quadratic formula:

$0 = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$ when a=1 and c=1, the radicand reduces to:

$b^2 - 4$ setting this expression equal to 0 (the smallest positive value for a radicand) and solving for b:

$0 = b^2 - 4$

$b^2 = 4$

$b = \sqrt{4} = 2$

We see that | b | must be equal to 2 just to "break even" into the positive realm for a positive value radicand. If | b | is less than 2 (given a=1, and c=1) the radicand will be negative and the solutions for N are imaginary. Due to these facts, the equation is now:

$y = 2 = N + \frac{1}{N}$: 2 is the min. value for real solutions of N, therefore:

$y = 2 = e^x + e^{-x}$: this is true when x=0. Dividing both sides by 2 we have:

$y = 1 = \frac{e^x + e^{-x}}{2}$: Hence 1 is the minimum value for cosh. This happens when x=0

If both sides of the equation were initially subtracted by 2, rather than divided by 2, and so as to set y=0, this would be incorrect since the minimum value of y, as noted above, is always 1 (when x=0) and not 0. This helps answer the question as to why the denominator is 2 and not some other number.

The actual amount of gravity, specifically gravitational acceleration (g), due to a mass such as a planet, moon, etc.,, will not affect the (natural forces) shape of a catenary curve. If the distance between the supports are the same that catenary curve will have the same identical shape on both the Moon and Earth. (g) of the (local) mass or body is not included as a variable or part of the catenary curve equation. The forces acting upon the chain or catenary curve will be proportional to the amount of (local) gravity upon the chain. In short, all catenary curves are similar in shape and one is simply a magnification of the other. The catenary curve equation is expressed as a very natural mathematical representation of a very natural effect of the (downward) force of gravity upon the entire curve and (changing, force) the tension needed to support the weight of the curve material at points along it. The shape of a catenary curve is somewhat like an "upside-down" bell curve. In short, the catenary curve is the curve of the value of the natural tension forces along the curve. Each end of the catenary curve is supporting half the weight of that material used, and therefore, the tension is half (1/2) for each side, and this is also a reason that the denominator of the equation is 2.

Regardless of the height of the curve above the surface of the ground, the catenary curve will still have the same shape and equation describing it. Excluding the 2 in the denominator, here is an analysis to consider of the sum of a power value of (N) and the reciprocal of that same power value:

$N^x + N^{-x} = N^x + \frac{1}{N^x}$ combining these fractions:

$\frac{N^{(2x)} + 1}{N^x}$, when N and-or x is high, the added 1 becomes more meaningless and the equation reduces to:

$N^{(2x)} / N^x = N^{(2x - x)} = N^x$, and this can also be seen above when $(1 / N^x)$ becomes a small value and is practically equal to 0 and negligible.

Also consider other equations where when x=0, the corresponding value of y is 1:

$y = \cos x$, if $x = 0$, $y = \cos 0 = 1$: a trigonometric equation

y = n^x , if x = 0 , y = n^0 = 1 : an exponential equation

At what value will y=2 for the cosh function or equation?

y = 2 = 0.5 (e^x + e^-x) mathematically dividing each side by 0.5, we have:
4 = (e^x + e^-x) rather than evaluating e^x, we can let N = e^x, then we have:
4 = N + 1/N =
4 = (N^2 + 1) / N it was found by manual trial and error that N is about equal to 4.236068 , therefore:

N = e^x =~ 4.236068 : This can also be found using a program with the fast equation solver algorithm
as shown in this book. Search this book for FANA or FESA and update what variables
to now utilize , and mainly for this example: 4 and use ((x^2 - 1) / x

x =~ ln 4.236068 =~ 1.44363548

If the curve was nearly at the ground, then at x =~ 1.44363548 , y =~ 1

The cosh curve is a result of only the natural tension in the rope due to gravity. The weight of the rope to uphold at the bottom center of the curve is 0 and the tension forces from each side of the rope are equal in value and opposite in direction, hence a net force of 0. Each supporting end of the curve will support (1/2) the weight of the rope. It is also of note that the weight of the rope is proportional to its own length and regardless of how it is straight, knotted, bent or curved.

MODULUS OPERATION

Though one of the less used operations, the modulus operation is still worth mentioning due to its use in computer programming, and occasional use elsewhere, and is unrelated to logarithms, etc.. The modulus operation is also known as the "remainder operation" since this is essentially what it does or returns (the result). The result of a modulus operation is the (whole number) remainder of the division of its two operands. The commonly used symbols for a modulus operation are MOD and the percent symbol (%); as opposed to using the standard division symbol of: (/).

The modulus operation was briefly mentioned before in this book during a discussion of converting any given angle value so as to be an equivalent value between 0° and 360°. As the value of an angle increases to greater than 360° and beyond, the output or resulting angle value of the MOD operation will cycle from 0° up to 360° and then "restart" or "reset" at 0°. In short, the "output" or "result" of a MOD mathematical operation is a range of values that are cyclical (ie., repeats).

The format of a modulus operation is:

operand_1 MOD operand_2 : MODULUS OPERATION

, where operand 1 is essentially the numerator, and operand 2 is essentially the denominator. Since division by 0 is unacceptable, operand 2 cannot be 0.

Ex. 10 MOD 5 = 0 since: : 10%5 would be the notation or "syntax" used in some computer programs

since $\frac{10}{5} = 2$ with a remainder of 0

Ex. 10 MOD 3 = 1 and:

since $\frac{10}{3} = 3$ with a remainder of 1

checking: 3 x 3 = 9 and 10 - 9 = 1

Ex. 7 MOD 7 = 0

since $\frac{7}{7} = 1$ with a remainder of 0: 7 x 1 = 7, and 7 - 7 = 0

Whenever the numerator is greater than or equal to the denominator, the result of the MOD operation will always be between, and including: 0, and 1 less than the denominator operand:

Ex. 4 MOD 4 = 0

since $\frac{4}{4} = 1$ with a remainder of 0

Ex. 5 MOD 4 = 1

since $\frac{5}{4} = 1$ with a remainder of 1

Ex. 6 MOD 4 = 2

since $\frac{6}{4}$ = 1 with a remainder of 2

Ex. 7 MOD 4 = 3

since $\frac{7}{4}$ = 1 with a remainder of 3

Ex. 8 MOD 4 = 0

since $\frac{8}{4}$ = 2 with a remainder of 0

Whenever the numerator is less than the denominator, the result of the MOD operation will always be equal to the that numerator.

Ex. 6 MOD 8 = 6

since $\frac{6}{8}$ = 0 with a remainder of 6

Here is how you can perform a MOD operation by hand or with a calculator:

1. Divide the two operands and obtain the whole portion of the quotient.
2. Subtract the product of the whole portion of the quotient and the denominator from the numerator.

Ex. Evaluate: 17 MOD 8

$$\begin{array}{r} 2. \\ 8\,\overline{)\,17.0} \\ -\,\underline{16} \\ 1 \end{array}$$

: The division can stop here since the entire whole portion of the quotient has been found.

(17 MOD 8) = 17 - (8)(2) = 17 - 16 = 1 : 1 is the remainder, hence (17 MOD 8) = 1

In computer programming, the bits of a byte generally do not have a unique (ie. integer) memory address (location) assigned to them. Still, you can find out the status (set=1, not set=0) or numerical value of a bit by using a small amount of computer code or a program. This results in accessing (reading or writing) the entire (8-bit) byte a bit is part of, and then use various forms of logical or "bitwise (bit for corresponding bit)" operations or bit-shifting (such as with the C-programming language, binary value (bit) shift operators: << and >> which can be used to essentially rid or remove unwanted bits from a byte), etc. to find the specific value (0 or 1) of a bit. These methods are forms of "software addressing". Given the bit address value of a certain bit in memory, how do you find which actual byte address in memory that bit is within or part of? We can use the MOD operation to find what the byte number or byte address is. For example, and optionally using logical (you can think of this as referring to offset values from the start location of 0) rather than physical address values which start at 1 as for counting things.

Byte address:	0	1	2	3 . . .	: each byte has 8 bits
Bit address:	0 1 2 3 4 5 6 7,	8 9 10 11 12 13 14 15,	16 17 18 19 20 21 22 23,	24 . . .	"8 bits wide"

Below, the corresponding byte of which a bit is in is being found. An operation, somewhat like the concepts of a MOD operation is to be used, but here the quotient, and not the remainder, is to be used. Essentially then, the MOD operation is not needed here, but rather just a division or "quotient" operation, and we will use the notation of QUO for this. Though the logical bit position or offset of a bit within a byte do in fact cycle from 0 to 7, byte numbers do not cycle in such a manner.

Logical bit #5, or the bit at logical bit address 5 is at the byte address of : 5 QUO 8 = 0
Logical bit #14, or the bit at logical bit address 14 is at the byte address of : 14 QUO 8 = 1
Logical bit #16, or the bit at logical bit address 16 is at the byte address of : 16 QUO 8 = 2
Logical bit #21, or the bit at logical bit address 21 is at the byte address of : 21 QUO 8 = 2
Logical bit #25, or the bit at logical bit address 25 is at the byte address of : 25 QUO 8 = 3

To access bit #21 so as to find and-or change its value, first access the byte and its value at address 2 that contains that bit. Then find the value of the proper bit (logical 0 to 7) in that byte. 21/ 8 = 2 with a remainder of 5, ie: 2 + 5/8

For example, to access bit #21, we need to first access the byte (ie. find its value) at the logical byte address which also contains that bit as part of that byte value or data:

21 QUO 8 = logical byte number 2. The bit in question is at the logical (bit) offset of 5, as calculated here:

(logical bit offset in the byte containing bit # N) = (logical bit # N being accessed) - (8 x logical byte number)

5 = 21 - (8 x (21 QUO 8))
5 = 21 - (8 x 2)
5 = 21 - 16 = 5

To access (ie., read and-or write) a bit value of a byte, we will need to manipulate the value of that byte, such as with a (byte) shift operator, or with an (logical) XOR operation.

SOME ADVANCED FUNCTION CONCEPTS

COMPOSITE FUNCTIONS

A function that is a function of another function is called a composite function. A composite function is then composed of at least two functions.

If function (g) is a function of variable (y), this can be expressed with the notation of: g(y). If g(y) = 7y^2 + 2, and if (y) is a function (ie. depends upon) of another function (f) where (y) = f(x) = 3x, this composition can be expressed as the composite function gf. This composite function, for example, if set equal to (z), might be used to plot points: P(x, y, z), or perhaps better expressed as: P(x, y(x), z(y)) in a three dimensional coordinate system. Note that gf is the (function) notation for a composite function, and it does not mean the sum or product of function (g) and function (f). Here is an example:

y = f(x) = 3x : y is set equal to a function, and here, it is a function of x.
y is then simply described as a function of x.

z = g(y) = 7y^2 + 2 : z is set equal to function g of which is a function of y. And since y = f(x):

z = g(y) = 7(f(x))^2 + 2 : function g is now explicitly shown as a function of x on the right hand side:

z = g(f(x)) = 7(3x)^2 + 2 Using simplified notation:

z = gf(x) = 7(9x^2) + 2 : gf is a composite function, a function composed of two or more functions.
gf can be noted as a "function that contains another function".

z = gf(x) = 63x^2 + 2 : variable z is a function of the composite function gf

INVERSE FUNCTIONS

If (y) is a function of (x), you may want to solve for the corresponding (x) values which determined those (y) values. This can be accomplished by the substitution of the (y) value into the inverse equation and then solving for (x). However, here we are interested in a general or algebraic method in the form of a formula. The method to do this is to create an inverse function from the known function to essentially undo or "work backwards" to find the value of the variable (x). A given function and its corresponding inverse function are both inverse functions of each other. It should also be stated that these inverse functions are also not generally the mathematical reciprocal of each other.

If (g) is the inverse function of y=f(x), then evaluating (g) with this specific value of (y) will produce its corresponding value of (x):

y = f(x) : f(x), (f) is a function, here evaluated using or containing (x), hence f(x) is called a function of (x).
The actual function is an expression containing variable (x).

x = g(y) : g(y), (g) is a function, here evaluated using or containing (y), hence (g) would be called a function of (y).
If (g) is the inverse function of (f), and if (g) evaluates the output of function (f). which is the (y) value, it
it will find its corresponding value of (x).

The relationship of f(x) and g(y) can be considered as like the corresponding relationship of the (x) and (y) values of a point, except that (f) and (g) are used to find all the specific corresponding points. That is, (f) and (g) actually represent all the possible corresponding pairs of two values, rather than just a single specific pair. This can be expressed as:

p(x, y) = p(g(y) , f(x)) : a point is both a location and a corresponding pair of values, here, (x) and (y).
Here, y=f(x) and x=g(y) , f(x) and g(y) are inverse functions of each other.

Ex. Let f(x) = 7x

If g(x) is the inverse of f(x), then $g(x) = \frac{x}{7}$

This is so since x was multiplied by 7 in f(x). To make the inverse function, (x) must be divided by 7 as expressed for g(x) so as to remove its multiplying factor:

$y = f(x) = 7x$ therefore algebraically:

$x = \frac{f(x)}{7}$ since y = f(x):

$x = \frac{y}{7} = g(x)$

The above is mathematically correct, however for conformity, letting variable (y) represent the dependent variable, and variable (x) represent the independent variable, we will rewrite the above equation as:

$y = \frac{x}{7}$ letting function (g) represent this equation:

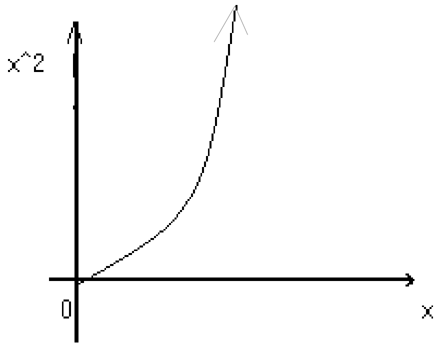
$y = g(x) = \frac{x}{7}$

Ex. If y = f(x) = x^2, what is the inverse function?

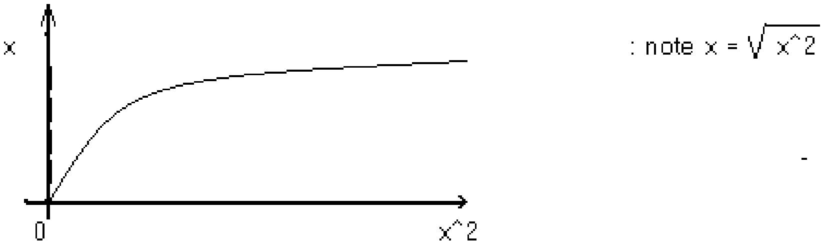
Let g(x) equal the inverse function of f(x). This may sometimes be mathematically noted as:

g(x) = f^-1(x)

Observe the two graphs below for a visualization of these inverse functions: [FIG 204]



Switching the axis, we have: [FIG 205]



However labeled, still the expressions on the horizontal axis represent the horizontal distance (ie. "x") from 0, and the expressions on the vertical axis represent the vertical distance (ie. "y") from 0.

To find the inverse function of f(x), solve for x given that function:

y = x^2 taking the square root

$\sqrt{x^2}$ simplifying:

g = x

Since the process only involved taking a square root, the inverse function is therefore a square root:

g(x) = $\sqrt{x^2}$ = x : that is, if x was squared, you would need to take the square root of that resulting value so as to find what x was

Since: y=f(x) and x=g(y) , f(x) and g(y) are inverse functions

Ex. If f(x) = n^x , find the inverse of this function where base (n) is a constant value.

n^x solving for x by taking a logarithm:
log$_b$ n^x

Or something as the following where y or z is set equal to the given function:

y = n^x taking the log of both sides:
log y = log n^x using the log exponent rule:
log y = x log n using a log with a base of n: logn n = 1 , and switching sides:
x = logn y since y = n^x :
x = logn n^x

Hence to solve for x, only a logarithm needs be taken. For example:

y = n^x : here, n is a constant, not a variable
y = 2^3 : if n=2
y = 8 expressing these steps with a general formula:

x = g(y) = log$_2$ y : Note the base is expressed as written right next to the word log, here it's 2, rather than as a subscript or other form such as log_2. It's a simple text alternative form of expressing logarithm expressions.

$x = g(y) = \log_2 8$
$x = 3$

$y=f(x) = 2^x = 2^3 = 8$
$g(y) = \log_2 y = \log_2 8 = 3$

Using standard functional notation where x is the independent variable and y is the dependent variable:

$y = g(x) = \log_2 x$
$y = g(8) = \log_2 x = 3$

Ex. $y = f(x) = 2x + 3$ find the inverse function.

$y - 3 = 2x + 3 - 3$
$y - 3 = 2x$ after dividing both sides by 2, canceling, and switching sides:

$$x = \frac{y - 3}{2}$$

Therefore, the inverse function will contain a subtraction of 3 and a division by 2. In standard function notation where y is set to the dependent variable, and x is set to the independent variable:

$$y = g(x) = \frac{x - 3}{2}$$

$f(6) = 2(6) + 3 = 12 + 3 = 15$

$$g(15) = \frac{15 - 3}{2} = \frac{12}{2} = 6$$

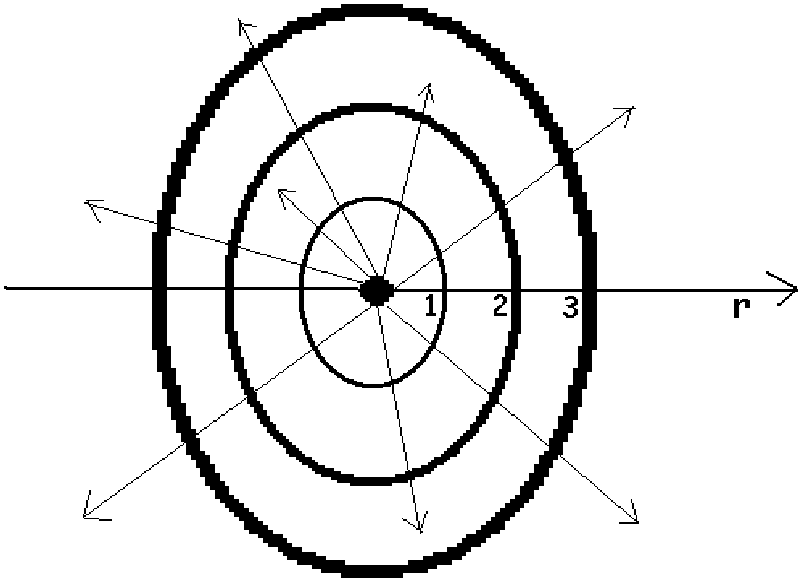
INVERSE SQUARE LAW

The inverse square law is a common name given to a relationship when values or variables are not only related to the reciprocal or inverse (ie. inversely related) of another value or variable, but related to the mathematical square (ie. value^2) of that reciprocal value.

$A = \frac{1}{B}$: Here, A is related to the inverse or reciprocal of B, and if given:

$A = \left(\frac{1}{B}\right)\left(\frac{1}{B}\right) = \left[\frac{1}{B}\right]^2 = \frac{1}{B^2}$: Here, A is related to the square of the inverse or reciprocal of B, and may be commonly spoken as: "A is related to the inverse square of B", or "A is the inverse square of B".

Common examples of this relationship are found when dealing with energy (or the measured intensity of it) as it expands outward in all directions from the (point) source. For example, light, sound, radiation, gravity fields and so on, often expand this way and their corresponding intensity or strength reduces dramatically by the square of the distance from that source. Below in the drawing we see a "point-source" (infinitely small and uniform source or distributor) of energy at the center of the (imaginary) concentric spheres drawn to be used for this analysis. This point could actually be an infinitesimally small object or a large object so far away as to be considered practically as a point (such as a star in the sky). Since the energy is uniformly distributed outward from the source, a surrounding "shell" or (surface of a) sphere at various distances or radius values from that source will be used for the analysis. [FIG 206]



$S_s = 4\pi r^2 \approx 12.56637061\underline{1}\, r^2$:Formula for the **SURFACE AREA OF A SPHERE** (essentially a ball) as derived by Archimedes is approximately: $12.566\underline{4}\, r^2$. Units are those used for (r).
If we let r = radius = diameter/2 = d/2, we have this for surface area of a sphere:
Ss = **4(pi)r^2** = 4(pi)(d/2)^2 = 4(pi)d^2/4 = **(pi) d^2** = (pi)(area of a square) = **CD**

$V_s = \frac{4\pi r^3}{3} \approx 4.1887902\, r^3$: **VOLUME OF A SPHERE (with units being the same as those used with r)** is approximately: Vs =~ 1.333... (pi) r^3 = $4.18879020\underline{5}\, r^3$ =~ 4.1888 r^3
The formula is credited to Archimedes. **Vs = (pi) d^3 / 6 = (pi) Vcube / 6** = **V sphere = 0.52398776 V cube** having the same diameter.

For inspiration and verification for the volume of a sphere formula, Archimedes may have used a sphere in container of water with a known volume, and then measured how much the sphere caused an increase in its volume when immersed in it. This increase in the volume of water is equal to the volume of the sphere.

In the drawing above, you can see (energy) ray or traversal lines coming from the point source indicating the direction of energy, and here it's in all directions outward or away from that point or source. Clearly, the total amount of energy coming from the source will then be distributed throughout a larger surface area (or volume) as the distance (indicated as a radius = r value) from that point increases. Though the total value or sum of energy available at each shell or sphere surface area remains the same as it expands outward, the measured value or intensity of energy will actually get or be less per unit area (of measurement) since the total amount of energy must remain the same (not more or less) as before. Though the area of each sphere increases, the total energy itself does not increase or decrease, and only the energy or intensity measured per unit area decreases. At this point in this discussion, we now can understand that the intensity (I) level of the energy per unit of area is inversely related to the distance (r) from the point source. Now note the ratios of surface areas of the spheres as (r) increases:

$S = 4(Pi)r^2$: basic equation for the surface area of a sphere , and if r increases by 1, area increases by 3 to be a total of 4 times more:

$\frac{S2}{S1} = \frac{4 (Pi) 2^2}{4 (PI)\ 1} = 4$: $\frac{\text{surface area of sphere at r=2}}{\text{surface area of sphere at r=1}}$, ie., related to the square of the radius , and if r increases by 1 again, the area increases by 5 to be a total of 9 times more than the original area.

$\frac{S3}{S1} = \frac{4 (Pi) 3^2}{4 (Pi)\ 1} = 9$: $\frac{\text{surface area of sphere at r=3}}{\text{surface area of sphere at r=1}}$

According to the basic equation for the surface area of a sphere, we see that the relationship of surface area to the radius is a squared relationship. Surface area is mathematically directly related to the square of the radius from the source. If we express the energy level or intensity (I) per unit area (A) we can call this the density (D) or concentration of energy per unit area, or "energy density". More technically, since energy has no form, it has no actual density either, and "energy density" could rather be considered as the "energy concentration" or "concentration of energy".

$D = \frac{I}{A}$: Let D = energy density or intensity (I) per unit area (A).
: For the calculation, use A = surface area of the sphere.

$D = \frac{It}{4(Pi)r^2}$: It = total energy or intensity emitted from the source.
r = distance from the source.

As the distance (r) from the source increases, the surface area (A) of the shell or sphere will increase. Surface area of a sphere is directly related to the square of the radius.

We see that for example, D, energy density or level, at r=2, will be only one-fourth (1/4) of that at r=1. This is so, since the (limited or constant amount of) energy (at r=1) will expand or be distributed into four times that area at r=1. At r=3, the density will be only one-ninth (1/9) of that at r=1, since the energy at r=1 will expand into 9 times the area at r=3. We can conclude that as (r) increases, the intensity per unit area decreases, and its value is inversely related to the square of the radius from the point-source.

Ex. At r = 1, if the measured intensity is 100 units.

At r = 2, (twice the distance from the source) the intensity is less by a factor of: $2^2 = 4$,
or $D1/4 = 100/4 = D2 = 25$

At $r = 2.5$, the intensity will be less by a factor of: $2.5^2 = 6.25$,
or $D1/6.25 = 100/6.25 = D = 16$

At r=2 from the source, for example, even though the intensity decreases by $r^2 = 2^2 = 4$, the surface area actually increases by 4, and the total energy passing through or received by each entire shell or sphere from the source is constant:

Total Energy In = Total Energy Out : considering no losses along the way
Intensity In = Intensity Out

From $D = \frac{I}{A}$: energy or intensity per unit area, we have $I = DA$: total energy at that area

Ex. If the density (D) or intensity per unit area was measured to be 100, and if A increases by 4, D will also decrease by a factor of 4, such as when r=2:

$I1 = I2$: total intensity or energy at surfaces at r=1 and r=2 respectively
$D1A1 = D2A2$: You may sometimes see proportions like: $D1/A2 = D2/A1$ when dealing with inverse square relationships. an alternate expression of these values is:
DnAn is Dn Rn^2 : R = radius , n = corresponding values of D and A
$100(1) = 25(4)$

$100 = 100$: showing that, the total energy at each (increased in size) shell or sphere is the same.

Ex. If r is now 3, what is the calculated density or intensity per unit area?

From: $D1A1 = D2\,A2$ mathematically:

$$D2 = \frac{D1A1}{A2} \text{ or= } \frac{D1R1^2}{R2^2} = (100)(1) / 3^3 = 100/9 =\sim 11.1$$

You probably have noticed that the intensity or level of sound and-or light changes as the distance between you and that source changes. A sound can be very loud if you are close to it, or barely heard if you are far from the source of that sound. As your distance doubles (at r=2) from that source (or possibly a reflection [and redirection]), the intensity of the energy received will be reduced (ie. divided by the factor) by $r^2 = 4$, or multiplied by factor of (1/4) = 0.25. Just the same, in a reverse type of manner, if the distance between you and the source is halved ($r/2 = 0.5r$), the intensity of the energy will increase or multiplied by the factor of 4.

An article in the appendix section of this book will contain another verification, ideas and examples; see
More About The Inverse Square Law

If the intensity (I) and-or measurement is inversely related to the square of the distance (r) from the source or a measurement location, we can express this as:

$$I = \frac{1}{r^2} = r^{-2} \qquad \text{solving for r:}$$

$$r = \sqrt{\frac{1}{I}}$$

If the distance (r) from the source has increased, the intensity (I) will decrease due to the inverse real (physical) and mathematical relationship. and if the intensity is measured to be a certain percentage (n) as that of the first measurement, this can be expressed as: nI , and for example, if I is now at its 50% level, n = 0.5 and nI = 0.5I. The corresponding distance (r) can be found by using this value in the above equation. Considering I as a relative value of 100%=1 value:

$$r = \sqrt{\frac{1}{n(I)}} = \sqrt{\frac{1}{0.5(1)}} = \sqrt{\frac{1}{0.5}} = \sqrt{2} = 1.4142...$$

: when (r) increases by the factor of 1.4142, the intensity (will) be decrease by the factor of 0.5

Checking:

From: $I = \frac{1}{r^2}$ If (r) increases by the factor of 1.4142, (I) will increase by the factor of 0.5, hence decrease by 2:

$$I = \frac{1}{r^2} = \frac{1}{(1.4142\ r)^2} = \frac{1}{(\sqrt{2}\ r)^2} = \frac{1}{2\ r^2} = (0.5)\frac{1}{r^2}$$

For the equation to be in balance, if we have performed mathematical operations of one side, such as essentially multiplying one side by a value, here (0.5), we must do the same to the other side of the equation, and we then have (0.5)I = 0.5I when (r) increases by the factor of 1.4142. I is then at half of its measured value at (r), when (r) changes by the factor of 1.4142. In short, and as shown in the above equation, if (r) changes by a factor of (n), (I) will then change by the factor of: 1/(n^2).

Given : $I = \frac{1}{r^2} = \left(\frac{1}{r}\right)^2 = r^{-2}$: It could be said that (I) is inversely related to the square of the reciprocal of (r).

Given : $I = \frac{1}{r^2} = r^{-2}$

, the instantaneous rate of the corresponding changes in (I) to the changes in (r) is the derivative of (I) with respect, or in reference to (r) :

$$\frac{dI}{dr} = -2\,r^{-3} = -\frac{2}{r^3}$$

: Clearly, as r increases the slope decreases rapidly till it is practically 0, and the curve resembles a line. That is, for large changes in (r), when (r) is about five times or more than that of the first measured distance, the intensity, though it is very small in value, it will not decrease by a larger and larger factor past these high values of (r). This situation allows us to still receive, see or detect extremely distant (but weak) starlight and radio signals.

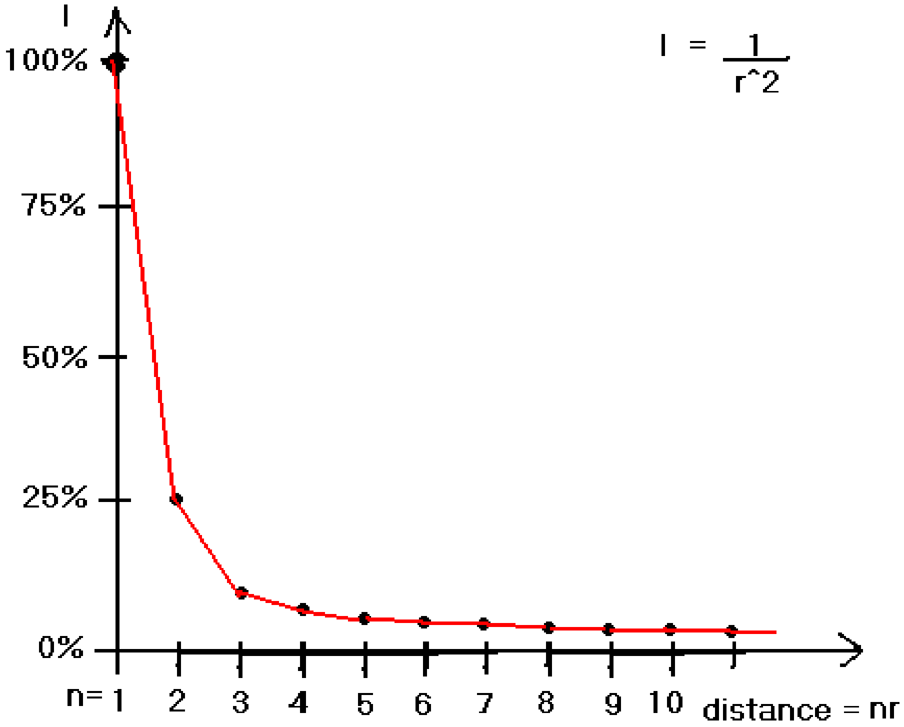
Given : $I = \frac{1}{r^2} = \left(\frac{1}{r^1}\right)^2 = r^{-2}$: It could be said that (I) is inversely related to the square of the reciprocal of (r^1).

This is a much steeper slope than if (r) was not squared:

$$\text{value2} = \frac{1}{\text{value1}^1} = \text{value1}^{-1} \quad \text{and} \quad \frac{d\,(\text{value2})}{d\,(\text{value1})} = -1\,\text{value1}^{-2} = -\frac{1}{\text{value1}^2}$$

This is essentially a "reciprocal equation" since value2 is the reciprocal of value1.

Here is a graph of: $I = \frac{1}{r^2} = r^{-2}$, and it is essentially the inverse of: $I = r^2$. [FIG 207]



(ie., multiples of (r))

Notice that at high values of (r), say past r=5, or 5r, that the intensity is a low value, but it remains relatively stable in value after that for very high values of (r), and this allows us to still receive and see enough light from a very distant star. A telescope with a large main (or "objective") lens or mirror can gather very small amounts of light and collect and concentrate them (into a smaller area or image) so as to effectively increase the intensity of that received light per unit area, and therefore, produce a brighter and more visible image.

PRODUCTS OF THE FIRST TERMS OF THE ODD, AND EVEN SERIES

Integer Series: 1 , 2 , 3 , 4 , 5 , 6 , 7 , 8 , 9, . . . : an arithmetic series where d=1
The value of the nth term is: 1(n) = n

Even Integer Series: 2, 4 , 6 , 8 , 10 , 12 , 14 , 16, . . . : the value of the nth term is: 2n
Odd Integer Series: 1, 3 , 5 , 7 , 9 , 11 , 13 , 15, . . . : the value of the nth term is: (2n - 1)

The following is a practical example of working with factorials. Lets begin with the product of the first (n) terms of the even series:

Product = (2)(4)(6)(8)(10)....(2n) : 2n is used and not just (n). This is since if we want to find the n=10 first terms that are even in value, we must go through 2(n) = 2(10) =20 total terms since there will also be n=10 odd terms in the series to go through to reach the 10th even valued term. (2n) is always an even number. (2n)-1 and (2n)+1 are odd.

By dividing each factor by 2, each factor can be expressed as a multiple of 2. For example: Since 8/2 = 4, factor 8 can be expressed as 8 = (2x4):

Product = (2x1)(2x2)(2x3)(2x4)(2x5)...(2n) Each factor has a factor of 2

(2)(1)(2)(2)(2)(3)(2)(4)(2)(5)...(2n) All these factors of 2 can be expressed as a repeated multiplication of 2:

(2)(2)(2)(2)(2)x(1x2x3x4x5...n) which can be expressed with a power of 2 as:

Product = 2^n (1x2x3x4x5.....n) : The second factor is equal to n**!**

Product = $(2^n)(n!)$: Product of the first (n) terms of the even arithmetic series.
This value will be used in the following derivation:

Now let us find the product of the first n terms of the odd series:

If we take the factorial of the first (2n) integers (both odd and even), and divide out the unneeded factors such as the even series, we should have the product of the first (n) factors of the odd series:

$$\frac{1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8 \ldots (2n)}{2 \times 4 \times 6 \times 8 \ldots (2n)} = \frac{(2n)!}{(2^n)(n!)}$$

: Product of the first (n) terms of the odd series.

As a check, multiplying the odd and even products (ie. the divisor and quotient) of the first (2n) terms, we get the quotient of :

$$(\text{even products})\ (\text{odd products}) = (2^n)(n!)\ \frac{(2n)!}{(2^n)(n!)} = 2n!$$

, and dividing by 2 to have half of the values we get: (n**!**)

Ex. Find the product of the first 3 odd terms, or the first 3 terms of the odd integer series: (here, n=3):

$$\frac{(2n)!}{(2^n)\,n!} = \frac{(2 \times 3)!}{(2^3)3!} = \frac{6!}{(8)\,(3!)} = \frac{720}{(8)(6)} = \frac{720}{48} = 15 = (1)(3)(5)$$

[This space for edits.]

THE BINARY NUMBER SYSTEM

The reader may skip the section below about binary numbers and read it at a later time if they become interested in this topic. The binary number system will not be discussed further in this book, except that it may possibly help with the included computer programs and with further study about some methods of computer programming.

Before this discussion begins, some people may be worried as to what great of an extent they may need to understand binary numbers as to be a computer programmer. With most modern computer languages, working directly with binary bits and bytes and-or their signed value computer representation is often not needed as rather their equivalent and common decimal values are used directly in computer programs.

The word "binary" has a "bi" prefix which means double, two or 2. "Unary" is a word meaning single, unit or 1. The binary number system uses only two counting symbols (0 and 1). Hence, a "highest count" of only one (1) can be reached before positional notation, just like that used with the decimal number system, is required to represent larger quantities or numeric values. That is, in binary addition, 1+1 = 0 with a carry of 1. This can be shown as 1+1=10. As an aid to avoid ambiguity and to be certain which system is being used, letter b for binary (base 2), or letter d for decimal (base 10) can be explicitly expressed or indicated. For example: 1b+1b = 10b. 10 ("one, zero") is the binary representation or equivalent of the decimal notation for 2: 10b = 2d.

Lets increment a binary value of 0 by 1, using the binary system and positional notation:

```
   0
 + 0
   0                 : 0b = 0d

   0b      0d            :  Same as:   1b     : using the commutative law.
 + 1b    + 1d                        + 0b
   1b  =   1d                          1b    ,    1b = 1d

  1 <------------------: This is a carry of 1 from the previous column or position sum.
   1b      1d        : As in the decimal system, leading zeros are also possible, for
 + 1b    + 1d           example:  1 + 1  =   0001 + 0001  =  0010
  10b      2d        : "1 plus 1, equals zero with a carry of 1".  The result is "one, zero" in
                        binary, or 2 in decimal.  10b = 2d

  10b          10b       2d
 + 1b    or:  + 01b     + 1d
  11b          11b   =   3d            : 11b = 3d

 11            11
  11           011          3d
 +  1    or:  + 001        + 1d
 100b          100b   =    4d          : 100b = 4d
```

Decimal Equivalent	=	Binary Equivalent	
0d		0b	After incrementing each by 1 successively :
1		1	
2		10	
3		11	
4		100	
5		101	
6		110	
7		111	
8		1000	
9		1001	
10d	=	1010b	: 10d = 1010b

Notice in the above table of binary values, that you can immediately tell if the binary value is odd or even. Odd binary values will have the least significant bit or position of the entire number value set to 1. Even (exactly divisible by 2) binary values will have the least significant bit or position of the entire number set to 0. Binary values can also have fractional (a part of 1, and that are less than 1) values just like decimal values do following the decimal point, but for the binary system, the correct terminology is the binary point.

The numeric base of a number system is the number of unique counting symbols for each integer and before positional notation is required. The base in the decimal system is "ten" = 10d, and the base in the binary system is "two" = 10b = 2d. A more formal word for base of a number system is the radix of the number system. "Radix" is a word based on the common word "root" and which for this discussion means the root or base (ie. start, based upon) of the numeric system. The word "radical" is also a form of the word radix, and is the notation and operation to find a root (ie.source, common factor) of a value. These words and others such as "radius" (from the center of a circle) and "radicle" (pre-root or first root of a plant) are based upon the very old word "wrad" which means a root or branch (from a source or tree which extends outward).

From the letter "b" in the word binary, and the letters "it" from the word digit, binary digits are frequently called "bits". A binary number will have a series of these digits or bits and their corresponding bit positions in a binary number consisting of several bits. A bit can have a numeric value of only 1 or 0. A binary number composed of a series of 8 bits together is called a byte.

The maximum numeric value for a byte is 255, that is, $11111111_b = 255_d$. Since the binary number system uses only two values, it is easily implemented with mechanical, electro-mechanical (ie., electrical and physical-motional), and high speed electronic systems such as with electronic computers. A simple on-off switch or settings is a simple binary system. Something set to "on" can be represented logically (ie. the truth=1 or falseness=0) and mathematically in binary as 1, and something set to "off" can be represented logically and mathematically as 0. Computer circuits such as electronic memory (storage of information), the data bus (communication wires or lines), and the micro-processor (electronically processes data or information and programs) are usually set up to work with whole bytes of data (information) at once rather than a bit at a time as for serial communication which is usually slower (although it might be simpler and cheaper). This is accomplished by using 8 wires or "data lines", one for each bit of the byte, and this method is called parallel data and-or communication. For the internal computer system, data is placed in the form of a binary number representation (which may be optionally coded) which is implemented electronically where a high voltage signal represents a bit set to 1 ("a 1 bit"), and a low voltage signal represents a bit set to 0 ("a 0 bit"). For example, with the American Standard Code for Information Interchange (ASCII), letter A is numerically $65_d = 01000001_b$, letter B is $66_d = 01000010_b$, and so on. It must be noted that fundamentally, data storage media such as hard-disks (magnetic), floppy-disks (magnetic), CD-DVD (optical) drives, and many portable "memory sticks or cards" often use only 1 data line, hence serial communication, and therefore 8 bits, one after the other (ie., serially or sequentially), must be accessed to essentially build an 8 bit byte that can then be accessed (read or written) for internal processing by the computer. Therefore, accessing a byte on disk is often at least 8 times slower than accessing a byte at a time in the computers electronic (byte sized) memory. This time can be reduced in many cases by using an electronic memory cache (storage) where extra bytes, just beyond those requested, are automatically read from the disk and stored in this cache for possible immediate use.

Here are the binary number system weights of the bits of a byte which is a binary encoded number or value, having a "width" (digits or bit count) of 8 bits:

most significant part of the number   least significant part of the number

2^7 , 2^6 , 2^5 , 2^4 , 2^3 , 2^2 , 2^1 , 2^0 : binary weights in powers of 2 (binary)
128 , 64 , 32 , 16 , 8 , 4 , 2 , 1 : equivalent decimal values

Notice that in the binary number system that each weight is twice (2) that of the previous bit position weight, rather than ten (10) times that of the previous position weight as with the decimal number system.

For either the decimal or binary number system, a positional product is the product of the digit or bit value and the weight of the position it is in. This is so since each digit or bit value is a multiple of the weight value of that position.

Since a bit can only be 0 or 1, each positional product of a binary number can only be either 0, since (0 x any_weight) = 0, or (1 x weight) = weight. This makes it easy to find the decimal equivalent of a binary value since no multiplication needs to be done, and essentially, just the addition of the binary weights (ie., positional significance, value) is needed.

Ex. What is the decimal equivalent of the byte: 00100011 , or without the leading 0's as: 100011 ?

0 0 1 0 0 0 1 1 : 00100011b

0 + 0 + 32 + 0 + 0 + 0 + 2 + 1 : position products =
bit value x weight value or=:
position value x position weight

By simply "skipping over the 0 bits", that have no value:
32 + 2 + 1 = 35b : positional sum
00100011b = 35d

Ex. What is the binary equivalent of 35 = 35 decimal = 35d ?

First, since the value is less than or equal to 255d, only one byte, or= 8 bits, is needed to represent this value in binary. Actually, only 6 bits are needed to represent this value since the leading two bits are 0.

Since the binary weights of 128 and 64 are larger than 35, they will not be included or set (to 1) in the binary representation. If building a (8-bit) full byte they should rather be indicated as 0, and since leading 0's wont add to the value. It is possible in some electronic systems that if they are not deliberately set to zero (or "cleared"), that they may still contain a previous ("garbage", incorrect) value that could result in an error if those bits are possibly considered and included as part of the value.

0 0 . . . . . . : first two bits of the byte set to 0. Since these bits actually represent a larger part of the number, they are called most significant bits. The logical bit numbers of these are bit #7 and bit #6 from left to right. The first physical bit has a logical bit number of bit #0.

The bit corresponding to the weight of 32 can be set to 1 since 32 is less than or equal to 35, that is 32 is part of, or within 35, and therefore it needs to be included or represented in the binary number:

001 . . . . .

The remainder of decimal value must now be considered so as to keep building the equivalent binary value.

35 - 32 = 3 : Subtracting 32 out from the given decimal value since it is now accounted for in the binary number. 3 is the remainder of the decimal value left that must be converted to its equivalent binary value and added into the binary value being built.

The three next lower value binary weights of 16, 8 and 4 are larger than the remainder of 3, and therefore, their corresponding bits will be set to 0::

001000 . .

Continuing the process, we find that we can use the second bit, which has a weight of 2, since it is less than or equal the decimal value of 3. The remainder left is then 3 - 2 = 1. The first bit has a weight of 1 and can be used to represent this value. Since the remainder is now 1 - 1 = 0 , the conversion process stops, and the binary equivalent of 35d is found to be:

$35_d = 00100011_b$

With the binary number system, you can quickly multiply a number by 2, by moving all the bits one position leftward. Likewise, You can divide a binary number by 2, by moving all the bits one position rightward. This is the same basic procedure when multiplying and dividing a number by 10 as with the decimal number system.

Repeatedly shifting this byte, 1 position leftward:

Binary System Numeric Value	Decimal System Numeric Value
0000 0001	1
0000 0010	2
0000 0100	4
0000 1000	8
0001 0000	16
0010 0000	32
0100 0000	64
1000 0000	128

If each bit of a 8 bit byte is set, the equivalent maximum decimal numeric value of this is found to be:

11111111b = 255d : = (2^8) - 1 = 255d : 2^8=256d, notice that the exponent of 2 is the number of bits

If 0 binary = 0b = 00000000b = 0d is considered, a byte can actually represent 256 unique, whole values. 2^8 = 256

More about binary numbers to consider:

Given any number (n) of binary digits or "bits", the maximum value it can represent is 2^n -1 in the decimal number system. If just another binary digit is included, the maximum value becomes twice that value less one:
((2)(2^n)) -1 = ((2^1)(2^n)) -1 = 2^(n+1) -1.

Given any number (n) of binary digits, the maximum value is when they are all set to 1, and this value is 2^n -1. If this value is multiplied by itself, it will yield a maximum value of the product of two binary values, such as say two 8 bit bytes shown here: (2^n)(2^n) -1 = (2^n)^2 -1 = 2^(2n) -1 : and this product will require a maximum of (2n) or twice the number of bits to hold that value as shown here:

Ex. With 8 bits = 1 byte numbers: (11111111b)(11111111b) -1 = (256d)(256d) -1 = 256^2 -1 = 65535d is the maximum value. (2^8)(2^8) = 2^(8+8) = 2^((2)(8)) = 2^16 = (256)(256) = 256^2 = 65536. The product of two bytes will require a maximum of (2n) bits, here (2)(8) = 16 bits = 16bits / (8bits / byte) = 2 bytes

NEGATIVE BINARY VALUES

When not explicitly specified, binary values are assumed as being positive values. It is possible to have a system of signed (positive and-or negative) binary values. The usual way to accomplish this is to assign the first or most significant bit as the "sign bit". If the bit is set to, or has the value of 0, the entire binary value is a positive value. If the bit is set to, or has the value of 1, the entire binary value is a positive value. This following discussion about how negative binary values are expressed is generally only for technical, near circuit level, or for computer programmers only, and may be skipped over if the reader does not need it.

Since a bit of the byte is used for the sign, there is now a "trade off" or loss, and that is that the signed binary value can now only have an absolute value of about half of what would normally be possible with that given number of bits in the binary number. For an unsigned 8 bit binary number, the maximum value is 255d:

According to the above discussion, if the first bit is the sign bit:

10000001 = -1
10000010 = -2
11111111 = -127 : 127 is nearly half of 255 which is the decimal value of a full byte where each bit is set to 1.
-127 is the maximum negative value of a 8 bit byte. The maximum positive value of a
8 bit byte is : 01111111 = +127.

Though the above is the practical method to express negative numbers, the actual way a computer does it is slightly different, and it is to encode the negative value using a well defined manner so as it can then be used with the computers (preexisting) addition (or "combine") circuitry and produce the correct result of a signed number addition operation. Essentially then, the (coded) negative value will be considered as an operand in a subtraction operation of which is then performed using the addition circuitry of the computer.

Here is how is a negative value encoded so as to be used by the computers addition circuitry:

11111111b = 255d : maximum value for an 8 bit unsigned binary value

If you were to then add 1 to this binary value, all of the 8 bits will "roll over" (as if on a wheel, such in a cars mechanical mileage counter mechanism) to 0, and the (final) carry will be discarded ("dropped", or "lost" if its unused).

11111111b = 255d
+ 00000001b = + 1d
100000000b 256d if this last or final carry is dropped (unused) we have this value remaining:

00000000b = 0d when the carry bit is dropped.

A decimal system analogy to this would be for example: if given a 4 decimal digit system, when the max. value of 9999d is reached, and if 1 is then added to it, the value of 9999 will "roll over" to all 0's, and the (final) carry is dropped:

111 <--------- carrys from the previous column or digit position. Each carry is a value that is 10 times the previous
9999d weight value.
+ 0001d
10000d = 0000d = 0d when the last or final carry is dropped (unused)

Now consider, given 0000000b, if you were to "go back" one or subtract 1 from this given value of 0bso as to have the previous value before 1 was added to it, the result would be the value just before this "roll over" value of 0, and that value is: 11111111b. You can also consider this verification:

1 00000000b : A 9 bit binary value if the carry was kept, and which will help for any possible borrowing.
\- <u>00000001b</u> : Subtracting 1 to "go back" to the previous value just before rollover to all "zeros" or 0 bits:
11111111b

Now observe how negative binary numbers are usually expressed:

011111111b = +127 : max. signed positive value for an 8 bit binary number, now repeatedly subtracting 1:
.
.
.
00000001b = +4d
00000011b = +3d
00000010b = +2d
00000001b = +1d

00000000b = 0d Repeatedly subtracting 1:

11111111b = -1d : consider that this is the value just before "roll over" when adding 1 to it.
11111110b = -2d : = -1 -1 = -2 : subtracting 1 is the same as adding negative 1
11111101b = -3d
11111100b = -4d
.
.
10000000b = -128 : max. signed negative value for an 8 bit binary number

As a check on this system, consider that when you add (-1) and (+1) the result is 0:

+1d = 00000001b
\+ <u>-1d</u> = + <u>11111111</u>b
0d 100000000b : the carry is once again dropped, and the result is:

= 00000000b : as expected

Because of the way negative binary values are expressed, it also allows the existing electronic addition circuitry of the computer to easily add signed binary values, and the result will be properly signed automatically during the process.

For most computer programmers, it is interesting to know how negative numbers are usually implement within a computer, however there is relatively few times when there is a need for a person to convert these negative value representations to their equivalent decimal value.

A method to convert a negative binary value to its corresponding unsigned or positive equivalent value is to invert or change all the 0 valued bits to 1, and all the 1 valued bits to 0, and then add 1 to the resulting inverted value. A name for an inverted or "flipped" bit or byte is the complement of that bit or byte. Two corresponding complements will sum to 0 when the final carry is unused.

Here is an example that converts a coded or signed binary negative value to its corresponding signed decimal value.

Ex. 11111101b = -3d , with inverted bits:
00000010b, adding 1 to this, we have:
00000011b = +3d

If we know the binary equivalent of 3d, we can do the same as the above process to show the computers binary number representation of -3d:

00000011b = +3d Inverting each bit:
11111100b adding 1:
11111101b = -3d

On a technical or computer programming note, for various reasons and usually other than the concepts of a computers representation of negative binary numbers, each bit of a binary value can be inverted by XORing (with the XOR binary "bitwise" operation; bit by bit, or bit to corresponding bit position) it with a bit set to 1. The resulting value is sometimes called the (ones) complement of the given binary value. An entire 8 bit binary value can also be complemented in just one step by XORing it with an 8 bit binary value with all of its bits set to 1. 255d = 11111111b which has all 8 bits set to 1. Subtracting a binary value by a value with each byte set will also create the complement of that byte value.

Ex. 10000001b XOR 11111111b = 01111110b

The C-computer language also has a special bitwise operator to easily complement all the bits of a byte value, and this uses the "tilde" symbol of (~). If variable (a) was set equal to 1d = 00000001b , then if variable (b) is set equal to the complement of variable (a): b = ~a , then b = ~1d = ~00000001b = 11111110b = 254d when non-signed or unsigned values are only being considered.

The inverse of each bit creates the 1's or binary complement of the value. The sum of a byte value and its 1's complement will result in a sum of 0 with a carry of 1 which can be discarded. The 2's complement of a binary value is equal to the binary complement and add 1 to it. A binary value and its 1's complement will be equal to a value with each bit set. The computers addition circuit can be used to subtract a value by converting the value to be subtracted to its 2's complement value before adding it and discarding the carry. For example, 15d - 5d = 1111b - 0101b = 1010b = 10d this bit by bit subtraction is correct since it is the reverse of addition bit by bit, however, for the computer to utilize the existing addition circuitry to subtract, we must use: 15d + (2's complement of 5d) = 15d + (1's complement of 5d + 1) = 1111b + (1010b + 0001b) = 1111b + 1011b = 1010b = 10d. For another example: 1d - 1d = 0d = 1d + (2's complement of 1d) = 1 + (1's complement of 1d + 1) = 0001b + (1110b + 0001b) = 0001b + 1111b = 0b = 0d when the carry is discarded.

Extra: What is a nibble?

A **nibble** is a play on the word byte (which sounds like bite) which is defined as 8 bits of data and-or 8 bits in width or wide. A nibble is a "small byte" being just 4 bits wide: 0000b = 0d through 1111b = 15d ,and this is a total of 16 possible values (0d to 15d). Since the hexadecimal numbering system has 16 digits and-or counting symbols: (00h = 0d through FFh = 16d), a 4 bit nibble number can be expressed as 1 hexadecimal value, and-vice versa. Ex. 1111b = Fh An 8 bit binary value or byte, can be expressed as two nibbles or two hexadecimal digits. Ex. 11111111b = 1111 1111 = FFh , Ex. 10100010b = 1010 0010 = A2h

FRACTIONAL BINARY VALUES

The concepts of expressing fractional (<1) binary values is nearly identical to that of expressing fractional decimal values, except that for the binary system which is based on 2, will use negative integer powers of 2 instead of negative integer powers of 10 as it is for the decimal number system. Here are the binary weights and their equivalent decimal equivalents, and note for example that 2^-1d = 1/2d = 0.5d , that is a negative indicated power is equivalent the reciprocal of the corresponding positive indicated power. Here are the decimal equivalents of the bit positions of a binary number:

2^7 , 2^6 , 2^5 , 2^4 , 2^3 , 2^2 , 2^1 , 2^0 . 2^-1 , 2^-2 , 2^-3 , 2^-4 , 2^-5 , 2^-6
128 , 64 , 32 , 16 , 8 , 4 , 2 , 1 . 0.5 , 0.250 , 0.125 , 0.0625 , 0.03125 , 0.015625

Notice that going from left to right, or from the most significant weights to the least significant weights, that each is half of the previous. Going in the other direction, each is double (2 times, twice) the previous.

Convert 1.1b and 1.01b to their corresponding decimal equivalent value and representation:

Showing many intermediary steps:

1.1b = 1(2^0)d + 1(2^-1)d = 1d + (1/2^1)d = 1d + 0.5d = 1.5d

1.01b = 1(2^0)d + 0(2^-1)d + 1(2^-2)d = 1d + 0(1/2^1)d + 1(1/2^2)1d = 1d + 0(1/2)d + 1(1/4)d =
= 1d + 0(0.5)d + 1(0.25)d =
= 1d + 0.0d + 0.25d
= 1.25d

To convert a binary value that has a both a whole part and a fractional part, simply convert the whole part and then the fractional part to their corresponding and equivalent decimal values, and place the (.) symbol between them. This same method can be used to convert a decimal value to its corresponding and equivalent binary value.

How To Make A Random Number Using The Concepts Of Binary Numbers

Use a two-sided object such as a coin. You can label or consider one side as 0 and the other side as 1. Flip it into the air and see what side lands upward. You can write this value down onto paper. Repeat the process to create as many binary digits or bit-positions as needed. You would usually then convert this binary value to its equivalent decimal value.

If your tying to create a random number between a certain range of numbers, you will have to use a certain minimum number of bits to create that value:

bits	binary	decimal
1	1	1
2	11	3
3	111	7
4	1111	15
5	11111	31
6	111111	63
7	1111111	127
8	11111111	255

Each next value will be: (2 x current value)+1 :

Ex. To create a random decimal number between 0 and 100, we will need a binary value composed of 7 binary digits, or bits.

A set of 7 randomly created binary bit values are:

0100101b after converting this to its equivalent decimal notation value:

0100101b = 37d

If the random number generated was greater than 100, you can redo the process.

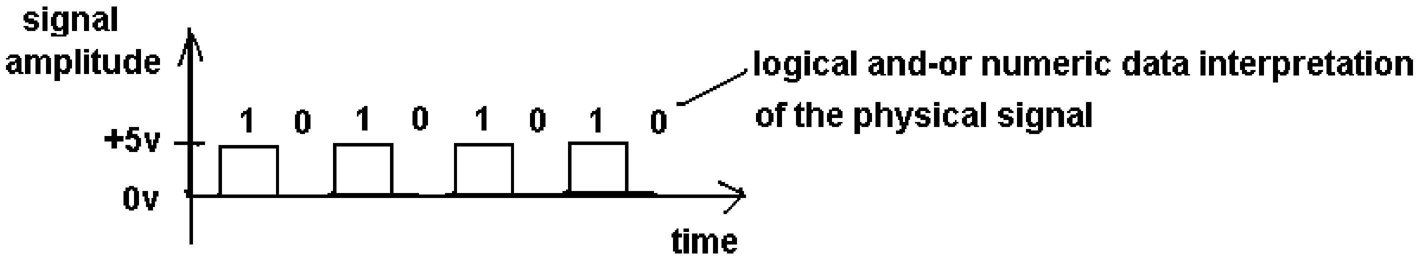
If you only want to consider only decimal values when creating or generating a random number, you can put numbers 0 through 9 on similar objects, such as paper or balls into a bag and pick out a ball to create a digit for a random number. If you do not put each randomly chosen ball back into the bag after recording its value, that value will not be available and possible for the next digit in the random number. If this is the case, and If you took out 3 balls, the minimum random number generated or possible would be 012, and the maximum random number would be 987. If you want to give each digit the same chance or possibility of having a value of 0 through 9, then you must put the ball back into the bag to have all the balls available for the next random selection.

This book includes a computer program to create random values, that can be viewed, searched, saved and loaded into a computer file.

The **Morse Code** system of "dots and dashes" is actually a simple and efficient binary or two-state(s) of information system. Two different signals are used to represent each smallest bit of information such as the coded series used for each letter. A series or more of these pieces of information can be used to construct a letter, and many can then be used to construct a sentence of a message. Consider graphing paper with many horizontal and vertical lines creating many uniform (ie., similar to) and regularly spaced small squares, boxes, or picture elements (tiny "bits" or "pieces" of, "**pixels**" = "picture elements") on that paper. Each box can be set to be either one of two states, either filled with a color or left empty. Each box can be a pixel element of an entire two color or black and white picture such as seen in some books and newspapers. The more pixels, the finer or more detailed an image can be, and this "fineness" or "image precision" is given a measurement called its image resolution which can be summarized here as pixels per distance on the photo. We can communicate this image by letting number 1 mean to fill a box, and 0 to keep it unfilled. A longer binary number say for example: 10101010 might numerically represent the upper row of a text character (ie., the image of a letter) or a picture being drawn. We see that a binary, two state system and-or numbers is the simplest way to represent information, and it can be transmitted as very fast electronic pulses through a wire of an electric circuit, including the telegraph or radio communication system. It should be also of note that each letter and-or text character is usually given a unique 8 bit code or binary number such as with the ASCII code system. A computerized, "8 by 8, dot-matrix" printer will effectively have in its memory storage a matrix or array of picture elements for each ASCII text character to be printed, say printed or displayed using 8 horizontal bits in each of 8 rows. Each row of pixel element information can be stored as if it is an 8-bit binary number or information. A pixel of an image is also the smallest discernible or resolvable (ie., resolution) piece of an image.

With binary picture elements being either 1 or 0, how can colors or gray scales be used since we can not have half a bit of information and we can only have "full bits", each with just two possible states only? The answer for example would be to use a binary number coded (gray or "color intensity") scale of values. We can create a 256 shades of gray using an 8 bit binary number. We can let 00000000b represent no gray in the box, hence clear or white, and 11111111b represent full black. Values in between 0 and 255 will represent a particular shade of gray, say increasing in darkness as the binary value increases. This system can display what is called a "black and white" picture, but the image or picture is technically seen as a "**gray scale**" picture that has been printed with just one available color, usually black. Now that an image can become better and-or more accurate or representative, we see that more information must be used, and here we see that each picture element now requires 8 bits now instead of just 1 bit. The entire image will require 8 times the information or data and its storage, and 8 times longer to transmit it.

As mentioned previously, 1's and 0's are numeric and-or logic values, that can be thought of as either a signal or presence, and a lack of signal or presence. For example the signal or presence can be a voltage value say +5 volts to represent a "high" or 1 value, and 0 volts to represent a "low" or 0 value. The signal could be a charge storage or lack of it such as in a capacitor, or it could be a magnetized spot or location on a metallic hard-disk drive, or it could be a transistor setting considered either on or off. Here is a basic graphical image of 1's and 0's such as that which could also be visualized using an electronic oscilloscope that can display a visualization of a signal and-or waveform: [FIG 208]



When a computer program receives and senses 8 bits of data at its communication port or input, it will convert this to a byte of binary data that the computer can store it in a file and-or process it further, such as displaying it as a text character on the screen.

CHANCE

If given a certain range of values from say 0 to 99, hence one-hundred known and unique values, and when you randomly ("blindly", non-specifically) pick or choose just one of those values, that value chosen is then called a random value. If you were hoping that the value was a specific or certain valued number between the given range, this is a concept of the larger topic of "chance", "odds" or "probability". If the range was smaller, say from 0 to 9, you will have a higher chance or success, on average after many attempts of picking a certain value. As the range increases, say from 0 to 999, you will have a lower chance or success, on average, of picking a certain value randomly.

The word probability is related to the word "probable" and the concept of something that is likely to, or may happen. It should be fairly obvious that the more digits a number has, the larger in value or numerically it is, and the more difficult to guess, select or pick a certain valued number among that complete set of many possible random values from 0 up to the maximum number that all those digits could represent. There is a higher chance, success or probability of you selecting a 1 digit number out of 10 numbers: 0 to 9, than there is of selecting a 2 digit number out of 100 numbers: 0 to 99.

Ex. A 3 digit decimal (each digit being a one value from 0 to 9) number can represent any value, or random-like value, from 000 to 999. That is a total of 1,000 = 10^3 possible values. For the probability or numerically predicted average of 1,000 guesses or chances (but could actually be more or less guesses in reality and current luck), and to have the 1 correct guess of a random value in that range is 1 in 1000 = 1/1000 = 0.001 , hence a fairly low probability, and commonly said to be as a "low or small chance(s)", and-or "a low probability", and-or "low odds".

Digits	Total Possible Values Or "Combinations"	Chances of picking a certain value, expressed mathematically.
1	10 , 0 through 9	1 in 10 = 1/10 = 0.1 : "one in ten" , "one out of ten" , "a tenth"
2	100 , 0 through 99	1 in 100 = 1/100 = 0.01 This could also be thought of as since each digit has a 1 in 10 chance, the new or total chance becomes less, and now becomes equal to only a fraction of a fraction, and the new net result or chance is equivalent to the product of the chances, odds or probabilities of each new chance, step or digit: Even if the first digit is right, there is still only a 1 in 10 chance that the next, or second, digit is right. The "combined chances" of each digit can be expressed as one new total chance equal to their product: $(1/10) / 10 = 1/100 = (1/10)(1/10) = (0.1)(0.1) = 0.01$ "a tenth of a tenth" = "a hundredth" = "one in a hundred"
3	1,000 , 0 through 999	1 in 1,000 = 1/1,000 = 0.001
4	10,000 , 0 through 9,999	1 in 10,000 = 1/10,000 = 0.0001

The **probability** of an event or outcome happening and being considered a successful (calculated) prediction can be numerically expressed as the ratio of it happening (success) to the total number of possible events or outcomes:

$$\textbf{probability}\text{ of event happening} = \frac{\text{total number of favorable events or outcomes happening}}{\text{total possible events or outcomes}}$$

Since the numerator is always less than the denominator in a probability ratio, the ratio value will be between 0 and 1.

If there is a set of 10 values labeled from 0 through 9 in a bag, and if only one is being picked out from, the probability of each different number, or picking a certain number, is: 1/10 = 0.1 : "one in ten" = 1 in 10 = 1 out of 10

If a second set of the same 10 values: 0 to 9 was initially combined into the first set of 10 values, the probability of each different number, or picking a certain number, is: 2/20 = 1/10 = 0.1 , hence the same probability as before

If an event or outcome is 10% probable, then it could be said that it is (100% - 10%) = 90% "not likely" or "not probable":

"odds" of something happening = "probability" odds $= \dfrac{\text{probable}}{\text{not probable}}$, ex: $\dfrac{10\%}{90\%} = \dfrac{0.1}{0.9} = 0.1111 = 11.11\%$

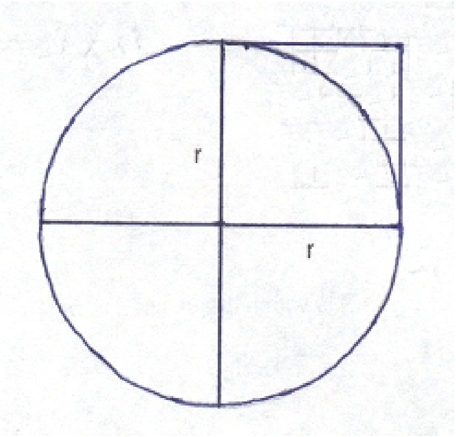
SCIENCE AND APPENDIX SECTION

This book section contains some helpful derivations of the formulas previously mentioned in this book, and it was initially written for the initial basic math, algebra, trigonometry, and advanced topics sections of this book before the science topics were placed in it. This section also contains other useful supplemental material and it is therefore a mix of topics, and yet it could still be considered as a natural continuation or extension of much of the previous material in this book.

A DERIVATION OF PI, AREA AND CIRCUMFERENCE OF A CIRCLE

Below is a drawing of a circle and in the upper right quadrant, a square is overlaid whose side is equal to the radius length of the circle. The area of the this square is therefore: As = (r)(r) = r^2. [FIG 209]
If you were to draw or imagine an identical square in each of the remaining three quadrants, the area of the circle (Ac) would be clearly seen to be less than that of the total area of those four squares:



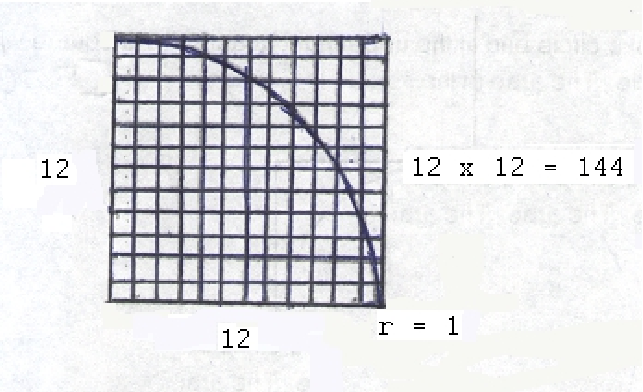
Below is a drawing of a circle and in the upper right quadrant, a square is overlaid whose side is equal to the radius length of the circle. The area of the this square is therefore: As = (r)(r) = r^2. If you were to draw or imagine an identical square in each of the remaining three quadrants, the area of the circle (Ac) would be clearly seen to be less than that of the total area of those four squares:

Ac < r^2 + r^2 + r^2 + r^2 combining like terms:
Ac < 4 r^2 : Each side of this larger square is 2r, hence its area is: (2r)^2 = 4r^2

Comparing the (smaller) area of the circle to the larger square area of 4r^2, we find that the coefficient of r^2, which is 4, effectively causes that square area to be slightly more than that of the circle. If were to then write an equation for the area of the circle, a value less than 4 would be the proper numerical coefficient of r^2. We can set a variable (n) equal to the actual or proper numerical coefficient of r^2 so as to have an equation that represents the exact value of the circle = Ac:

Ac = n r^2 : n < 4

All sorts of geometric methods can be used to find a formula for the area of circle. Most divide the circle into smaller areas, such as a large number similar triangles all having the same vertex at the center, and then these are summed to find a close approximation of the area of a circle. Perhaps the simplest method is to divide the square (shown in the upper right quadrant) up into many small identical squares or square units, and the more used, the better the approximation of the area of the circle will be. More squares can also be drawn by starting with a large drawing of the square and quadrant of the circle so as to have a closer approximation for Ac. For example: [FIG 210]



Obviously, in the figure directly above, the portion of the area of the circle that is within the square (ie. a quadrant, or quarter of the circle) is only some fraction (or percentage) of that square's area. The area of this portion of the circle is less than 1 r^2, but greater than half of it or $r^2/2 = 0.5\ r^2$, as can be seen by drawing a diagonal line from the upper-left to the lower-right corner in the drawing above. Letting variable (x) represent this portion, we algebraically get:

$Ac = xr^2 + xr^2 + xr^2 + xr^2$: $x<1$, combining like terms:
$Ac = 4 \times r^2$: Since $x<1$, therefore for Ac, the actual numerical coefficient (n) of r^2 is a fraction of this value of 4, and can be expressed as $n<4$:
$Ac = nr^2$: where $(n<4)$

(x) can be calculated from:

$$x = \frac{\text{Area of the circle portion in the square}}{\text{Area of the square}} = \frac{Aq}{As}$$: x is a ratio, Aq = area of a quadrant of the circle

Using the above graph, x can be geometrically (approximately) calculated without using a specialized formula as:

$$x = \frac{Aq}{As} \approx \frac{\text{number of small squares within the circle's portion of the square}}{\text{total number of small squares in the square}}$$

This ratio value can also be quickly estimated by observation. Obviously, the area of the circle that is within the square is clearly greater than 1/2 = 50% of the square (can check this by drawing a diagonal within the square from upper-left to lower-right), and less than 1 = 100% of the square. It appears to be a value about midway between these two values, and this is three-quarters of the square = 3/4 = 0.75 = 75%. Taking the average of these two values we have:

$$x = \frac{50\% + 100\%}{2} = \frac{150\%}{2} = 75\% = 0.75 \text{ in decimal form}$$

Substituting this value of (x) into Ac:

$Ac = nr^2 < 4 \times r^2$
$Ac = nr^2 \approx 4\,(0.75)\,r^2$
$Ac = nr^2 \approx 3\,r^2$: approximation, and this is similar to the approximation of the length of a circles circumference being about 3 times its diameter length.

If you solve for (x) by the geometric methods, you will see that this ratio value is slightly greater than 0.75 and therefore, the numerical coefficient (3) of r^2 shown is slightly lower than it should be. For a simple example, using the drawing shown and considering a small square in the circle's portion if half or more of it is within the circle's portion:

$$x = \frac{\underline{\text{number of small squares within circle's portion of the square}}}{\text{total number of small squares in the square}} = \frac{\underline{110}}{144} = 0.764$$

We find that this calculated value or estimation is slightly more than 0.75 , and is actually: 0.785398163 ... =~ $0.785\underline{4}$

Adjusting the formula, we have:

$Ac = nr^2 = (3 + c)\ r^2$: c = a slight adjustment or correction. $0<c<1$ since the coefficient of r^2 was shown to be less than 4. This means (c) is both greater than 0 and less than 1. Here, (c) is a constant and not a variable.

Verse 4:2 in the Second Book Of Chronicles in the (about 4000 year old) Old Testament book gives the first written indications that the circumference of a circle is 3 times greater than the diameter (widest) length of the circle. Today, the exact value of the constant $n = (3 + c)$ is formally called and identified as the constant of: "Pi" , and is also given the symbol of: π, but this may be also noted as using just common text characters as (Pi) if the (π) symbol is not available to be displayed.

$n = \pi = (3 + c)$: Pi is slightly greater than 3

$Ac = \pi r^2$: AREA OF A CIRCLE , (π = "pi" =~ 3.14159265...)

If you estimated (x) as 0.78 , PI = π can be expressed with three significant digits:

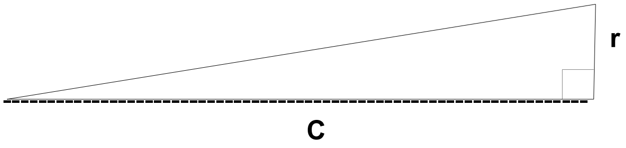
$\pi = 4x \sim= 4\,(0.78) = 3.12 = (3 + 0.12)$: 3.12 has 2 correct significant digits; the 3 and the 1

If you again estimated (x) as 0.785, π can be expressed with three significant digits, and with the two most significant being shown to be accurate when compared to the above value. All three digits shown below for (x) are accurate.

$\pi = 4x \sim= 4\,(0.785) = 3.14 = (3 + 0.14)$: 3.14 is the common approximation of Pi which is given the π symbol.

$Ac = 4x\, r^2 = \pi r^2 =\sim 3.14\, r^2$: formula for the area of a circle, and the approximate area of a circle

Now, let's try to find a formula for the circumference of a circle by using the formula for the area of a circle. Since circumference is a linear (as in a distance, one-dimensional) concept, let's convert the area value that represents the circular shape into an equivalent value of area that is represented by a triangular shape. As shown previously in this book, the area of a circle can be conceived and represented as the area of a triangle whose base is equal to the circumference (C) of the circle and whose height is equal to the radius (r) of the circle: [FIG 211]



Equating the area of a circle to that of this representative triangle:

$At = Ac$: $At = \dfrac{(\text{base})(\text{height})}{2}$ using substitution:

$At = (\text{base})\,(\text{height}) / 2 = Ac = (\text{pi})\, r^2$: set equivalent for this analysis only since the basic formulas for these area shapes are different, but it is sill possible to have a triangle and circle having the same exact area.

$\frac{C\,r}{2} = \pi r^2$: **AREA OF A CIRCLE** , r = radius of the circle = half the circles diameter (d or D).
r = distance from center point of the circle to its (curved-line) edge or circumference (C).

Solving for C:

$C = \frac{2\pi r^2}{r}$ canceling or dividing out common factors, here it's r^1:

$C = 2\pi r$: **CIRCUMFERENCE OF A CIRCLE**

Since 2r = D: : D = diameter = longest length, or width, across ("dia-") or through and measurement ("meter") of the circle. r = D / 2 , D / r = 2 ,

$C = \pi D$: hence, the circumference of a circle is about 3.14 times larger or longer than its diameter.

$\pi = \frac{C}{D}$: **"pi" = π** , is usually defined as the (constant) ratio of any circles circumference to its diameter
(pi) =~ 3.13159265... , $r = C / 2\pi = C / 6.283\underline{2}$... , $C / r = 2\pi = 6.2832$...

We could have found π if we knew before-hand that it was equal to the circumference of a circle divided by its corresponding diameter. Logically, or "truly", Pi is mathematically expressed as, and equal to exactly: C/D, however the value of Pi calculated by any means possible will always be an approximation no matter how "close" it is to the true value of C/D. Because of this, the value of Pi is said to be an irrational value or number. With the calculation of π using small squares as shown previously, the result will always an approximation. With advanced mathematical formulas, π can be calculated to a great and accurate precision ("preciseness", fineness, fraction) but it is still an approximation since Pi will always be an irrational value with endless digits.

It is not easy to measure the circumference of a circle using a typical and inflexible ruler. One method to measure the circumference of a circle is to mark a point on the circumference of the circle where it is tangent (ie. coincides, touches) to a flat surface, and also mark a corresponding point on the flat surface. Roll the circle along a straight, line-like path on that flat surface for one complete rotation and then mark another point on that flat surface where the point on its circumference is again tangent to the flat surface. The measure of this distance between these two points on that flat surface will equal the circumference (distance is equivalent to corresponding "straight" linear distance when "flattened") of that circle.

If the concept of Pi is already known, a basic verification to the above derivation(s) can be made by considering a more well known derivation for the area of a circle, and that is to divide the circle into an infinite number of similar isosceles triangles that have the same height and base side values. The height of each triangle will be equal to the radius (r) of that circle, and the base side of each triangle will be an infinitely small segment portion of the circumference. As the number of triangles gets larger in value, the base side of each will approach a value of 0, but will never actually be zero. Ac = (area of the sum of each triangle), and since all the triangles are the same, their areas are the same, and the circle area can then be expressed with multiplication of the area of just one similar triangle by the total number (n)of triangles. Ac=n(area of triangle). one might quickly say that the area of that circle will be infinite if the number of triangles to be summed is infinite, and this is a good thought, but we must also consider that the area of each triangle is infinitely small in value or close to 0. A practical version of this derivation is to then construct a rectangle from all these triangles by alternately placing upside-down next to each other in a row. The area of this rectangle construction will be:
Ar = (length)(width), and where the (length) = (circumference / 2), and (width) = (r). Ar = (length) (width) = (2(pi)r / 2) (r) = (pi) r^2 = Ac

A **disk** is a flat-like volume much like a circle but also having a thickness, hence 3-dimensional) structure that has circular shaped area, and its surface area on the top or bottom is equal to that of a circle (ie., two dimensional): Adisk = Acircle = (pi)r^2. A coin has a disk structure or shape, and technically, a disk is also a **cylinder shape** that has a low height compared to its width, radius and- or diameter.

If a two-dimensional (hollow) circle or (solid, filled circle) disk is moved a height upward, into another or the third dimension, it will create a three-dimensional volume called a (hollow, empty, non-solid) tube or cylinder, or solid tube or cylinder which is sometimes called a rod. The volume of this construction is simply the product of the two dimensional circle or disk area, often called the base area, times the distance or length that it was moved along the third dimension or "axis".

The formula for a cylinder is very similar to the formula of a cube shape which is the base area times the height that the base area is moved vertically: Vcube = (base area) x (height). and for a cube, the base area is that of a square, hence base area = s^2, and since the height is also equal to (s), Vcube = (s^2)(s^1) = Vcube = s^3. Other (rectangular solid, prism) volumes have a rectangular base areas and various heights, but the formula is still the same:

V = (base area) x (height).

Vcylinder = (circular base area) x (height) and:

Vcylinder = (Acircle) x (height) = ((pi)r^2) h = **(pi) r^2 h** **: VOLUME OF A TUBE, CYLINDER, OR ROD**
A rod is a long and solid cylinder construction.

A **tube** (ie., usually a flexible pipe, like a garden watering hose) or **pipe** is essentially a hollow cylinder shape and having an outer surface or wall having a thickness to it, and therefore, there is an inner and outer diameter to consider in your calculations:

outer diameter = inner diameter + wall thickness
inner diameter = outer diameter - wall thickness
wall thickness = outer diameter - inner diameter :cross sectional wall area = cross sectional area of the cylinder if it were solid - cross sectional area of the hollow region

As indicated previously, the formula above is very similar to that derived when moving a square area along a third dimension so as to construct a volume called a rectangular prism. The word "prism" is a fancy word for an object having plane (flat, planar) shaped sides or "faces". A solid rectangular prism is also called a block. A hollow rectangular prism is called a box. A cube is a rectangular prism with all dimensions or sides having equal lengths. If all the side lengths are 1 unit in length, it is called a cubic unit or cubic unit of (volume) reference or measurement for any other volume.

V rectangular prism = (V rectangle) x (height moved) = (LW)H = **LWH** **: VOLUME OF A RECTANGULAR PRISM, BLOCK, OR BOX**

Or:

V rectangular prism = (rectangular base area) x (height moved) = (base area)(height) = LWH
In your calculations, be sure to consider or take account of any wall thicknesses, for this will reduce its holding capacity or volume of some material placed into it.

A triangle shape or surface moved a height will create a volume called a triangular prism.

$$V_{\text{triangular prism}} = (\text{base area})(\text{height}) = \left(\frac{bh}{2}\right)\left(\frac{h}{1}\right) = \frac{bh^2}{2}$$

: VOLUME OF A TRIANGLULAR PRISM

A pyramid is a polygonal (flat, multi-straight sided) shape or volume that diminishes (gets smaller, reduces) to a single point (called the apex) at a height above it. The formula for the volume of a triangular pyramid or cone is:

$$V = \frac{(\text{base area})(\text{height})}{3}$$

: VOLUME OF A PYRAMID OR CONE
= 1/3 VOLUME OF ITS CORRESPONDING, OUTER CYLINDER

This formula for the volume (Vp) of a pyramid can be verified by using the volume of a cube. A cube has 6 sides that we can consider as base areas of internal pyramids. We can construct 6 internal pyramids within that cube with each having its apex at the center point of this cube. Therefore, the volume of each pyramid is 1/6 that of volume of that cube (Vc):

$$Vp = \frac{Vc}{6} = \frac{LWH}{6} = \frac{(\text{base area of each pyramid})\ H}{6}$$

: Vc = volume of cube, Vp = volume of pyramid.
base area of each pyramid = area of each side of cube
