The height of each pyramid is only half of that of the cube. h = H/2. Therefore, we cannot use just H in the formula for the volume of each internal pyramid. We can create an equivalent fraction by dividing both the numerator and denominator by 2:

$$Vp = \frac{\dfrac{(\text{base area of each pyramid})\ H}{2}}{\dfrac{6}{2}}$$

Expressing (H/2) as the height of the internal pyramid:

$$Vp = \frac{(\text{base area of pyramid})(\text{height of pyramid})}{3}$$

:**VOLUME OF A PYRAMID OR CONE**

This formula also works for the volume of a cone since it can be considered as a unique pyramid with an infinite number of very thin (approaching 0 in width) sides extending up from its polygon base area. The word "cone" is rooted in the word of "point", "combine" and "concentric" which means all having the same center or point of reference. A cone can also be thought of as an infinite number of concentric circles or disks that get smaller and smaller until the radius is just the size of a point. The rate at which the diameters or radius get smaller and smaller as the height or base value changes (ie., increases) will determine the specific shape (ie., side slant or "slope") of that cone.

For the surface area of a cylinder or rod shape, imagine taking the curved surface area portion of a cylinder or rod and making a straight cut along its length, and then flattening that surface into a rectangle plane shape.

A = lateral or side area of the rod + circular area at both ends of the rod
A = area of curved portion + circular area of both ends

A = area of rectangle created from the curved portion + area of both circles at the ends

$A = (\text{length})\ (\text{height}) + 2(\text{pi})(r^2)$: r = d/2 = (outer width or thickness of the cylinder or rod) / 2

The height (h) of this rectangle corresponds to that of the circumference (c) of the cylinder or rod:

$A = (\text{length})\ (2)(\text{pi})(r) + 2(\text{pi})(r^2)$ factoring $2(\text{pi})r$ from each term:

$A = (2)(\text{pi})(r)\ (\text{length} + r)$

$A = (c)\ (l + r)$: SURFACE AREA OF A CYLINDER OR ROD SHAPE
c = circumference of cylinder or rod , r = radius
l = length of the rectangle = height or length of the cylinder or rod

If a regular, circular or right (created by rotating a rectangle [having right or 90° angle sides] about its side) cylinder is cut at an angle which is not perpendicular (90°) to its axis and-or sides, it will produce a cross-sectional shape and-or surface area of an ellipse, and a cylinder with this constant cross sectional shape is called an **elliptical cylinder**. The full or longest length of the diagonal cut will be the major-axis (a) of the ellipse, and twice the radius of the cylinder with be the minor-axis (b).

SURFACE AREA OF A CONE

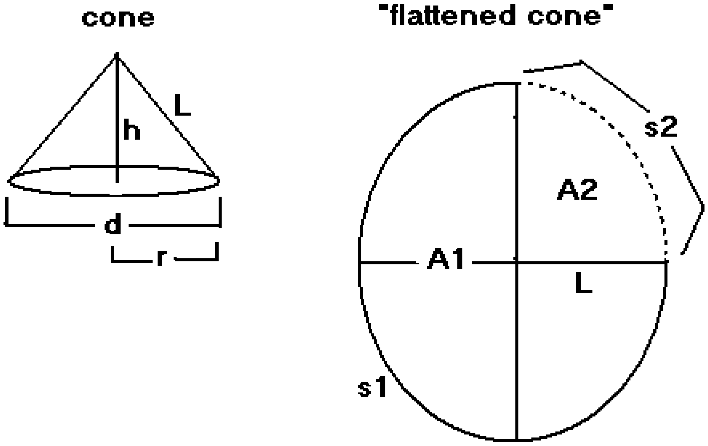
When a two-dimensional right triangle is rotated about one of its "leg" sides, a three-dimensional cone shape is created. For the surface area of a (right) cone shape:

A = surface area of the (lateral or side, "pointy part" of the) cone shape + area of the base or flat side of the cone

The length or height of the cone, and the radius of the base are the major factors for both the surface area and volume of a cone. The length of the lateral side of the cone can be found from the Pythagorean Theorem:

lateral side or "slant" length of a cone = L = $\sqrt{r^2 + h^2}$: r = radius of base of cone , h = height of cone
r = (diameter of base of cone) / 2
L is essentially a hypotenuse length

If you were to cut the side straight, unfold, expand, "roll-out" or "flatten" a hollow cone shape or surface area, it would look like a circle with a triangular-like portion or sector of it missing as shown below as sector A2: [FIG 212]



The area of the circle segment that is actually there is equal to the area of the lateral surface area of the cone. The "slant" length (s or L) is equal to the radius of this created circle, and is generally not equal to the radius of the base of the cone. The length of the circumference that is actually there is equal to the circumference of the base of the cone. The length of the circumference (Ct) of the entire possible circumference including the portion of the circumference of the missing sector, is equal to:

Ct = 2(pi) r = 2(pi)L = s1 + s2 , s1 = arc length 1 and it corresponds to the circumference of the base of the cone. s2 is the arc length of the circles segment area not present.

At = (pi)r ^2 = (pi)L^2 = A1 + A2 : At = total area of this circle created from the "flattened" cone.
: A1 = corresponding area of the lateral surface of the cone
: A2 = sector area created that was not part of the cones lateral surface area.

The figure in the particular example above clearly shows that a quarter (here A2) of the circle is not present, and it will help verify that the ratio or fraction of the arc length (s2) to the circumference (C = St, total sector length in a circle) of the circle, is equal to the ratio of the corresponding sector area (A2) to that of the total area of the circle (Ac = At = A1 + A2). Clearly, s2 is a quarter ("one-fourth" = 1/4) of the circle's circumference (Ct), and A2 = As = sector area is a quarter of the circle's area (At). The angle the arc length suspends or corresponds to is also 1/4 of the total angle of a circle which is 360° Expressing this, we have:

s2 = C / 4 = 0.25C and A2 = Ac / 4 = 0.25At and C / s2 = 1/4 = 0.25 and sector ¢ = **¢s** = 360° (C / s)

$S2 / C = 0.25$ and $A2 / A c = 0.25$ and $\frac{s\text{¢}^\circ}{360^\circ} = \frac{s}{C} = \frac{As}{Ac}$ **: equivalent fractions of a circle when considering sectors of it**

* Extra: $s2 / A2 = 0.25Ct / 0.25At = C / At$: the ratio of the arc length of a (area) sector, to the corresponding area of that sector, is equal to the same ratio of the circumference and corresponding total area of the circle. The circumference of a circle is also the largest arc length of a circle. Technically these types of fractions are incorrect due to that the units are different in the numerator and denominator, and therefore are not a proper fraction in terms of units, however it is algebraically correct. **This ratio is also not a constant:**
$C / A = 2 (\pi)r / (\pi) r^2 = 2 / r = 1 / 0.5r =$ and therefore, this type of ratio value depends on the value of the radius (r). As the value of (r) increases, this ratio then decreases in value.

When the ratio of s1 and A1 are also considered:

$\frac{s2}{A2} = \frac{s1}{A1}$ mathematically: $\frac{s1}{s2} = \frac{A1}{A2}$: the ratio of are lengths of a sector of a circle is equal to the corresponding ratio of their sector areas

$A1 = (s1 / s2) A2$: sector area A1, this is the cones lateral (or "side") surface area.
$A2 = (s2 / s1) A1$: sector area A2

Expressing the above (*) into a more generalized formula:

From: $s2 / A2 = C / At$: At = total area of a circle = Ac, mathematically:
: C = circumference can be thought of as total arc length in a circle = St

$$\frac{\textbf{arc length of circle segment}}{\textbf{circumference of circle}} = \frac{\textbf{area of circle segment}}{\textbf{area of the circle}} = \frac{s2}{C} = \frac{A2}{At} = \frac{\textbf{sector angle}^\circ}{360^\circ}$$

We find that the ratios of arc lengths (s) is equal to the ratio of their corresponding sector areas (As). Arc lengths and sector areas are proportional. From these equations, other helpful equations can be derived:

$s2/A2 = C/At$ and: $As / Ac = \text{¢}s / 360^\circ$: As = sector area , Ac = At , ¢s = sector angle
$As = Ac (\text{¢}s / 360^\circ)$

$A2 = (s2/C) At$: A2 is a sector area of a circle , and in general for any circle where Ac = At :

sector area = $As = (s / C) Ac$: As = sector area and s = arc length of the corresponding sector area,
Ac = total area of the circle , C = circumference or arc length of the entire circle.
Extra: **$As = Ac (s\text{¢} / 360^\circ)$**

or=: $As = s (Ac / C)$, substituting the known formulas for these variables:

sector area = As $= s (((\pi)r^2) / ((2)(\pi)(r))) = s (r / 2) = s$ **$r / 2$, $s = 2 As / r$**

sector area $= \frac{s\, r}{2}$: **SECTOR AREA OF A CIRCLE** , with units of a square unit of the length units used.
(r) = radius of the circle , s = S = arc length of the sector area
Another derivation here that is easy to remember is: **$s\, r = 2As$**

As a check on this formula, if the arc length (s) is equal to the circumference C):

sector area = $\frac{C\, r}{2} = \frac{2(\pi)\, r\, r}{2} = (\pi) r^2$: as expected since the corresponding sector area is that of the entire circle

When using radian angles: s = ¢r , then: **sector area** = s r / 2 = (¢r) r / 2 = **¢r^ / 2** **: ¢ in radians**

Continuing onward with the area of a cone discussion:

The radius (R) of this circle created from the "flattened" cone is equal to the slant length (L) of that cone:

R = L = $\sqrt{\text{(height of cone)^2 + (radius of cone base)^2}}$: **length of the slant length of a cone**

The circumference of this complete circle is equal to: C = 2(pi)R = 2(pi)L

arc length s1 = circumference of the base of the cone = 2(pi)(r)
arc length s2 = circumference of the complete circle - s1 = 2(pi)L - 2(pi)r = 2(pi) (L - r)

The total area of this circle is equal to: At = (pi)R^2 = (pi)L^2

The total area of this circle minus the segment portion missing is equal to the lateral surface area of the cone:

Acone = (Acircle - Asegment missing)

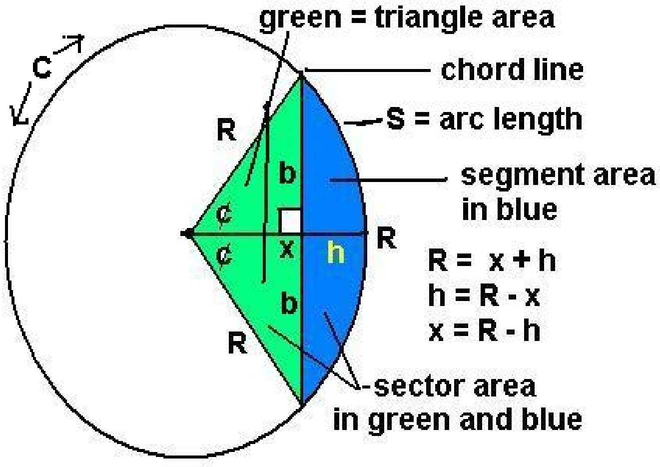
By now knowing the concepts of equal ratios for segment areas and arc-lengths, and observing the above figure:

$\frac{s1}{A1} = \frac{Ct}{At}$: A1 = lateral or side surface area of the cone, and mathematically:

$\frac{s1}{Ct} = \frac{A1}{At}$, mathematically:

A1 = $\left(\frac{s1}{Ct}\right)$ At = $\frac{2(pi)r}{2(pi)L}$ (pi)L^2 = **(pi)(r)(L)** **:(Lateral) SURFACE AREA OF A CONE**
L="slant length", r = radius of the base circle.
The base area is: (pi)(r^2)

Extra: A **segment area of a circle** is the area between the chord and the circumference arc of that circle. The area of this circle segment, or segment area part of the circle is the sector area defined by the chords endpoints on the circle, and the inner equal-lateral triangle created with its vertex at the center of the circle and whose base side is that chord. The segment area is a smaller part of the total sector area minus the area of the isosceles triangle which is basically two identical right triangles connected . [FIG 212B]



sin ¢ = opp. / hyp = b / R , b = R sin ¢
2b = chord length = 2R sin ¢

tan ¢ = opp. / adj. = b / x
x = R cos ¢ = b / tan ¢

Atriangle = (base)(height) / 2 = (2b)(x) / 2 = bx
= (chord length) (x) / 2

As/Ac = ¢s/360° , As = Sector area = (Ac) (¢/360) =
As = (pi) R^2 (¢/360°)

Sector Area = Triangle Area + Segment Area

S / C = ¢ / 360 , S = C (¢ / 360) = (2)(pi)(R) (¢ / 360)

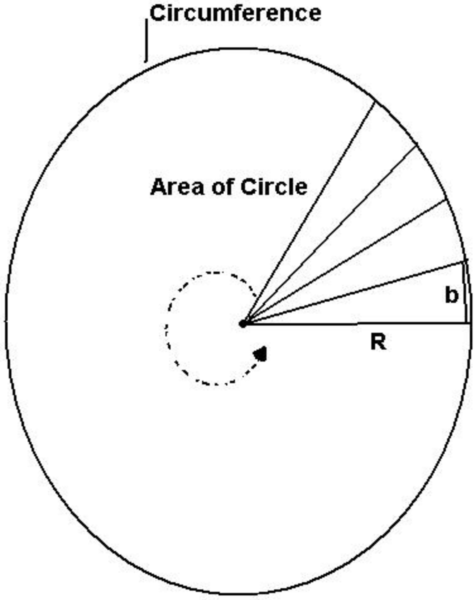
With respect to the central angle, S=arc length and sector area are linear, however, segment area and the isosceles

triangle area are not even though these two values always sum up to the sector area. From the above equations:
Segment Area = Sector Area - Triangle Area

TRIANGLE SEGMENT METHOD TO DERIVE FORMULAS FOR CIRCUMFERENCE, PI AND AREA OF A CIRCLE

Since all circles are similar, and-or are essentially just magnifications of each other, this analysis considers any circle of any size, and the value of (Pi) will always be the same result. (Pi) is therefore a constant for each circle.

Given a circle, you can divide its area into many triangular segment areas with each being the same area (At) and each having its vertex at the center of that circle, and its base (b) along the circumference (C) of that circle. When the number (N) of triangles is large, the base (b) of that triangle gets smaller and approaches (nearly becomes equal to in value) that of a straight line segment, the height of the triangle approaches R, and the triangle shape and area approaches that of a right triangle (however more exactly, it is an isosceles triangle which can be considered as two right triangles connected - hence an automatic doubling of the right triangles considered), and the area between the chord line (b, the triangle base) and the corresponding arc on the circumference becomes negligible. The arc length will approach the value of (b).
(Pi) = C / D = C / (2R) for any circle. [FIG 212C]



$C = b1 + b2 + ... + bn$: the more triangles, the smaller (b) is, and the more accurate the sum equals C. Geometrically, (b) is a chord beneath the arc segment of the circle, and therefore, it is slightly shorter than the arc or curve segment since (b) is the straight-line, shortest distance. Since each base (b) is the same length, this can be expressed as:

$C = N b$: N = n , is the number of triangles considered , If N increases by a factor, (b) decreases by that same factor, and the formula for C remains consistent, and C gets more accurate.

For each triangle: tan ¢ = opp / adj , and if we let R=1=adjacent side, we have: tan ¢ = b / 1 , and b = tan ¢

The smaller the triangle area, the smaller (b) is, and to do this, the angle must be smaller. If the area is exactly half, then the base (b), or height of a triangle, is exactly half. If we let the angle be 1°:

b = tan 1° = 0.017455065

How many (b) values or terms are along the circumference will be considered into the sum?

N = 360° / (angle of each triangle segment) = 360° / 1° = 360 : **¢= 360° / N , where N and-or angle is an arbitrary amount, and the higher the better accuracy of the result.**

C = N b = 360 (tan 1°) = 360 (0.017455065) = 6.283823374 : *** , N = C / b**

Here, the calculated ratio of: C / R = 6.283823374 / 1 = 6.283823374 , since D = 2R , D = 2 (1) = 2
C / D = 6.283823374 / 2 = 3.14191167 : = **(Pi)** approximation, for all circles.
: Mathematically: **C=(Pi)D = (pi) 2R = 2 (pi) R**
Circumference of a circle

If the number of triangles was N=1000, (Pi) would approximate as: 3.141633996
If the number of triangles was N=10000, (Pi) would approximate as: 3.141593067
If the number of triangles was N=100000, (Pi) would approximate as: 3.141592658
Here : ¢ = 360 / N = 360 / 100000 = 0.000360° ,
b = tan 0.000360° = 0.00006283185307 = 6.283185307 (10^-5)
C = N b = 100000 (0.00006283185307) = 6.283185315 = C / R = C / 1 ,
C / D = Pi = C / 2R = 6.283185315 / 2 = 3.141592658
If the number of triangles was N=1000000, (Pi) would approximate as: 3.141592654 =~ **Pi ,** to 9 decimal places of precision and accuracy.

Using the expressions derived above, we can now derive the formula for the area of a circle:

Ac = (N) At : At = area of each similar sector areas or central triangle , N = number of similar triangles

Ac = N At = N (b h / 2) = N (b R) / 2 = (C / b) (b R) / 2 = ((2 Pi R) / b) ((b R) / 2) = (**Pi) R^2 : * , Area of a circle**

A METHOD TO REMEMBER PI AND EPSILON (e)

Below is a non-mathematical method to obtain the first ten digits of π = "Pi". To do so, you must first know that it is approximately equal to a value of 3.0 and that it is slightly higher in value, say someplace between 3.0 and 4.0, but closer to 3. The next closest integer value greater than 0 is 1, hence we now have:

3.1 , For the third digit, add the first two digits to produce 4:
3.14 , The next integer value greater than the digits of 14 is 15:
3.1415 , Summing the last digits of 14 and 15 we have 9:
3.14159 , Summing the first two digits of the 14 and 15 we have 2:
3.141592

These last two digits above could have also been found by summing 14 and 15, producing 29, and then reversing these digits to have 92.

So far, we have used the integers: 1, 2, 3, 4, and 5, but have not used 6 yet, and this is also the sum of the 1, 4, and 1 digits, or the next number after 5:

3.1415926 , The next two descending integers after 6 are 5 and then 4:
3.141592654 **π** = (pi) rounded to ten total digits (or 9 decimal places)

As a check, the sum of the first ten digits of π is 40. In this close approximation, there was no digit used here with a value of 7 or 8.

In a similar manner, below is a method to obtain epsilon (e) to 10 digits. First you must know that epsilon is approximately equal to 2.7 and is slightly larger in value. Given 2.70, the next higher integer value greater than 0 is 1:

2.71 , Summing the digits of 7 and 1, we have 8:
2.718 , The first and the fourth digits are 28:
2.71828 , Repeating the last four digits of 1828 we have:

2.718281828 : Epsilon (e) to ten digits (or 9 decimal places)

As a check, the sum of the first 10 digits of (e) is 47. The digit values used are: 1, 2, 7 an 8.

Here is a mnemonic (a shorthand or a way to memorized) where the number of letters for each word corresponds to a digit value of the number (e):

2. 7 1 8 2 8 1 8 2 8 4
"If natural e constant is pleasing, a circular Pi inspires math"

Some other options or choices: 8 : pleasing , tasteful, fruitful, delivers, flattens, embraces, inspires
4 : food, hope, good, love, math

A METHOD FOR CALCULATING POWERS AND ROOTS

The process shown below for finding integer roots is an iterative (repeat, repetitive, iteration, do again) process. You simply end the process when you have obtained enough accurate or correct digits of the true result.

A root of a number is a single and constant factor value, that when it is repeatedly multiplied by itself, it produces a power value equal to the given number of which the root is being found. The square or second root of 4 is 2 since (2)(2) = 2^2 = 4. The square root of 9 is 3 since (3)(3) = 3^2 = 9. The cube or third root of 8 is 2 since (2)(2)(2) = 2^3 = 8. The fourth root of 10000 = 10 since (10)(10(10)(10) = 10^4 = 10000.

The square root process below is based of the fact that if the square of R is equal to N, that is, if (R)(R) = R^2 = N , then:

R is the square root of N, and this is usually expressed as: $R = \sqrt{N}$

N = (R)(R) Since the factors of N are identical, R is the root of N.
Mathematically, after dividing both sides by R:

$R = \frac{N}{R}$: This implies a method so a to find the value of R.

For this repetitive process to find the root of N, we will let R1 be the initial guess or estimate of the square root of N, and let R2 be the next closer and calculated value of the actual root. Expressing this concept in a formula:

$R2 = \frac{N}{R1}$: a square root iteration formula

To begin to find $\sqrt{N}$, first guess or estimate (R1) the root. The estimate can actually be any value (except 0, of course), but the closer it is to the actual root, a less number of iterations (repetition) of this process are needed for a given precision (fineness, minuteness) and accuracy (correctness). For values between 1 and 10 you can use a value of 2 or 3 as the first estimate. For values between 0.1 and 1, you can use the same given number modified so that it has a value of 2 greater in the most significant digit (the tenths position). Actually, when the given number is around 0.8 to 1, the square root approaches the same value as the given number, hence you may not want to add in the recommended value. Consider that since a fraction of a fraction results in a lower value, the root of a fraction is actually a higher value, symbolically:

$$(\text{fraction})(\text{fraction}) = (\text{fraction}^2) = (\text{lesser fraction}) \quad \text{, therefore:} \quad \sqrt{(\text{lesser fraction})} = \text{fraction}$$

Ex. An estimate of $\sqrt{0.5}$ would be 0.7, the actual root is about 0.7071.

To verify this, consider expressing the radicand with scientific notation to have an idea of the square root.

Ex. $\sqrt{0.5} = \sqrt{(50)(10^{-2})} = \sqrt{50}\ \sqrt{10^{-2}}$

$$\sqrt{10^{-2}} = 10^{(-2/2)} = 10^{-1} = (1)(10^{-1}) = 0.1 \quad \text{or:}$$

$$\sqrt{10^{-2}} = \sqrt{(1)(10^{-2})} = \sqrt{\frac{1}{10^2}} = \frac{\sqrt{1}}{\sqrt{100}} = \frac{1}{10} \quad \text{or=} \quad 1(10^{-1}) = 0.1$$

checking: $(10^{-1})(10^{-1}) = (10^{-1})^2 = 10^{(-1(+)-1)} = 10^{(-1-1)} = 10^{-2}$

$\sqrt{0.5} = \sqrt{50}\ \sqrt{10^{-2}}$ And the estimate of the root is therefore:

$\sqrt{0.5} \simeq 7\ (10^{-1}) = 0.7$: checking, $(7)(7) = 49$, $49\ (10^{-2}) = 0.49$
or: $(0.7)(0.7) = 0.49$, (almost 0.5)

Ex. $\sqrt{0.00267} = \sqrt{26.7}\ \sqrt{10^{-4}}$

And the estimate of the root is therefore:

$\sqrt{0.00267}$ = about: $5\ (10^{-2}) = 0.05$: $(5)(5) = 25$ which is almost 26 , and
$(0.05)(0.05) = 0.0025$

A square root formula. Here are the iterative (repetitive) steps to find a square root:

1. Since N = R^2 = RR , a check of the root estimate can be made by dividing the radicand by an estimate of the root:

$$R2 = \frac{N}{R1}$$

: N = the number to find the square root of, hence it is the radicand. When R2 = R1 , you have found the exact value of the square root, and this process can stop

When the first or leading digits of R2 match the corresponding digits of R1 you have found correct or accurate significant digits of the root. Note that if you "go high" in the estimate value of (R1), then R2 will "be lower" than the actual root, or vice-versa, due to the inverse mathematical relationship between a quotient and divisor. Since R2 is not usually equal to R1, to get closer, your estimate (ie., R1) must be corrected and reused. Too send R1 and R2 into closer agreement, the average of these two values can be taken for the next estimate. Note also, that if you did not take their average, but just assign R1 equal to the value of R2, that the next result of the division will be the original value of R1 and the process will be endlessly "circular" (repetitive) without getting closer in value to the true square root.

2. Since root $= \frac{R + R}{2} = \frac{2R}{2} = R$

, a new closer estimate can now be made by taking the average of the previous estimate and check values:

$$R3 = \frac{R1 + R2}{2}$$

: new modified (calculated and adjusted) estimate

3. Now, R3 is a modified estimate which is closer to the actual root. Set R1 equal to R3 and repeat the iterative steps (1,2 and 3). This process of repeatedly reusing the value output of an equation or function as the new input for the same equation or function is called recursion.

Summarizing the above steps into a single square root approximation formula:

Since $R2 = \frac{N}{R1}$, using algebraic substitution of R2 in: $R3 = \frac{R1 + R2}{2}$, we have:

$$R3 = \frac{R1 + \frac{N}{R1}}{2}$$

:R1 is an approximation, and R3 is the next closer approximation. Summarizing this into a more general formula for iteration:

$$Rn+1 = \frac{Rn + \frac{N}{Rn}}{2}$$

Mathematically, this can also be expressed as::

$$Rn+1 = \frac{Rn^2 + N}{2Rn} = 0.5\left(\frac{Rn^2 + N}{Rn}\right)$$

: **SQUARE ROOT SUCCESSIVE APPROXIMATION (RECURSION = repetition and reusing) FORMULA**

Ex. Find $\sqrt{10}$

With an initial estimate of Rn = R1 = 3, and using the above formula:

Iteration	Result = Rn+1
1	3.166666666
2	3.162280702
3	3.16227766
4	3.16227766

: for computer programs, an iteration, cycle or repetition of a process is called a loop

For the fourth iteration, since there were no new changes in any of the digits, we can assume that this is the accurate or correct (at least for the limited number of digits, or precision shown) square root.

Using a similar method to finding square roots, cube and even higher integer roots can be found.

A description of the cube root successive approximation formula is: The coefficient of the first term in the numerator is 1 less than the indicated root (x), and the denominator of the second term in the numerator is also raised to an indicated power of 1 less than the indicated root. The entire numerator is divided by a value equal to the indicated root. Summarizing this into a general formula for iteration:

The (x) root of N is expressed as $R = \sqrt[x]{N}$, and R can be calculated using:

$$R_{n+1} = \frac{(x-1)R_n + \frac{N}{(R_n)^{(x-1)}}}{x}$$

: **A FORMULA FOR CALCULATING ANY INTEGER ROOT**
Here x = indicated root , such as 2, 3, etc.
The appendix section of this book contains a computer program that utilizes this formula to find any root or power.

Ex. For the 3rd, or cube root of N, use:

$$R_{n+1} = \frac{\frac{2R_n}{1} + \frac{N}{(R_n)^2}}{3}$$

Not only can this general formula be applied for solving integer roots, but it can just as easily be applied for solving for a root or power of any real number. The appendix section of this book contains a computer program using this method to solve for a root. Real is a general mathematical name given to all the integers and mixed number values which are values with a possible whole portion and-or a possible fractional ("decimal") portion whose digits terminate at some point, or where some or all of its digits repeat endlessly to be classified as a "rational" (real) number. Any rational (real) number can be mathematically expressed as the division of two integers. "Irrational" (real) numbers are values that are not rational, such as "pi" and roots where the decimal portion is non-ending and non-repeating. Real numbers or values are sometimes called "floating (adjustable, position) point" values in computer programming, where point essentially means the decimal point that separates the whole portion from the fractional portion that is less than 1.

Ex. Here is how to find the 2.7th root of N:

$$R_{n+1} = \frac{\frac{1.7R_n}{1} + \frac{N}{(R_n)^{1.7}}}{2.7}$$

: For this example: (x-1) = (2.7 - 1) = 1.7

However, as you can now see, you must raise Rn to a non-integer power. Computer languages and machines, or scientific calculators, can handle such computations easily. It appears almost impossible to calculate by hand, but there are several methods. Here is a simple method besides the others presented in this book:

Given N^(x+y) , this can be factored into:

N^(x+y) = N^x N^y

If (x) represents the whole portion of an exponent, and (y) represents the fractional portion of an exponent, we can solve for real or fractional powers using only integer roots and powers.

Ex. Find N^1.7

N^1.7 = N^1 N^0.7
N^1.7 = N^1 N^(7/10)
N^1.7 = N^1 10√ N^7 or= N^1 (10√ N)^7

Ex. Find 4^0.3. This example also shows a similar, but alternate method.

Let: X = N^0.a raising each side to the 10th power:
X^10 = (N^0.a)^10
X^10 = N^a

Hence to solve for X, the power value we are looking for, take the 10th root:

X = 10√ X^10

Since X^10 = N^a, this can be written as:

X = 10√ N^a = N^0.a

Solving the initial example:

X = 4^0.3 = 4^(3/10) = 10 √ 4^3 = 10√ 64 = 1.515716566

You would usually calculate integer powers by repeated multiplication or with the aid of a calculator. For calculating very high powers, rather than perform an enormous amount of repeated multiplication or using other computational methods, you can simply use the concepts of a "power to a power". Actually, many calculators will display an error message (usually as "E") if the power to be calculated is too high, and hence, you must resort to calculating it the old fashioned way "by hand" using pen and paper.

Here are some examples of factoring the exponent,that you may utilize:

N^2 = N^1 N^1
N^10 = (N^5)^2 : hence for example, to find the 10 power of a value, you can find the 5th power and then square it.
N^100 = (N^10)^10 = ((N^5)^2)^10
N^1000 = ((N^10)^10)^10

N^735 = N^(700 + 30 + 5) = N^700 N^30 N^5
N^735 = (N^7)^100 (N^3)^10 N^5
N^735 = ((N^7)^10)^10 (N^3)^10 N^5

As a calculating aid, many calculators are programmed so that by repeatedly pressing the enter (=) key, the last operation and operand will be applied to the current displayed value. The current displayed value will then act as if it's the first operand of the last operation entered. Integer powers can be easily found this way,and without the need for entering a factor (here the base of the power) repeatedly. For example, to calculate N^3, you would first enter N x N = to get N^2 (actually on many calculators you can also simply enter: N [x] [=], that is, first enter the number, then press the multiplication or "times" button, and then press the "equals" buttons to get the square of N, and this is of great aid when N has many awkward digits). Pressing the [enter] key or [=] again will yield N^3, pressing [enter] again will yield N^4, and finally pressing [enter] again will yield N^5 and so on.

Here is another note on solving for integer powers using repeated multiplication. The (portable or "hand-held") calculator is a limited precision device, that is, it is built to display only a specific number of maximum digits (usually 8 or 10). Any least significant values that cannot be entered or displayed are lost. However insignificant those digits are, it can eventually result in less accuracy in the displayed results. For example, if you have an 8-digit calculator, we know that multiplying two 8-digit operands usually yields a 16 or 17 digit product. Since the calculator can only enter, process and display 8 digits, the other 8 or 9 least significant digits are essentially lost and not displayed on the calculator. If this result is used "as is" for an operand of further operations, errors or differences from the actual or true values can possibly start to "show up" beginning in the least significant digits of the result(s) displayed. These errors can grow in value, and become a significant error or difference from the true value, when these values are used for operands of further operations. For most practical cases, where say being accurate to 3 to 6 decimal places or a "thousandth", this will not be of a concern. In general, when the calculator returns (ie., the result or output) a value of one of the function key operations such as for the square root of the operand, that value is usually accurate for all of the digits displayed except perhaps the last digit if it was rounded. The calculator generally does not know if any entered and-or reused is accurate or not, and essentially considers any entered and-or reused value as a user desired operand.

The same formula for roots can be applied for calculating any power of N. You might ask what root of N results in a value equal to a certain indicated power of N? The answer is easily determined if you express this question in a mathematical form as:

$$\sqrt[x]{N} = N^y$$

Solving for (x), the indicated root, by placing the radical into exponential form:

$N^{(1/x)} = N^y$ equating the exponents by observation (or by taking the log of both sides and dividing by (log N)):

$\frac{1}{x} = y$ solving for x:

$x = \frac{1}{y}$: we see that the index and exponent of N are reciprocals of each other

For example, to calculate the second power of N using the root formula shown, you would calculate the 1/2 = 0.5 root of N since $\sqrt[0.5]{N} = N^{1/0.5} = N^2$.

It is possible to calculate odd roots, such as cube roots, by using square roots. Here is a method:

$R = \sqrt[3]{N}$: R = cube root of N, therefore (raising each side to the 3rd power):

$R^3 = N$ after dividing each side by R:

$R^2 = \frac{N}{R}$ taking the square root of both sides:

$R = \sqrt{\frac{N}{R}}$ expressing this with successive approximation notation:

$$R_{n+1} = \sqrt{\frac{N}{R_n}}$$

: **A METHOD TO FIND CUBE ROOTS USING SQUARE ROOTS** (This works, but it is not the most efficient method, ie., it is "slower" meaning more iterations are usually needed to have a convergence to the true result).

In general, for (d) correct digits, repeat the formula (3d+1) times.

Though not obvious, it is incorrect to solve for R, the cube root, using the iteration formula below since it does not converge to any result:

From, if (R)(R)(R) = (R^1)(R^2) = R^3 = N , mathematically: R = N / R^2 and:

$$R_{n+1} = \frac{N}{(R_n)^2}$$

: Though algebraically correct, this is an incorrect iteration method, however, there is a computer method that can be used to solve for cube roots using this equation. The method shown can be adapted to solve many difficult equations. See A METHOD TO SOLVE DIFFICULT EQUATIONS further ahead in this book.

A GENERAL METHOD FOR FINDING ANY POWER

Previously, a method was shown to calculate a power of a base value where the exponent had only one digit in the fractional portion. Here is a similar method which is generalized to calculate any possible power. Though you may generally not use these types of methods to find a power or a root, the knowledge or "know-how" aspect could have potential use in various mathematical situations and understanding.

Consider this:

$N = X^{a.bcd}$ "factoring" the right hand side:

$N = X^{(a + 0.b + 0.0c + 0.00d)} = X^a \quad X^{0.b} \quad X^{0.0c} \quad X^{0.00d}$ OR:

$N = X^a \quad (X^{0.1})^b \quad (X^{0.01})^c \quad (X^{0.001})^d$

$N = X^a \quad X^{0.1b} \quad X^{0.01c} \quad X^{0.001d}$

$N = X^a \quad X^{(b/10)} \quad X^{(c/100)} \quad X^{(d/1000)}$ expressed in radical notation:

$N = X^a \quad (\sqrt[10]{X^b}) \quad (\sqrt[100]{X^c}) \quad (\sqrt[1000]{X^d})$ or for the purpose here:

$N = X^a \quad (\sqrt[10]{X})^b \quad (\sqrt[100]{X})^c \quad (\sqrt[1000]{X})^d$:GENERAL METHOD

$N = X^a \quad (\sqrt[10]{X})^b \quad (\sqrt[10]{\sqrt[10]{X}})^c \quad (\sqrt[10]{\sqrt[10]{\sqrt[10]{X}}})^d$: a working method

The best way to solve the last equation is to first find the 10th root of X and then you can reuse this result to find the 100th root of X and so on since:

$$\sqrt[10]{\sqrt[10]{X}} = \sqrt[100]{X}$$

$$\sqrt[10]{\sqrt[100]{X}} = \sqrt[1000]{X}$$

If the exponent is negative, the simplest method to evaluate the power is to first find the power with an equivalent positive exponent and then take the reciprocal of this power since:

$N^{-x} = \frac{1}{N^x}$, also taking the square root of both sides: $\sqrt{N^{-x}} = \sqrt{\frac{1}{N^x}}$ or= $\frac{1}{\sqrt{N^x}}$

If the base of the indicated power is negative, things can get somewhat cloudy. For example:

$(-2)^2 = (-2)(-2) = +4$

$(-2)^3 = (-2)(-2)(-2) = -8$

So far so good, you can check these with a (scientific) calculator, and get the same results. By observing the above examples, it seems quite logical that if you make the exponent equal to a value anywhere between 2 and 3 then you should also be able to have an answer (the evaluated power of the base -2). After all, for example, $+2^2 = 4$, $+2^{2.5} = 5.6585...$, and $+2^3 = 8$. Now take notice if the base is negative and the indicated power is a mixed number:

(-2)^2.5 = **HAS NO SOLUTION**, unless you consider the concept of **imaginary numbers**. (-2)^(-2.5) also has no solution. The reason is that the exponent of 2.5 contains a whole portion and a fractional portion. When the base value is negative, to be able to solve for the indicated power value, the exponent must be a whole number. If you try this expression on a (scientific) calculator, you will get an error message. Here is a verification why:

First: Only odd roots, not even roots, can be taken for negative values. The root will also be negative in sign.
Ex. $\sqrt[3]{-8} = -2$:since (-2) (-2) (-2) = (-2)^3 = -8

Let's find out just what an imaginary number is. Even indicated (with the index) roots of negative numbers are formally known as imaginary numbers. First consider that when the square root of a number is multiplied by itself, it will be equal to that number or radicand.

root = $\sqrt[2]{\text{radicand}}$

root x root x . . . = root^2 = radicand

Ex. $\sqrt{100}\ \sqrt{100} = 100$ or= ($\sqrt{100}$)^2 = (100^1/2)^2 = 100^(2/2) = 100^1 = 100

checking: (10) (10) = 100

Ex. $\sqrt{-4}\ \sqrt{-4} = -4$: has the form of: root x root = (root of radicand) x (root of radicand) = radicand

Though the above should be true, the square root of -4 itself cannot be evaluated in the standard or normal way, so therefore, it can only be indicated or represented with an expression since any number or root, either positive or negative in sign, multiplied by itself is always positive in sign according to the basic rules for signed numbers. Factoring the radicand in the above example we find:

$\sqrt{-4} = \sqrt{(-1)(4)} = \sqrt{-1}\ \sqrt{4}$ simplifying further, we find this equal to:

$2\sqrt{-1}$: note also that $\sqrt{-4}\ \sqrt{-4} = -4 = 2\sqrt{-1}\quad 2\sqrt{-1}$: checking

$= (2)\ (2)\ \sqrt{-1}\ \sqrt{-1}$

$= 4\ (-1) = -4$: checks with the given radicand

The square root of -1 is called the "**imaginary unit**" since its rationalized and specific numeric value can only be imagined to exist, and in the following example, we see that there are 2 imaginary units being summed or combined:

$\sqrt{-1} + \sqrt{-1}$ each value can be expressed as having a numerical coefficient of 1:

$1\sqrt{-1} + 1\sqrt{-1}$: here, showing the understood numerical coefficients of 1. Adding like radicals, values or variables, we combine or add their numerical coefficients and keep that same value:

$2\sqrt{-1}$

You can imagine this value as a distance of 2 units along or into an imaginary zone or imaginary number line or axis that is perpendicular to the normal or real number line that we are all familiar with. We know the effect of multiplying a number by -1 is essentially a 180° shift or rotation of its position on the number line. This produces the negative, number line inverse or counterpart of a number. For example, (+5)(-1) = -5, and (-5)(-1) = +5. The effect of multiplying a number by $\sqrt{-1}$ is that only half of that 180°, or= a 90° degree rotation, or "half-way to a sign change" on this **complex** (both real and imaginary) number plane. If you were to multiply a value by $\sqrt{-1}\ \sqrt{-1}$, it would result in a 180° rotation since the square root of a number times the square root of that same number is equal to that number: $\sqrt{-1}\ \sqrt{-1} = -1$, and that is 180°

from +1 on the real number line. The square root of -1 is called the **imaginary unit** (which we can imagine as equal to some constant value) and is often given the identifying symbol of: (**i** or j) so that you can work with **i**maginary numbers in a manner similar to that with working with typical algebraic variables. Therefore:

$2\sqrt{-1} = 2i$: sometimes the letter j is used instead of i, for example $2i = 2j$

What is the connection between real numbers and imaginary numbers? As already shown above, a real number can be a coefficient of an imaginary number. Another important fact is that the product of two imaginary numbers is a real number. First consider the square roots of -1:

$\sqrt{-1}\ \sqrt{-1} = -1$ or:

$i \quad i = i^2 = -1$: -1 is a real number. Negative numbers are 180° from the positive side of the real axis, and this could be thought of as being in the opposite direction. Imaginary numbers on the imaginary number line could be thought of as being in a sideways (90°, right angle) direction from the real number line.

Ex. $(2i)(5i) = (2)(5)(i^2) = 10(-1) = -10$: multiplying by i^2 is the same as multiplying by (-1)

Also note: $i^3 = i^2\, i^1 = -1i = -i$: Numbers 180° from positive side of imaginary axis. This is equivalent to a 270° rotation of a number from the positive real number axis.

$i^4 = (i^2)^2 = (i^2)(i^2) = (-1)(-1) = +1$: Numbers on the positive side of the real axis.

A **complex number** is a number that is part real and part imaginary. You might have already encountered a root of a quadratic equation that is a complex number. The pseudo and formal algebraic forms of a complex number are:

$(\text{real} + \text{imaginary}) = (a + bi)$: Basic form of a complex number. (a) represents the real part, and (b) is a real number numerical coefficient of the entire imaginary number part. We see that a complex number is expressed as the sum or union of its real and imaginary part,

Ex. $5 + 2i$: 5 is the real number, and 2i is the imaginary number. Commonly said as 5 is the real part, and 2 is the imaginary part.

The sum or product of a complex number and its corresponding conjugate (ie., with a "sign change") complex number is a real number.

Ex. $(5 + 2i) + (5 - 2i)$ removing parentheses or grouping symbols:
$5 + 2i + 5 - 2i$ after combining like terms:
$5 + 5$
10

Ex. $(3 + 5i)(3 - 5i)$: the product of a complex number and its conjugate. Distributing:
$(3)(3) + (3)(-5i) + (5i)(3) + (5i)(-5i)$
$3^2 + (-15i) + (15i) + (-25i^2)$ since $i^2 = -1$:
$3^2 - 15i + 15i + (-25(-1))$ combining like terms:

9 + 25 : the result is a binomial (two terms) of the squares of the numerical parts of the complex number.
34 Special thanks to Mr. Barry Gale from Australia for improving this here.

Now we will continue with the discussion on finding any power.

Ex. $\sqrt[2]{-8}$ = CANNOT BE SOLVED normally unless the imaginary solution is considered since there is no (root) value (positive or negative) that can be multiplied by itself any number of even times (such as 2 indicated here) that can ever be negative in sign. Essentially, even indexed roots for negative radicands (numbers) are not allowed.

Ex. $\sqrt[10]{-23}$ = CANNOT BE SOLVED normally, as indicated above, since the radicand is negative and the index (the indicated root to be taken) is even.

Given (-2)^2.5 , which as indicated above, cannot be solved normally since 2.5 is not an integer. It can be solved if an imaginary solution is acceptable:

Factoring (-2):

(-2)^2.5 = (-2)^(2 + 0.5) = (-2)^2 (-2)^0.5 : Now take note of this second factor just shown :

(-2)^0.5 = (-2)^(5/10) = (-2)^(1/2) = $\sqrt{-2} = \sqrt{2}\ \sqrt{-1} = \sqrt{2\ i}$: again, an even root of a negative radicand, or :

(-2)^2.5 = (-2)^2 (-2)^0.5 = (-2)^2 ((-2)^0.1)^5 = (-2)^2 ((-2)^(1/10))^5

(-2)^2.5 = 4 ($\sqrt[10]{-2}$)^5 : There is no real number solution to any indicated even root (here, 10th) of any negative value number (here, -2).

The basic fact from the above discussions is that the square root (or any other even root) of -1 has no real solution, and is rather an imagined or imaginary solution. Consider the basic fact that any real or physical length can only be positive in value, and that a negative length can then only be imagined, hence an imaginary length having an imaginary value. Once signed numbers and negative (or reverse) directions are considered, then it is possible to describe negative directions and-or lengths, but still, on a fundamental, real or physical level, there is no such thing as a negative length.

Also shown in the above discussion is that N^x can not be solved when N is negative and x is not an integer.

[This space for edits.]

A METHOD TO FIND A LINEAR (LINE) EQUATION GIVEN A SET OF POINTS

There are many methods to find a (representative) linear equation given a set of points or data that appear to be linear and could be graphed using a single (representative or approximate) line . A simple method is given below that will provide very reasonable results. This method is what can be called an "upper and lower average method" and-or the "**average line method**". Many "scientific" calculators have some statistical (the key is often labeled as "stat") functions such as averaging a series of input data values.

If there is an excessive amount of data values or points to consider, then simply choose a manageable and representative sample amount to use, and in particular, discard any extreme values that appear as very high or low as compared to most of the data values since these "extreme [too high,or too low] and-or erroneous values" can affect the accuracy and effectiveness of the entire representative line being created. Sometimes it may help to visually plot the points so as to determine if there area any "extreme" values.

Another quick test to determine if there is a linear or linear-like relationship is to take some of the data values (to be plotted or graphed as points) and find a rough or basic slope (m) value by dividing a few dependent (y) values by its corresponding independent (x) value of that point, and then using this (roughly constant) value for comparing and determining if a data value or point is "out of (the linear or line) range", possibly due to some anomaly or measurement error. These "extreme values" can then be discarded and-or eliminated from this line analysis.

1. Given a set of acceptable points (that are graphed and appear to be linear in nature), find the average of the x coordinates of all the points, which can be expressed as x with a short line over it, and then find the average of all the y coordinates of all the points. An **average value** of a set of values can be found by summing up all those values and then dividing by the total number of the values used or included in that sum.

   $Pa = (\bar{x} , \bar{y})$: main average point, at the average x value and average y value of the given points, the more the better the line equation will represent and-or predict the data.

   On a point plotting graph and-or coordinate (location) system of points, you may wish to draw a horizontal and vertical line at this point (Pa). All points to the right of Pa will have greater x values and will be used to find the upper-x average value. All points to the left of Pa will have lower (x) values and will be used to find the lower-x average value. This same reasoning will be used to find the upper and lower y average values.

2. Given the set of all points whose coordinates are less than the average, find the lower-x and lower-y average point:

   $Pl = (\overline{x_l} , \overline{y_l})$: average point of points lower than the main average

3. Given the set of all the points whose coordinates are greater than the average, find the upper-x and the upper-y average point:

   $Pu = (\overline{x_u} , \overline{y_u})$: average point of points greater than the main average

We now have three points on the line: Pa , Pl , Pu These points can be connected to display the **average line**. To make an equation of this line so as to plot any general point on that line given an (x) value, we need to write the equation for that specific line, and we will need to find the slope value (m) of that line, and the y-axis intercept point: Pi (0 , b)

4. With the upper and lower average points, these two points can be used to determine the slope (m) of the corresponding line of which those points are on:

$$m = \frac{\overline{yu} - \overline{yl}}{\overline{xu} - \overline{xl}}$$: slope of the line between the upper and lower average points

5. (b), the y-axis intercept where x=0, can now be found knowing the basic equation of a line. This will also give us another point on that so as to draw that line using a ruler and pen:

From: $y = mx + b$ mathematically solving for (b):

$b = y - mx$: b = the "y-axis" intercept of the line and where x=0 , p(x=0 , b) = p(0 , b)

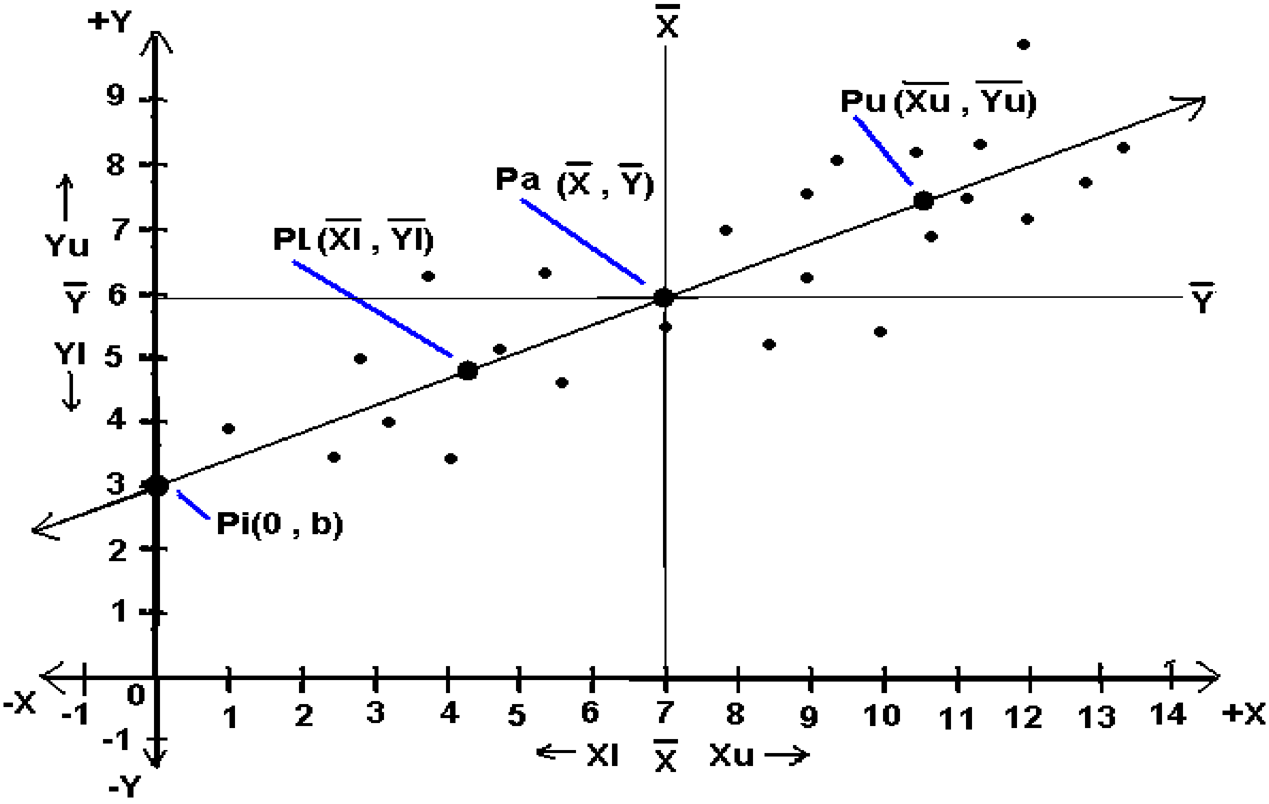
Clearly, we need the corresponding values of (x) and (y), and the slope (m) so as to solve for (b) of that line.

To find a value for (b), we can substitute the coordinates of the average point (Pa) of the entire set for (x) and (y):

$b = \overline{y} - m\overline{x}$: b = the "y-axis" intercept of the line and where x=0

6. The equation of a representative line for the data is: $y = mx + b$: where (m) and (b) are constants for the particular line

You can now plot all the given and new points from both the data, and line (from the created linear equation) on a graph and see how close this line is to the actual data, and vice-versa. This line which represents the known data values can now be used for predicting other data values and-or for comparison to other similar lines. If the data and-or points change due to some reason, perhaps the points are now having a lesser or greater (y) value on average, the line needs to be recalculated so as it can properly and-or truly represent that data. [FIG 213]



A DERIVATION OF SIN ¢ SERIES

In order to give you validity and confidence in using the SIN ¢ and other similar series, the fundamental steps of its' derivation are presented below. It is recommended to first view the previous topic of: Understanding Basic Calculus.

In theory, many functions (the mathematical relationship of variables) can be expressed as a series of terms. For a very simple example, consider this:

$y = f(x) = 5x$ Expressing the function 5x using repeated addition which is a series of terms:
$y = f(x) = 1x + 1x + 1x + 1x + 1x$: You can solve for the value of $y = 5x$ by using this sum of terms.
Expressing this series of terms using "summing notation":

$$y = f(x) = \overset{5}{\underset{1}{S}} \; 1x$$

: sum the terms, where each is term is 1x, and for a total of 5 terms of these terms

Here is the general format for a **Power Series** representation of a function:

$$y = \text{a function of } x = f(x) = \sum_{n=0}^{n=\infty} Cn\, x^n$$

: General format for terms of a power series.
C or c are constants that are specific to the function.
Sometimes "inf." is used in place of the infinity symbol: ∞ ,
n is a variable, here starting at 0, and is to be incremented by 1 for each and every successive term. For Cn, n is a subscript corresponding to the term number less 1. For example: c0 = "constant zero", which is actually the first constant in the series. c1 = "constant 1".

Expanding some of the terms of the general power-series format shown above:

$$y = f(x) = c0\, x^0 + c1\, x^1 + c2\, x^2 + c3\, x^3 + \ldots$$

: Power Series (in, or of variable x) general format. $c0\, x^0 = c0\,(1) = c0$

Here is a simple verification of the power series, however, the terms used are finite (not infinite) in number since you should expect a definite result for an algebraic function (as opposed to the non-algebraic functions such as the trigonometric functions):

$$y = f(x) = (x + 2)^3$$

$$y = f(x) = (x + 2)^3 = (x + 2)^2\,(x + 2)^1 = (x^2 + 4x + 4)\,(x + 2) = x^3 + 6x^2 + 12x^1 + 8$$

Arranging these terms into an ascending series of expressed or indicated power of x:

$$y = f(x) = 8 + 12x^1 + 6x^2 + x^3$$

: note the ascending exponents or powers of the variable

Note that the first constant (c0) can be evaluated by setting the value of the variable (x) to 0, effectively eliminating all the terms containing that variable (x), after all, 0 is often a possible value for any variable in a function. In the above expression, $C_0 = 8$. In mathematical notation:

$c0 = f(0)$: f(0) = evaluate the function after setting the value of the variable (here, x) to 0.
This value is also the "y-axis intercept" of the curve of the equation, and where the corresponding value of (x) is 0. y intercept point = point(x, y) = p (0 , 8).

By taking the derivative (term by term, of the terms that represent an equivalent [equal] in value sum expression of that same function) of the formal or general Power-Series expression above, and its resulting derivatives, we can find a formula for the constants (cn) of the general Power-Series. For example, the first derivative of:

$y = f(x) = c0\,x^0 + c1\,x^1 + c2\,x^2 + c3\,x^3 + \ldots$ is:

$\frac{dy}{dx} = y' = f'(x) = c1 + 2c2x^1 + 3c3x^2 + \ldots$: a derivative of a sum of terms is equal to the sum of the derivatives of each term. The derivative of the term: $c0\,x^0$ is 0.

Now, the (logical) second constant (here, c1) can be evaluated by setting the value of the variable (x) to 0 in this derivative:

$c1 = f'(0)$: c1 is the numerical coefficient of x^1

Taking the derivative of the first derivative will give us the second derivative of the original function:

$y'' = f''(x) = (1)(2)c2 + (2)(3)c3x1 + \ldots$

Now, the third constant (c2) can be solved for by setting the value of the variable (x) to 0 in this derivative of the previous derivative:

$f''(0) = (1)(2)c2 = (2!)\,c2$ hence mathematically: $c2 = \frac{f''(0)}{2!}$

We see that the pattern and general format for the constant term in each derivative is:

$cn = \frac{f^n(0)}{n!}$: where f^n is the notation for the nth derivative of the function, and not the nth power of the function. Some other mathematical notations for the third derivative, may be expressed as: $y''' = f''' = f^3 = f'3$

By placing the above formula for the constants into the general Power-Series, we have:

$$y = f(x) = \sum_{n=0}^{n=\infty} \frac{f^n(0)}{n!}\,x^n$$

: The Power Series expressed this way is called a (Colin) **Maclaurin Series**. **Brook Taylor** made the initial progress for these types of Taylor series expansions of functions in about 1715. Note that "derivative 0" = f^0 which is the function itself, and 0**!** is defined to be equal to 1**!** = 1 A Maclaurin series is a successive approximation series or expansion of a function, and where x is set to 0 when using a Taylor series expansion of that same function. Maclaurin created his method and series in about 1730.

Expanding some initial terms:

$$y = f(x) = f(0) + \frac{f^1(0)\,x^1}{1!} + \frac{f^2(0)\,x^2}{2!} + \frac{f^3(0)\,x^3}{3!} + \frac{f^4(0)\,x^4}{4!} + \ldots$$

Notice that in each term, the indicated derivative number, the indicated (exponent) power of (x), and the indicated factorial have the same basic numerical value equal to (n).

Let's make a check on this series using the basic formats of the linear and quadratic equations.

y = f(x) = ax + b : basic linear equation and function

y(0) = f(0) = a(0) + b = b : evaluating the function with (x) set equal to 0, and this is actually the y-axis intercept where x=0. point(x , y) = p(0 , b)

The first derivative is:

y' = f'(x) = (1)ax^0 = a(1) = a

The second and all further derivatives are 0, that is, the derivative of any constant (such as (a), or even 0) is equal to 0. If you consider the line y=a, where (a) is a constant, it is a horizontal line which has no slope, hence 0. After substituting this into the general Maclaurin Series:

y = f(x) = b + ax^1 + 0 + 0 . . .

y = f(x) = b + ax : This is actually the same original function except that the terms are rearranged.

Now consider the basic form of a quadratic equation:

y = f(x) = ax^2 + bx + c : basic quadratic equation, or by rearranging terms for an ascending order of increasing powers of the variable (x):

y = f(x) = cx^0 + bx^1 + ax^2 : in relation to the general power series, we see that constant c0 = c, c1 = b and c2 = a

y(0) = f(0) = a(0^2) + b(0) + c = c

The first derivative of this quadratic equation is:

y' = f'(x) = 2ax^1 + b : this is a linear equation

The second derivative of the quadratic equation, and which is the derivative of this linear equation is:

y'' = 2ax^0 = 2a : this is a constant, and this is common for the derivative of linear or line equations.

The first derivative where x is set equal to 0 is:

y'(0) = f'(0) = 2a(0^1) + b = b : 0^1 = 0

The second derivative where x is set equal to 0 is:

y''(0) = f''(0) = 2a(0^0) = 2a(1) = 2a : Note that: 0^0 = 1

0^0 = 1, and to verify this, remember that any value raised to the 0 power is equal to 1. The value can be very huge or infinitely so small that it is practically considered as equal to 0. Be sure to also remember 0^1 = 0, that is, any value raised to the first (1) power is equal to that value. It does seem natural or intuitive to think that a value with a higher exponent should result in a greater value than the base value (here 0). 0^1 might be thought of as being greater than 0^0, but it is not. Consider that a number very close to 0, or infinitely small, raised to the 0 power is still equal to 1. For example: (0.000,000,000,001)^0 = 1. One point argued about this is "nothing (0) raised to the nothing (0), or no (0) power should still be equal that nothing (0)". But then with that same mindset, in division, a value that is divided by nothing (0) should still be equal to that undivided value since no (0) division has actually taken place. Formally, division by 0 is undefined (not defined, having no definite or specific result, hence it is considered an error to even try to divide by 0).

Substituting the above information into the general Maclaurin series:

$$y = f(x) = \frac{c}{0!} + \frac{bx^1}{1!} + \frac{2ax^2}{2!} + 0 + 0 + \dots$$: 0! is defined as equal to 1

$$y = f(x) = c + bx + ax^2$$: This is actually the same original function except that the terms are rearranged into ascending powers of (x).

Writing a (algebraic-like) Maclaurin Series (approximation) for the (non-algebraic) SIN x function:

(Note, the derivatives of the SIN and COS functions shown below are verified in the next discussion.)

f (x) = SIN x : the given function, here a trigonometric function of SIN x, its derivative is:
f1(x) = COS x : the first derivative of the SIN x function is equivalent in value of the COS x function
f2(x) = -SIN x : the second derivative of the SIN x function is equal to the derivative of the COS x function
f3(x) = -(COS x) = -COS x : the third derivative of the SIN x function

c0 = f(0) = SIN 0 = 0 : after evaluating the function: SIN x, at x=0
c1 = f1(0) = COS 0 = 1 : after evaluating the first derivative of SIN x, at x=0
c2 = f2(0) = - SIN 0 = 0 : after evaluating the second derivative of SIN x, at x=0
c3 = f3(0) = - COS 0 = -1 : after evaluating the third derivative of SIN x, at x=0
c4 = f4(0) = SIN 0 = 0 : after evaluating the fourth derivative of SIN x, at x=0

At the fourth derivative of SIN x, we see that it is the same as the original function given (SIN x) and therefore, the derivatives and constants (cn) are starting to repeat:

f4(x) = -(-SIN x) = SIN x
c4 = f4(0) = SIN 0 = 0 Placing these constants into the SIN x series:

$$\text{SIN } x = f(x) = 0 + 1x^1 + \frac{0x^2}{2!} + \frac{-1x^3}{3!} + \frac{0x^4}{4!} + \frac{1x^5}{5!} + \dots$$

Since any variable or value multiplied by 0 is 0 or "nothing", those terms, here which are the even powers of the variable x, are effectively eliminated from the sum of terms, and the expression reduces or simplifies to:

$$\text{SIN } x = x^1 - \frac{x^3}{3!} + \frac{x^5}{5!} - \dots$$: x is a radian angle value

This, and the other trigonometric series shown below were first developed in the late 1600's and early 1700's by Newton (1642-1727) from England, Gottfried Leibniz (1646-1716) from Germany, Brook Taylor (1685-1731) from England, Colin Maclaurin (1698-1746) from Scotland, and James Gregory (1638-1675) from Scotland. **Madhava Of Sangamagrama** (1340-1425) was a mathematician and astronomer from India and had previously made some independent progress in series and calculations before Newton and Leibniz made their own independent and discoveries, proofs and the formalization (ie., set standards, awareness and usefulness) of calculus. Some modern texts indicate a joint discovery credit for some mathematical series to both the western discoverers and Madhava from the eastern culture of India. Before this time frame of discoveries and advancements, ancient Greek mathematicians such as **Archimedes** (287 BC - 212 BC), of Syracuse, Sicily-Italy, have found some solutions to geometric problems by using what could be described today as infinite sums and pre-calculus, and this must of inspired Newton. **Srinivasa Ramanujan** (1887-1920), a mathematician from India, made some surprising and useful mathematical algorithms, series and curiosities of which are being studied until this day so as to be applied and make some other advancements in mathematics. This book has a discussion and computer program about his amazing ellipse perimeter approximation formula(s).

COS ¢ SERIES

$$\text{COS } X = \sum_{n=0}^{n=\infty} (-1)^n \frac{X^{(2n)}}{(2n)!} \qquad : X \text{ is a radian angle value}$$

Expanding the terms:

$$\text{COS } X = \frac{1}{0!} - \frac{X^2}{2!} + \frac{X^4}{4!} - \frac{X^6}{6!} + \frac{X^8}{8!} - \frac{X^{10}}{10!} + \frac{X^{12}}{12!} - \ . \ . \ .$$

Simplifying the factorials in the denominators:

$$\text{COS } X = 1 - \frac{X^2}{2} + \frac{X^4}{24} - \frac{X^6}{720} + \frac{X^8}{40{,}320} - \frac{X^{10}}{3{,}628{,}800} + \frac{X^{12}}{479{,}001{,}600} - \ . \ . \ .$$

The results to be expected are similar to those of the SIN X series. When the angle decreases, the greater the accuracy achieved for a given number of terms. When X=1 (about 57°) you can expect an accuracy of 6 digits when using only 6 of the terms shown. Note that when the angle X is 0, that sin 0 = 0, and cos 0 = 1, and hence as to why the cos x series has the initial "1 term". The main difference between the sin and cos series is in the use of all odd or even powers of (x).

Notice the last term given for the series, if you only have an 8 digit calculator, you cannot enter the 9 digit denominator of this fraction. The method to overcome this limitation is to factor the denominator, resulting in numbers (factors) with less digits. For a quick method to simplify or process the resulting fraction, the numerator will be divided by one of the factors in the denominator, and then the resulting quotient will be divided by the other factor in the denominator. Perform the division as shown below:

$$\frac{X^{12}}{479{,}001{,}600} = \frac{X^{12}}{(10)(47{,}900{,}160)} = \frac{\ \frac{X^{12}}{47{,}900{,}160}\ }{\frac{10}{1}} \qquad \text{or:} \qquad \frac{\ \frac{X^{12}}{10}\ }{\frac{47{,}900{,}160}{1}}$$

You can also evaluate COS X from one of the other trigonometric identities previously shown, for example:

$$\text{COS } X = \frac{\text{SIN } X}{\text{TAN } X} = \sqrt{1 - \text{SIN}^2 X}$$

The series above for COS X is derived from the SIN X series since the derivative of SIN X and its equivalent series is the COS X series. Taking the derivative of the expansion of the SIN X series term by term will yield the COS X series:

$$\text{COS } x = \frac{d\,(\text{SIN } x)}{d\,x} = \frac{1\,x^{(1-1)}}{1} - \frac{3x^{(3-1)}}{3!} + \frac{5x^{(5-1)}}{5!} - \ . \ . \ .$$

$$\text{COS } x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \ . \ . \ .$$

As previously indicated, taking the derivative of this series, term by term, will yield the negative of the SIN series:

$$\frac{d\,(\text{COS } x)}{d\,x} \;=\; -\,\text{SIN } x$$

A FORMULA FOR EVALUATING TAN ¢

Like the other trigonometric functions, there are several series and methods to evaluate TAN ¢. Below is a method that involves continued fractions which are basically "never-ending" compound fractions where each successive denominator is predictable via a formula. The advantage of using the continued fraction below is that many "levels" of it can be simplified to a single fraction, hence only one division operation needs to be performed. Showing this simplification process algebraically using a generic representative or symbolic continued fraction:

$$\cfrac{A}{B + \cfrac{C}{D + \cfrac{E}{F + \;.\;.\;.}}} \qquad \text{OR=:} \qquad \cfrac{A}{B + \cfrac{C}{D + \cfrac{E}{F + \;.\;.\;.}}}$$

To simplify continued fractions, begin by combining the fractions in the denominators, starting with the "lowest denominator" or fraction and working "upwards" to the first numerator:

$$D + \frac{E}{F} \;=\; \frac{FD + E}{F}$$

and the partially simplified continued fraction is:

$$\cfrac{A}{B + \cfrac{C}{\cfrac{FD + E}{F}}}$$

continuing the simplification process:

$$\cfrac{A}{B + \cfrac{CF}{FD + E}}$$

$$\cfrac{A}{\cfrac{BFD + BE + CF}{FD + E}}$$

$$\frac{AFD + AE}{BFD + BE + CF}$$

: a simplified form of several levels of the continued fraction shown above.
This simplification has only one numerator, and one denominator.

The continued fraction shown below for TAN ¢ was developed by a Swiss-German mathematician named **Johann Heinrich Lambert** (1728-1777) born in Switzerland, and it based upon **Euler's Continued Fraction Formula** made in 1748 and of which a (converging in value) compound fraction can sometimes be made to solve for certain values. These compound fractions are actually another form or notation of the more standard common series of terms used to find the same value, such as for e^x, log(1+x), sin x, cos x, arcsin x, arctan x, etc. Continued, compound and converging fractions can be an interesting mathematical study in itself.

Below, in the continue fraction, the angle (X) must be a radian angle since degree units for angles are rather arbitrary man-made values, whereas radian units are essentially defined naturally with the dimensions of any circle.

$$\text{TAN } X = \cfrac{X}{1 - \cfrac{X^2}{3 - \cfrac{X^2}{5 - \cfrac{X^2}{7 - \cfrac{X^2}{9 - \cfrac{X^2}{11 \; . \; . \; . \text{ (and so on)}}}}}}}$$

: TAN X continued fraction

The simplified form of all the 6 "tiers", "levels" or divisions shown is:

$$\text{TAN } X = \frac{10395X - 1260X^3 + 21X^5}{10395 - 4725X^2 + 210X^4 - X^6}$$

: **A FORMULA FOR EVALUATING TAN ¢**

With the expression above, you can expect almost 7 decimal places for an angle of 70° (about 1.2217 radians). Expect 9 decimal places for an angle of 57.3° (about 1 radian), and more for lower angles when using the same number of "tiers" or "levels" (ie. denominators or divisions).

Note for example that you can quickly calculate powers of a value (here, such as X) by "reusing" precalculated values:

$5^4 = (5^2)(5^2) = (25)(25) = 625$ then:
$5^5 = (5^4)(5^1) = (625)(5) = 3{,}125$

This can be algebraically expressed as: $X^n = (X^{(n-1)})(X^1) = X^{(n-1)}X$

For angles greater than 45°, in particular those closer to 90°, you can use the derivation below for improved accuracy.

From the trigonometric co-functions of angles A and B of a right triangle:

$$\text{TAN } A = \frac{\text{SIN } A}{\text{COS } A} = \frac{\text{COS } B}{\text{COS } A} = \frac{\text{COS } B}{\text{SIN } B} = \frac{\text{SIN } A}{\text{SIN } B} = \text{COT } B = \text{COT }(90° - A) = \frac{1}{\text{TAN } B} = \frac{1}{\text{TAN }(90° - A)}$$

, and $90° = 1.570796327$ radians $= \pi/2$ radians

$$\text{TAN } X = \frac{1}{\text{TAN }(\pi/2 - X)} = \frac{1}{\text{TAN }(1.570796327 - X)}$$

: X is a radian angle

Here is an identity and a short table which will allow you to calculate TAN X by evaluating the tangent of a smaller angle, in particular as shown below, an angle of 10° or less where you can expect an accuracy of 9 or more significant digits when using the simplified continued fraction shown above:

$$\text{TAN }(\text{¢}1 + \text{¢}2) = \frac{\text{TAN ¢}1 + \text{TAN ¢}2}{1 - (\text{TAN ¢}1)(\text{TAN ¢}2)}$$

: TANGENT OF THE SUM OF TWO ANGLES FORMULA

A small table is presented below to aid your calculations. The second column contains the radian equivalent of the degrees angle. The appendix contains a table with more values entered.

TAN degrees = TAN radians = TAN ¢

TAN 1° = TAN 0.017453292519943 = 0.0174550649282
TAN 2° = TAN 0.034906585039887 = 0.0349207694917
TAN 3° = TAN 0.05235987755983 = 0.0524077792830
TAN 4 ° = TAN 0.069813170079773 = 0.0699268119435
TAN 5° = TAN 0.087266462599716 = 0.0874886635259
TAN 6° = TAN 0.10471975511966 = 0.1051042352657
TAN 7° = TAN 0.1221730476396 = 0.1227845609029
TAN 8° = TAN 0.13962634015955 = 0.1405408347024
TAN 9° = TAN 0.15707963267949 = 0.1583844403245

TAN 10° = TAN 0.1745329251994 = 0.1763269807085
TAN 20° = TAN 0.3490658503989 = 0.3639702342662
TAN 30° = TAN 0.5235987755983 = 0.5773502691896
TAN 40° = TAN 0.6981317007977 = 0.8390996311773
TAN 50° = TAN 0.8726646259972 = 1.191753592594
TAN 60° = TAN 1.047197551197 = 1.732050807569
TAN 70° = TAN 1.221730476396 = 2.747477419455
TAN 80° = TAN 1.396263401595 = 5.671281819618

Ex. Evaluate TAN 74°

We can look-up (find) the value of TAN 70° from the above table, and then use the continued fraction to calculate the value of TAN 4°:

$$\text{TAN } 74^\circ = \text{TAN } (70^\circ + 4^\circ) = \frac{2.747477419 + \text{TAN } 4^\circ}{1 - (2.747477419)(\text{TAN } 4^\circ)}$$

: only one division needed, especially when done "by hand" without a calculator.

TAN 4° = TAN 0.06981317 = 0.069926811

$$\text{TAN } 74^\circ = \frac{2.747477419 + 0.069926811}{1 - (2.747477419)(0.069926811)}$$

TAN 74° = 3.487414444

When one of the angles used is 45°, the tangent of the sum of two angles formula reduces to simply :

$$\text{TAN } (45^\circ + ¢) = \frac{1 + \text{TAN } ¢}{1 - \text{TAN } ¢}$$

: special tangent rule for the sum of two angles

You can also evaluate TAN X indirectly as indicated in the above trigonometric identities for TAN X, from one of the other trigonometric identities, and vice-versa. For example:

$$\text{TAN X} = \frac{\text{SIN X}}{\text{COS X}}$$

A DERIVATION OF THE ARCSIN SERIES

To give you validity and confidence using the ARCSIN X and other similar series, the fundamental steps of the derivation of the ACRSIN X series are presented below.

First, the Binomial Series is a series expansion for expressions of the form: $(x+1)^a$, or its equivalent: $(1+x)^a$. We see that this expression is a power of a binomial or two terms expression. The Binomial Series can be derived from a Maclaurin Series expansion of $(1+x)^a$, or from the Binomial Formula that is discussed ahead. Remember, binomial means two terms, and for the binomial series below, one term must be the value of 1. The binomial series will be used further ahead in this derivation of the series for ARCSIN X.

Binomial Series general format:

$$(1 + x)^a = 1 + \frac{ax^1}{1!} + \frac{a(a-1)x^2}{2!} + \frac{a(a-1)(a-2)x^3}{3!} + \frac{a(a-1)(a-2)(a-3)x^4}{4!} + \ldots \qquad : \textbf{Binomial Series}$$

Here is a simple example to verify the Binomial Series by solving $(1 + 4)^3$. First, this could easily be solved by using the order of operations or by "extending" the binomial by using distribution. The result is $5^3 = 125$. Letting a=3 and x=4:

$$(1 + 4)^3 = 1 + \frac{(3)4^1}{1} + \frac{(3)(2)4^2}{2} + \frac{(3)(2)(1)4^3}{6} + \frac{(3)(2)(1)(0)4^4}{24} + \quad \text{(all further terms will also include the factor of 0).}$$

$$(1 + 4)^3 = 1 + 12 + \frac{96}{2} + \frac{384}{6} + 0 + 0 + \ldots$$

$$(1 + 4)^3 = 1 + 12 + 48 + 64$$

$$(1 + 4)^3 = 125$$

The derivative of ARCSIN X is: $\frac{1}{\sqrt{1 - X^2}}$ or= $(1 - X^2)^{(-1/2)}$, and this is derived below:

Since ARCSIN X is the corresponding angle (¢) associated with the sine value that is equal to X, the derivative of ARCSIN X is the instantaneous rate of change of the angle (¢) with respect to the SIN value = X, of that angle. It was previously shown that the derivative of SIN ¢ with respect to the ¢ is equal to COS ¢. If we let X represent the angle here, this can be expressed as:

$$\frac{d(\text{SIN } X)}{d(X)} = \text{COS } X$$

There is a simple way to verify this: notice on the graphing of the SIN X curve, that at 0°, the slope of the curve, and hence derivative, appears to be 1 (such as for the tangent value of 45°), and that is what COS 0° equals. At 90°, the slope of the (now horizontal) curve is obviously 0, and that is what COS 90° equals. This leads to the fact that the COS and SIN curves are essentially a derivative curve of each other. The actually numeric values of the SIN and COS derivatives are also negative in value to each other, and this can bee seen on the curves where as one curve is sloping upward with a positive value, the other curve is sloping downward with a negative value for a given angle in question.

Given ¢ = Y = ARCSIN X = SIN^{-1} X, therefore, X = SIN Y

We are to find $\frac{dY}{dX}$: the derivative of Y with respect (in reference) to X.
Or in common words: The derivative of the angle with respect to the SIN of that angle: d¢ / d SIN ¢

Since $\text{¢} = Y = \text{ARCSIN } X$, the above is equivalent to:

$$\frac{dY}{dX} = \frac{d(\text{ARCSIN } X)}{dX} \quad \text{or: } = \frac{d\,\text{¢}}{d\,\text{SIN } \text{¢}} \quad \text{, therefore:}$$

Since $X = \text{SIN } Y$, then $d(X) = dX = d(\text{SIN } Y)$: expressing the derivative or differential (infinitely small change) of both sides

And we know now: $\frac{dX}{dY} = \frac{d(\text{SIN } Y)}{dY} = \text{COS } Y$: here, Y is an angle

From the "Pythagorean-like" trigonometric identities:

$\text{SIN}^2 Y + \text{COS}^2 Y = 1$ mathematically:

$\text{COS}^2 Y = 1 - \text{SIN}^2 Y$

$\text{COS } Y = \sqrt{1 - \text{SIN}^2 Y}$ therefore:

$\frac{dX}{dY} = \text{COS } Y = \sqrt{1 - \text{SIN}^2 Y} = \sqrt{1 - X^2}$: since as noted above, $X = \text{SIN } Y$

By taking the reciprocal of the above:

$$\frac{dY}{dX} = \frac{d(\text{ARCSIN } X)}{dX} = \frac{1}{\sqrt{1 - X^2}} \quad \text{or=} \quad (1 - X^2)^{-1/2}$$

It can also be shown that $\frac{d(\text{ARCCOS } X)}{dX} = -\frac{1}{\sqrt{1 - X^2}}$: nearly the same expression, but is negative in sign

As a verification to this derivative, let's consider using the chain rule for finding derivatives.

Let $x = \sin \text{¢}$ then $\text{¢} = \arcsin x$

Taking the derivative of both sides:

$$\frac{d(x)}{dx} = \frac{d(\sin \text{¢})}{dx}$$

Using substitution, we can show that we have a function of a function, and that the chain rule should be employed:

$$\frac{d(x)}{dx} = \frac{d(\sin(\arcsin x))}{dx}$$

We see that sin ¢ is the outer function which is then a function of the inner function of: $\text{¢} = \arcsin x$. That is, sin ¢ is a function of the angle. The derivative of x with respect to x is 1. The derivative of sin ¢ is cos ¢. Continuing with the derivative, we find:

$1 = \cos \text{¢} \left(\frac{d\,\text{¢}}{d\,x}\right)$ using the trigonometric identity for cos ¢, and $\text{¢} = \arcsin x$:

$1 = \sqrt{1 - \sin^2 ¢}\ \frac{(d \arcsin x)}{(dx)}$ since x = sin ¢:

$1 = \sqrt{1 - x^2}\ \frac{(d \arcsin x)}{(dx)}$ which can be expressed mathematically as:

$$\frac{d \arcsin x}{dx} = \frac{1}{\sqrt{1 - x^2}} = \frac{1}{(1 - x^2)^{(1/2)}} = (1 - x^2)^{(-1/2)}$$

Note also that the derivative of this trigonometric-transcendental function is a definite algebraic function.

Expanding the ARCSIN X derivative using the Binomial Series, letting $a = -\frac{1}{2}$, and $x = -X^2$:

$$1 + \frac{\left(\frac{-1}{2}\right)\left(\frac{-X^2}{1}\right)^1}{1!} + \frac{\left(\frac{-1}{2}\right)\left(\frac{-3}{2}\right)\left(\frac{-X^2}{1}\right)^2}{2!} + \dots$$

Note: $(-X^2)^2 = (-1X^2)(-1X^2) =$
$(-1)(X^2)(-1)(X^2) = +1\,X^{(2+2)} = X^4$

$$1 + \frac{X^2}{(2)} + \frac{3X^4}{(2)(4)} + \dots$$

Integrating (essentially the reverse of the derivative process, that is, finding the anti-derivative or function that the derivative was derived from) this term by term and keeping the products in their factored form so that a mathematical pattern can be seen, we get the actual function from which the derivative given above was derived:

$$\text{ARCSIN } X = \frac{X}{1} + \frac{1X^3}{(2)(3)} + \frac{3X^5}{(2)(4)(5)} + \dots$$

$$\text{ARCSIN } X = X + \frac{1X^3}{3!} + \frac{3X^5}{5!} + \dots$$: ARCSIN X SERIES

FINDING ARCCOS X

Rather than use a new series or some continued fraction to solve for ARCCOS X, you can reuse the ARCSIN X series in a simple formula. The verification of this formula will be presented. Remember, the formula returns a radian angle and then you can convert it to its equivalent degree angle if needed.

ARCCOS X = $\frac{\pi}{2}$ - ARCSIN X : X is a radian angle, this is equivalent to: ARCCOS ¢ = 90° - ARCSIN ¢. This trigonometric identity is due to complementary angles which sum to 90°.

$\frac{\pi}{2}$ = 1.570796327...

ARCCOS X = 1.570796327 - ARCSIN X

The above method to solve for ARCCOS X using the ARCSIN X series is derived from the concept of the complementary angles of a right triangle:

COS A = SIN B : the trigonometric cofunctions of complementary angles that sum to 90° are equivalent in value

and: A = 90° - B
A = 90° - ARCSIN (SIN B) in terms of radians:
A = $\frac{\pi}{2}$ - ARCSIN (SIN B)

A = 1.570796327 - ARCSIN (SIN B) Due to the cofunctions of complementary angles: COS A = SIN B:
A = 1.570796327 - ARCSIN (COS A) or in a more general form:
¢ = 1.570796327 - ARCSIN (COS ¢) : using radians for the units of the ¢

Ex. If COS ¢ = 0.3 , what is the angle?

¢ = 1.570796327 - ARCSIN (0.3)
¢ = 1.570796327 - 0.304692654
¢ = 1.266103673 = 72.54239688°

Here are some other trigonometric identities:

From: COS ¢ = $\sqrt{1 - \text{SIN}^2 ¢}$

ARCSIN X = ¢ = ARCCOS (COS ¢) = ARCCOS $\sqrt{1 - \text{SIN}^2 ¢}$: also, ¢ = ARCTAN (TAN ¢)

Since X = SIN ¢:

ARCSIN X = ARCCOS $\sqrt{1 - X^2}$

From: SIN ¢ = $\sqrt{1 - \text{COS}^2 ¢}$

ARCCOS X = ¢ = ARCSIN (SIN ¢) = ARCSIN $\sqrt{1 - \text{COS}^2 ¢}$

Since $X = \text{COS}$

$$\text{ARCCOS } X = \text{ARCSIN } \sqrt{1 - X^2}$$

If you want to use the ARCTAN X series to evaluate ARCCOS X:

From: $\text{TAN } ¢ = \dfrac{\sqrt{1 - \text{COS}^2 ¢}}{\text{COS } ¢}$

Therefore: $\text{ARCCOS } X = ¢ = \text{ARCTAN } (\text{TAN } ¢) = \text{ARCTAN } \dfrac{\sqrt{1 - \text{COS}^2 ¢}}{\text{COS } ¢}$

Since $X = \text{COS } ¢$

$$\text{ARCCOS } X = \text{ARCTAN } \frac{\sqrt{1 - X^2}}{X}$$

SERIES FOR ARCTAN ¢

$$\text{ARCTAN } X = \sum_{n=0}^{n=\infty} (-1)^n \frac{X^{(2n+1)}}{2n+1} \qquad : |X| \le 1$$

Expanding the terms:

$$\text{ARCTAN } X = X - \frac{X^3}{3} + \frac{X^5}{5} - \frac{X^7}{7} + \frac{X^9}{9} - \frac{X^{11}}{11} + \frac{X^{13}}{13} - \frac{X^{15}}{15} + \frac{X^{17}}{17} - \ldots$$

When X is greater than one you can convert X to the angles equivalent sine value and evaluate this value in the ARCSIN series. This series above is based on the term by term expansion of the derivative of TAN X, and then taking the anti-derivative of each term. The ARCTAN X series shown above, created by Leonhard Euler, converges to the true value so slowly that it is practically useless to use. There are some other similar ARCTAN series that converge to a specific (true) value using much fewer terms and their derivation is beyond the scope of this book. Here are some more practical ways or formulas to evaluate ARCTAN X :

From: $\text{SIN } \text{¢} = \dfrac{\text{TAN } \text{¢}}{\sqrt{1 + \text{TAN}^2 \text{¢}}}$

$$\text{ARCTAN } X = \text{¢} = \text{ARCSIN}(\text{SIN } \text{¢}) = \text{ARCSIN}\left(\frac{\text{TAN } \text{¢}}{\sqrt{1 + \text{TAN}^2 \text{¢}}}\right)$$

But since X = TAN ¢,

$$\text{ARCTAN } X = \text{¢} = \text{ARCSIN}\left(\frac{X}{\sqrt{1 + X^2}}\right)$$

These equations at first do look a bit odd, but given any angle with its unique SIN, COS, and TAN values, the INVerse or ARC of each resolves back to the exact same angle:

$$\text{¢} = \text{ARCTAN}(\text{TAN } \text{¢}) = \text{ARCSIN}(\text{SIN } \text{¢}) = \text{ARCCOS}(\text{COS } \text{¢})$$

Here is another derivation of a formula for ARCTAN X:

From $\text{COS } \text{¢} = \dfrac{1}{\sqrt{1 + \text{TAN}^2 \text{¢}}}$

$$\text{ARCTAN } X = \text{¢} = \text{ARCCOS}(\text{COS } \text{¢}) = \text{ARCCOS}\left(\frac{1}{\sqrt{1 + \text{TAN}^2 \text{¢}}}\right)$$

Since X = TAN ¢,

$$\text{ARCTAN } X = \text{ARCCOS}\left(\frac{1}{\sqrt{1 + X^2}}\right)$$

: this is almost identical to the ARCIN X equivalence for ARCTAN X shown above except that it has X in the numerator.

Here is a continued fraction developed by a mathematician named **Johann Lambert** (1728-1777), from Switzerland-Germany-France, so as to evaluate ARCTAN X. The result is a radian angle. The result here is much easier to obtain than by using the series previously shown:

$$\text{ARCTAN } X = \cfrac{X}{1 + \cfrac{1X^2}{3 + \cfrac{(2X)^2}{5 + \cfrac{(3X)^2}{7 + \cfrac{(4X)^2}{9 + \cfrac{(5X)^2}{11}}}}}}$$

: **ARCTAN continued fraction**

This continued fraction is similar to the one for TAN X. This fraction also converges slower, but it is still practical. The pattern is not too difficult to recognize. Each denominator is the next odd integer plus a term that contains the square of the product of the next integer and X. This method is good for values of X less than or equal to 1 (X<=1). The lower X is, the less "tiers" or "levels" (essentially divisions) of the continued fraction required for a specific number of correct digits.

Here is a simplified form of the 7 levels of the continued fraction shown above:

$$\text{ARC TAN } X = \frac{387660\,X + 300680\,X^3 + 50332\,X^5}{387660 + 429900\,X^2 + 116100\,X^4 + 8100\,X^6}$$

To give you an idea of the results using the above expression, when X is close in value to 1, you can expect 3 decimal places of accuracy. When X = 0.5, you can expect 5 decimal digits of accuracy, and when X = 0.2, you can expect almost 9 decimal digits of accuracy. Using this expression, all results will be slightly lower than the true value.

Here is a method you can use when x>1:

From the trigonometric co-functions of the complementary angles being equal:

$$\text{TAN } A = \text{COT } B = \frac{1}{\text{TAN } B}$$

: where (TAN B) has a value > 1,
then COT B and TAN A will be < 1

And from the sum of complementary angles:

$$B = 90° - A$$

in terms of radians:

$$B = \frac{\pi}{2} - A$$

$$B = 1.570796327 - A$$
$$B = 1.570796327 - \text{ARCTAN}(\text{TAN } A)$$
$$B = 1.570796327 - \text{ARCTAN}(1/\text{TAN } B)$$

or in a more general form:

$$¢ = 1.570796327 - \text{ARCTAN}(1/\text{TAN } ¢)$$

Ex. If the tangent value in question is 1.333333333, the angle is:

Since this tangent value is greater than 1, lets convert it to its corresponding tangent value of its complementary angle:

If we let 1.33333333 = TAN B , then for its complementary angle, angle A, TAN A, is:

$$\text{TAN A} = \frac{1}{\text{TAN B}} = \frac{1}{1.333333333} = 0.75$$

$\text{¢} = 90° - \text{ARCTAN (TAN complementary angle)}$ converting 90° to its equivalent radian units angle:
$\text{¢} = (\text{Pi}/2) - \text{ARCTAN } (0.75)$
$\text{¢} = 1.570796327 - \text{ARCTAN } (0.75)$
$\text{¢} = 1.570796327 - 0.643501108$
$\text{¢} = 0.927295218 = 53.13010235°$

The ARCTAN X formula can also be utilized to evaluate ARCSIN X and ARCCOS X. Given the angles sine or cosine value, convert this value to the angles corresponding tangent value.

$$\text{From TAN ¢} = \frac{\text{SIN ¢}}{\text{COS ¢}} = \frac{\text{SIN ¢}}{\sqrt{1 - \text{SIN}^2\text{ ¢}}} = \frac{\sqrt{1 - \text{COS}^2\text{ ¢}}}{\text{COS ¢}}$$

Ex. Evaluate ARCSIN 0.8 using ARCTAN X

$$\text{TAN ¢} = \frac{0.8}{\sqrt{1 - 0.8^2}} = 1.33333333$$

$\text{¢} = \text{ARCSIN } 0.8 = \text{ARCTAN } 1.33333333 = 0.927295217 = 53.13010235°$:as shown above

THE BASIC FORMAT OF A C LANGUAGE COMPUTER PROGRAM

Below is a basic format of a c language program. The next program after this one contains some more notes about the C programming language. This book is not about C programming, but contains some helpful math computer programs written in the C programming language, and so some minimal discussion about it is needed for people who have not seen and-or used it before. The reader is also encouraged to obtain some entry level C programming books if they wish to know more and to create and-or edit their own programs which can do something useful such as calculate a value. The program addnumbers.c is shown further below and it utilizes this basic and common format discussed next.

```
/*-------------------------------------------------------------------------------------------
   myprogram.c

   C source and text code, and saved as myprogram.c

   (c) date,  name     Ex.  (c)  June 10, 2021 by J.P.A.

   Compiler and-or version used.

   Program description and or notes, edits and updates.

   Use a plain text editor to write a C program. This source
   code which is quite readable with practice, will be then
   converted to an .exe or executable code that the computer
   can utilize.  A C language compile program will do this conversion.

  This program below shows a basic format of a C programming
   language program.  Every C program must start with the default
   starting or entry point that is called: main and this is actually
   the name of an instance of a C programming structure called a
   function.  C can have many functions that are called by their
   uniquely assigned  name such as:   addnumbers()  or
   get_text_string(), etc.  A function is usually terminated from
   being run or executed when it encounters the return keyword
   and program flow command.  The program will resume after the
   point where the function  was called.  Data can be sent to a
   function to work with, and a function can also create a value
   within it and return it to the calling point in a program.  Once a
   function is written, it can be used over and over millions of
   times and with different data values sent to it, accessed by it,
   calculated by it, and-or returned from it.  When a function and-or
   its program code is called to be  ran or processed, it will have a
   format of:

   function_name(arguments to be sent to the function separated by a comma);
   or simply:

   function();  if the function is void (ie., absent) of any arguments
   such as the value(s) of the variable(s) to be sent to it, and so as to be
   used by it.

   For the actual function program itself, its syntax will also include the
   data type of each of the arguments or variables sent to it, with each
   separated by a comma:
```

function_name(data_type argument1 , data_type argument2 , . . .)
Ex: function_name(char c, int n, float height, float width);

Generally unseen, even to the programmer, is that when a function is called to be ran or processed, the current location and local variables and their values of the current function being ran or processed are first stored in a memory area called a "stack", and so that when that location, directly after the function call is returned to, that function or program code can continue directly after at where it was interrupted by the function call. Sometimes it is said that the "(local) environment" data is stored on the (memory) stack. In ("low-level, near pure machine language) Assembly language computer programming, it uses instructions or commands such as: PUSH to place data onto the stack, and POP to read and remove that data from the (memory) stack, in a reverse type of manner. The stack process is handled by the computer's operating system (such as DOS or Windows) which handles or oversees the .EXE ("executable") program being ran or processed.

The program below just has one function, the main function, and this can be expressed here as: main()

The "body" (program code) of a function or loop, etc., is placed within or "delimited" (defined, marked) by the formal syntax using curly braces: { };

This program was compiled in the same directory as the tcc.exe program. It can be compiled using a DOS or system command such as: TCC myprogram.c

A batchfile of commands is a list of DOS or system commands to be run, executed or performed one after the other, and you can use something like this text and save it as something like:

Compile_myprogram.bat
Double click on a batchfile to run it, much like how any other computer program is started or run:

```
REM  myprogram.bat to compile myprogram.c
@echo off
tcc ./myprogram.c
rem Or perhaps tcc myprogram.c
echo press a key
pause
```

The compiled program can be run by clicking on its icon, its filename.exe and-or by typing its name with or without the .exe filename extension on a new DOS or system command line.

If your computer system is in the DOS or command line mode, you can type EXIT to go back to the Windows system mode.

A simple batchfile to go to the current directory or folder of which it is in is:

```
REM CurrentDiretory.bat to goto the current directory
cmd.exe
EXIT
```

Type the above batch commands into a text editor as a plain, pure textfile and save and-or rename it with a **.**bat filename extension and not the **.**txt filename extension.

To see a list of files in a directory, enter DIR. To see a list of some or most DOS commands, enter HELP . To get information on using a DOS command enter the command name followed by /?. Books are available about creating batchfiles of DOS commands. A batchfile is essentially a program written with the DOS language (ie., commands).

Here is an actual basic C program example below that you may compile:

```
/*--------------------------------------------------------------------------------------------------
addnumbers.c

A program to add two user input numbers and displays the result or sum.

 (c) JPA  2021
  Version 1.0 , Compiled with the tinyC compiler.
--------------------------------------------------------------------------------------------------*/
void main(void)                /* : Required or default starting function of a C program. */
{                              /* : The function body is placed within braces */
double number1=0.0;            /* : Declares a variable to hold a data type that
                                    is a double precision floating-point data value
                                    or number,  and initialize or assign it with 0.0  */
double number2=0.0;            /* A float means floating-point, adjustable or movable */
                               /* decimal point location within the number  */
double result=0.0;

printf("Input Number 1 :  ");     /* : A statement to  display a line of text.       */
scanf("%lf",&number1);           /*  : Let the user input the value of number 1. */
                                 /*   Statements and other C programming
                                       structures are ended with a semicolon.  */

printf("\nInput Number 2 : ");   /* : Display a line of text on the next line */
scanf("%lf",&number2);          /* : Let the user input the value of number 2 */
                                /*   %f is a format specifier of the type of data
                                     that will be entered, and it will be stored
                                     in the address assigned to hold the data of
                                     the variable identified as  number2.        */
/* To add explicit numbers or "hard-coded numbers" and-or variables with
   any value they may be,  use the + = add operator.  Use - to subtract.
   Use * to multiply.  Use / to divide.                                       */

result = number1 + number2;   /* Add the value of number1 and number2
                                 and store the result in variable called
                                 result. */

/* Display the values and the result.  Note below that %lf format specifier
can be used but %g is used to eliminate any possible trailing 0's from being
displayed.  Each format specifier must have an argument associated with it,
and those are expressed one after the other with a comma. Format specifiers
```

```
are not displayed, but are placeholders and will be substituted with the print
function () argument or data associated with it in function call (ie., use). */

printf("\n%g plus %g is %g",number1,number2,result);

printf("\n\nPress A Key To End The Program: ");
getch();
return;
};        /*  : notice the semicolon syntax used here,and at the end of each full statement */
/*------------------------------------------------------------------------------------------------------------------------*/
```

For the C computer programming language, the syntax for the common math operations is:

Operation	Syntax	
addition	+	: this was shown in the example above, having the basic format of: operand1 operation operand2 = result operand1 + operand2 = sum Ex. 5 + 2 , and the result is 7
subtraction	-	: Ex. 5 - 2 , and the result is 3
multiplication	*	: Ex. 5 * 2 , and the result is 10
division	/	: Ex. 10 / 5 , and the result is 2

A C language, float data type formally means a floating (decimal) point data type. You can imagine a float as an integer value (ie., C's int data type) with some of the data being used as an indicated position where the decimal point should be located in that value. Each data type in C is declared in the program and is then assigned or allotted a fixed number of bytes so as to be large enough to hold that type of data (usually in the form of a binary number(s)).

In the program above, the data type of the numbers to be input by the user was declared as a double (ie., double float), and this is a more advanced form of the simpler float data type which has only about 6 decimal digits maximum of precision possible due to the limited number of bytes assigned to the float data type. A double (or double float) data type has twice the number of bytes assigned to it as compared to that of a float data type, and therefore essentially has twice the number of digits possible. In general, 15 to 16 digits of precision are possible with a double float (binary) data type, and this is good for nearly all practical mathematical applications. It must be remembered that the standard way to save numeric numbers in memory, etc, is in a binary (1's and 0's) numeric form. Numbers are displayed as graphic text characters that have an ASCII code and which can be converted back into numeric form with some of the (text, ASCII) string to numeric conversion functions available in the C programming language. It is also very educational and useful to write your own costume functions to do this such as your own function to input a string in stead of using gets().

The C language and other computer programming languages also have what is called as **unary operations** where the operand is just a single value such as a byte (0 to 255d). C's unary operators are:

Increment: ++   ,   ex: n++   : so as to increment the value of n by 1.0 , hence the same as adding 1 to n.
Decrement: --   ,   ex: n--   : so as to decrement or reduce the value of n by 1.0
Negation: -   ,   ex: -n   : so as to have the negative of the value of n, this is the same as multiplying n by (-1) = negative one
complement: ~   ,   ex: ~n   :so as to invert the state of each bit of n, 1 becomes 0, and 0 becomes 1 Also called the binary or ones complement.
logical not or negation: !   , ex: !n   : inverts the logical result of n , this is like an electric not gate , 0 to 1, or 1 to 0.

A COMPUTER PROGRAM TO MAKE A TRIGONOMETRIC TABLE

```
/* -----------------------------------------------------------------------------------------------------------------------------------*/
TrigonometricTable.c

   This program displays the trigonometric values of angles from 0 to 90 degrees using the C-language
   (input) source code compiler's "built in", or prewritten mathematics trigonometric functions.  Programs
   are shown in this book as to how to create and-or modify your own "homemade" trigonometric and
   other basic math functions for use with a computer.  You may use a text editor to copy the source code
   of these programs, so as to enter it into a compiler program that converts it into a machine or
   computer code ("running" or "executable" [.exe]) program which is basically a list of numbers which
   represent the data, instructions, and memory addresses that will be needed for that program.

   With a DOS compatible (PC) computer, you can redirect the screen output to a file for some programs.
   This method uses something such as shown here in symbolic form :  program_name.exe  >  textfile.txt

   (c) JPA July 20, 2017, March 2019

   The next program in this book briefly discusses some of the basics of the C computer programming
   language.
/*-----------------------------------------------------------------------------------------------------------------------------------*/
#include "stdio.h"
#include "math.h"    /* Used to access C's built in trigonometric functions that were prewritten. */

/*------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
int n=0;

double degreeangle=0.0;
double radianangle=0.0;

long double sin1=0.0;    /* long double float or floating point values have more precision available than a double or float */
long double cos1=0.0;
long double tan1=0.0;

printf("\nDeg       Rad              Sin              Cos              Tan");

printf("\n\n");                                                        /* display two blank spaces */

for(;n<=90;){

   if(n==90){  degreeangle=89.99999999999999; };  /* not generally needed, but keeps tan 90° = undefined,  from
                                                    rolling over to some negative value with the programming language,
                                                    here C, and remains a high value  */

   radianangle=degreeangle * 0.0174532925199433;  /* convert the degree angle to the equivalent radian
                                                      angle measurement needed for the std. sin() in the C language  */

    sin1=sin(radianangle);  /* Calculate the sine of a radian angle using the ANSI standard C's built in math function sin() */
    cos1=cos(radianangle);  if(n==90){ cos1=0.0; };       /* to correct a slight error, garbage; a very small negative value */
    tan1=tan(radianangle);
```

```
/* Lets display the trigonometric values for each angle: */

    printf("%2d  %16.14g  %16.14g  %16.14g  %16.14g",n,radianangle,sin1,cos1,tan1);
    printf("\n");              /* Above, %16.14g is the format specifier for a floating point number with a
                                  display  width of 16 spaces wide, and 14 maximum fractional decimal digits. */
    n=n+1;
    degreeangle=degreeangle+1.0;
    };

printf("\n\nPress A Key");  getch();             /* This keeps the displayed table on the screen and waits
                                                    for a key press by the user to end the program. */
return;
};
/*-------------------------------------------------------------------------------------------------------------------*/
```

Here is the output of the computer program as displayed on the viewing screen:

```
Deg          Rad                          Sin                          Cos                    Tan

 0               0                0                1                0

Before modern electric component, high-speed computers to do many calculations, there were, and still are hand operated calculators to do these calculations for you. A "scientific calculator" is an advanced calculator capable of doing many more mathematical operations than a standard 4-function (mathematical operations) "home calculator", and which came several years later. Before these electronic calculators, there were mechanical calculators that had often had just a few mathematical operations, and which were made of various gears and various levers (such as "cams" for mechanical functions) and other mechanical parts. A mechanical "cash register" is a good example of a mechanical calculator. A slide-rule is a mechanical calculator which could be thought of as an advanced ruler for some low precision calculations. As of the year 2021, slide-rules are rarely used and-or seen, and are more of a collectors item for people who collect all types of calculator machines, computers and devices. Before any type of calculators, look-up tables of previously (ie., pre) calculated values were made and available in books. Look-up tables and-or lists of many types are still used everywhere in modern society, except that they are generally not for mathematical calculations but for sets of corresponding data values that the many people in public can utilize.

A modern electronic computer being a high speed (fast), information processing (electric) machine is internally instructed with, and processes simple binary data ("1's and 0's"), numeric values and results. Decimal values, numbers and-or text can be entered or input at the keyboard, however it will be eventually converted to its binary representation so as to be utilized or processed by the computer, and then perhaps a result will be displayed as a decimal number and-or text character (visual alphabetical letter, number, symbol, etc) on the output screen or printer. In short, the internal language of the computer is binary values being either 1's or 0's (ie, [electronically] "on or off", "set or not-set" as like a switch), and can be thought of as a numeric language.

A COMPUTER PROGRAM TO CALCULATE THE SINE OF AN ANGLE

Below is a computer program to calculate the sine value of a degrees angle. The computer program is shown below and is written using the popular C programming language syntax (essentially the required grammar of the programming language used). By observation, it should not be too difficult to understand and convert it to the BASIC or any other computer language syntax. Some explanation about the program and its syntax will also be given. You may skip over this section if you have no need of learning or understanding any computer language that is used to program a computer to help do things. Most general computer users except a small percentage of people are non-programmers using programs with these necessary calculations done within the program(s).

For the following computer programs as written here, the user must be use a "plain" (ie. basic, using the ASCII text codes only in the source or origin text file) or unformatted (ie., not a [formatted] word processor) input and output text editor and a C language compiler. A compiler is a computer program that will transform or translates the input text, "source code", computer language program to its equivalent or effective "low level" machine-electronic numeric codes for the computers electronic circuitry. In short, the compiler program creates the executable (working, run time) program for the computer.

In program below, many extra notes about C programming and its syntax are given for clarification, however, a new computer programmer is invited to obtain some programming books about the subject of learning computer programming. This book here focuses upon writing some mathematical source code programs with the C Language syntax of computer programming, and specifically for user-made math functions often found on a scientific calculator or computer. These functions are built into the ANSI C language, but its of mathematical importance to show them here.
Here is the format or syntax of a programmers comment or note within programs in the C language: /* comment(s) */

```
/*****************************************************************************************************************************
SINE.C

Two examples of  functions to calculate the trigonometric sine of a
degrees angle value(s) input from the user.  The function implements
the SIN X series.

This function can be improved upon for use with more modern
computers that allow simplicity obtaining greater precision.

Comments are enclosed within these delimiters (bounding, set apart):
   Comments are placed between or inside the forward slash and the star
   character and then the comment is terminated by the  star character
   and a forward slash character.  Comments are not processed by the
   computer, but are notes for the writer or reader of the program to
   review later to help understand the computer program, parts or
   functions within it.  Comment syntax can also be placed around
   program code to omit it, such as for temporary test code.

This text or readable, "high-level" computer code or program requires
a C-compiler to convert it to a "low-level" executable or usable electronic
machine or computer code program consisting of only binary numbers
where each 0 or 1 bit will be represented by a high or low voltage level
to be used by the specific computer processor circuitry within the
computer.

The specific C programming language compiler used was the free (ANSI
compatible) TinyC Compiler which can be obtained or downloaded to your
computer from some websites.  The basic format of the command to compile
a c programming language file (ie. with a input filename like:  myfilename.c)
```

```
is:  tcc myfilename.c  , and this will create or output an .EXE (executable,
"runable" or "operational" computer program file with the file name of:
myfilename.exe    For example, the command:  tcc sine.c  will produce the
sine.exe file.

(c) J.A. 2014
*******************************************************************************************************************************************/

#include "stdio.h"       /* : Required header file, for the inclusion of some prewritten standardized input/output code,
                              such as the printf().   */
#include "math.h"      /* required for use of the prewritten pow() function used in the program */

double SINE(double angle);          /* : forward (prototyping) declaring a (C language, computer) function */
/*    A function, indicated by ( ), is code that can be written once and used over and over when needed,
      and  can be placed into any other program where it can be used or adapted-modified.  Some computer
       programmers concentrate on just writing small and specific computer functions, rather than full programs.

      "double"  essentially means a  double-precision floating point (non-integer) data type.  Here,
       the return value, and also the formal argument or "parameter" that is identified as "angle"
       are declared to have data types of double as opposed to for example an integer data type
       which has fewer bytes of memory assigned to hold its value.
       This function implements the SIN X series.
       The angle argument is in degrees measurement.
       The function's return value (data it sends back or "outputs" to the calling function/program) is
       the trigonometric sine of the angle.
       Accuracy of the return value is 9 digits for any angle between 0 to 90 degrees, almost 10
       digits for lower angles
*/

double SINE2(double angle);         /* : the function prototype of SINE2, and  this helps the programmer and compiler */
      /* This is an alternate method to calculate the sine of an angle.  This method uses
          a loop to calculate each term to add to the sum.  */

/*------------------------------------------------------------------------------------------------------------------------------------------------*/
void main(void)                        /*  an example program to use the SINE() function. */
{                                            /*  main() , or the "main function" is the formalized start of
                                             any C program, and you must include it   */
double angle;                         /* : declaring a variable for use, it is identified as "angle"
                                             and its data type (what kind of values angle will have) is
                                             double.  It is initially set or "initialized" to 45.0.  Technically,
                                             a data type also determines the amount of computer
                                             memory (bytes) to set aside to hold the value(s) of the
                                             corresponding variable.   Basically, a declared variable and
                                             its corresponding name or identifier resolves to be a pointer
                                             or address to a memory location that holds a value or data. */

for(;;){                         /* Defines a loop to be reused or redo the following program code or steps over and over.  */
            fflush(stdin);      /* Optional, clears out any possible garbage values from the keyboard (the standard input)
                                   memory buffer input line, so as to prepare for a  new text (keyboard) input from the user. */
            angle=0.0;
            printf("\n\nEnter the degrees angle (<=90%c) to find the sine value of, or 0 to exit:  ",248); /* 248 is the deg. sym.*/
            scanf("\n%lf",&angle);
```

```
          if(angle<=0.0){ printf("\a");  /* a beep sound */ exit(0);  };
          printf("\nThe sine of %.16g degrees is %.9g  and  %.9g",angle,SINE(angle),SINE2(angle));
        };    /* End of the defined loop, now go back to the start of the loop and let the user enter another value */

/*  This computer code, with a use of the printf() function, above will display the result (the angle and the sine of that
     angle) on the screen.  To "print" (ie., send) the std. output to a printer, disk or memory file, use the fprintf()  function.
     %g is a display or output text format specifier that indicates how the corresponding function argument is
     to be displayed on the computer screen.
     g means to display the corresponding data argument as a floating point value.  16 and 11 are the
     max. number of decimal digits to display, and these values can be changed to be more or less by the
     programmer.  When SINE(angle) is encountered (ie. the SINE function is called), the program code
     to be then run or processed will then take place at this SINE function (below), until a return (to the
     previous or calling code position) statement or other code is encountered.  */

 return;      /*  Essentially ends the computer program.  Sends the (computer processing) control back to the
                "calling program" that called this SINE.EXE program.  Often, the calling program is the computer
                 operating system or program.  */
};
/*-------------------------------------------------------------------------------------------------------------------------------------------------------*/
/*   SINE FUNCTION  ,  SINE()

      This computer function returns a result that is a double float sine value of the double float angle argument.  The angle
      must be a degrees angle.  This function uses the sin x series, in hard coded form,  to calculate sin x.

```

To make the function such as that above more easy to read and comprehend, rather than use many multiplications of the same value by itself, this book has a program to demonstrate a function called integerpower.c that can calculate an integer power of any value.

The trigonometric and other tables in the appendix section of this book were created with the aid of a computer program. Before mechanical or electro-mechanical and-or electronic computers with fast and easy calculations, the only method to create theses tables was manually by "hand" (pen, hand written [scribed], paper, and mind-calculation). Each entry in the table had to be calculated, often by many people working together so as to decrease the effort and time needed, and to check or validate each others results.

Mentioned above was using the fprintf(), "print to file" function to place data into a file. The file must be opened for writing, and it should be closed formally when done writing to the file. To print a string text characters to a file the %s format specifier is generally used. If your program has calculated some numerical values, you can use a function that converts these numbers to text strings first. When text is sent to and saved in a file, to display that text, you will usually name that file so as to have a **.**txt filename extension. Rather than use C's standardized, built in functions to convert numbers to strings, or write homemade functions to do similar, you can use the "print to string or string print" function of **sprintf()**. The alternative to the sprintf() is to say, convert each number to a string using a special function,and then using the strcat() function to catenate or join each string. Using sprintf() makes building strings easy to display on the screen and-or send to a file. The arguments to the sprintf() are very similar to the printf(). The format for sprintf() is:

```
sprintf(char *string, string_with _any_format_specifiers_or_tags , data_arguments_corresponding_to_each_format_tag);
```

Example Computer Program To Directly Make A Text File With Data

```

A COMPUTER PROGRAM TO CALCULATE ARCSINE

```
/*******************************************************************************************************************************
ARCSINE.C

A function to calculate the trigonometric arcsine, or angle value of the input sine value.
The function implements the basic  ARCSIN X series only, and may be improved upon.

(c) J.A. 2018

*********************************************************************************************************************************/

#include "stdio.h"       /* : Required header file, for the inclusion of some prewritten standardized input/output code,
                             such as the printf().   */

double ARCSINE(double sine);         /* : declaring a (C language, computer) function */
/*    Here,  the return value is the corresponding degrees angle value of the input sine value..
      This function implements the basic ARCSIN X series.  */

/*--------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
long double sine;

for(;;){                          /* a loop to reuse or redo the following program code over and over  */
          fflush(stdin);        /* clear out any potential garbage from the keyboard (the standard input)  memory
                                     buffer (temporary memory storage) of the user input text line */
         printf("\n\nEnter the corresponding sine value (up to 1.0)  of the  angle to find");
         printf("\n the corresponding angle, or 0 to exit:  ");
         scanf("\n%lf",&sine);
         if((sine<=0.0) || (sine>1.0)){ printf("*** Input Error ***   \a");  /*  <-- the ASCII bell or  beep sound */   exit(0);   };
         printf("\nThe corresponding angle of sin %.16g  is %.10g degrees",sine,ARCSINE(sine));
                                                                             /* Used .8g as a way to provided some rounding.  */
        };    /* end of the loop, now go back to the start of the loop and let the user enter another value */

return;
};
/*-------------------------------------------------------------------------------------------------------------------------*/
/* ------------------------------   ARCSINE FUNCTION  ----------------------------

     Returns a double float angle value of the double float sine argument.
     This function uses the arcsin x series to calculate arcsin x.   It is possible to
     calculate arcsin x in various other ways to improve accuracy, especially for
     sine values greater than about 0.65 which corresponds to an angle of about
     40 degrees.  For example, for improved accuracy for sin values > 0.5, you can
     convert that value to its corresponding cos value, and then use the arccos x
     series or a trigonometric identity, for example:

    To find arcsin (sin ¢) = arcsin  0.6  , we see that sin ¢ = 0.6, and we can convert this to the angles corresponding cos
    value:

    cos ¢  =  √ 1 - sin^2 ¢    =  √ 1 - 0.6^2    =  √ 1 - 0.36    =  √ 0.64    =   0.8
```

$\sin (x/2) = + - \sqrt{(1 - \cos x)/2}$: sine of half the angle trigonometric identity

$\sin (¢/2) = + - \sqrt{(1 - 0.8)/2} = \sqrt{0.2/2} = \sqrt{0.1} = 0.316227766$

arcsin 0.316227766 = 18.43494882° : multiplying this half-angle by 2 to find the actual angle

(18.43494882°)(2) = 36.86989765°

For the given SINE() function below, which can be improved upon, for increased accuracy, as mentioned above:

At sin 0.1 , the returned value is: 5.739170477 degrees
A calculator returns: 5.739170477 degrees

At sin 0.5 , the returned value is: 30 degrees .
A calculator returns: 30 degrees.

At higher values (>0.5) and higher, the ARCSINE() should be improved upon, as indicated above.

At sin 0.6 , the returned value is: 36.869893 degrees
A calculator returns: 36.86989765

At sin 0.7 , the returned value is: 44.426808 degrees
A calculator returns: 44.427004 degrees

(c) J.A. 2018

```
------------------------------------------------------------------------------------------------------------------------------------------*/

          printf("\nThe sine value of %.6g degrees is %.9g",angle , trigvalue(angle, 1));
          printf("\nThe cosine value of %.6g degrees is %.9g",angle , trigvalue(angle, 2));
          printf("\nThe tangent value of %.6g degrees is %.9g",angle , trigvalue(angle, 3));

        };    /* end of the loop, now go back to the start of the loop and let the user enter another value */

return;
};
/*-------------------------------------------------------------------------------------------------------------*/
```

/* This continued fraction to calculate tan x is credited to **Johann Lambert**:

$$\cfrac{X}{1 - \cfrac{X^2}{3 - \cfrac{X^2}{5 - \cfrac{X^2}{7 - \cfrac{X^2}{9 - \cfrac{X^2}{11}}}}}}$$

. . . (and so on)

Ex. of the above simplified to one fraction, as used below in this program:

$$\text{TAN } X = \frac{10395X - 1260X^3 + 21X^5}{10395 - 4725X^2 + 210X^4 - X^6}$$: A FORMULA FOR EVALUATING TAN ¢

For angles greater than 45 degrees, for improved accuracy with the limited number of terms used:

$$\text{TAN } X = \frac{1}{\text{TAN } (p/2 - X)} = \frac{1}{\text{TAN } (1.570796327 - X)}$$: X is a radian angle

Some trigonometric identities to calculate the other trigonometric values:

$$\sin \text{¢} = \frac{\tan \text{¢}}{\sqrt{1 + \tan^2 \text{¢}}}$$

$$\cos \text{¢} = \frac{1}{\sqrt{1 + \tan^2 \text{¢}}}$$

Another way to improve accuracy is to implement a short table and the trigonometric identity of:

$$\text{TAN } (\text{¢}1 + \text{¢}2) = \frac{\text{TAN } \text{¢}1 + \text{TAN } \text{¢}2}{1 - (\text{TAN } \text{¢}1)(\text{TAN } \text{¢}2)}$$: TANGENT OF THE SUM OF TWO ANGLES FORMULA

/*---------------------------------------------------------------------------------------------------------------------------------*/
```

A COMPUTER PROGRAM TO CALCULATE A ROOT (OR POWER) OF A NUMBER

```
/* -----------------------------------------------------------------------------------------------------------------------------------
    rootN.c    Calculates the nth root of a radicand value using a successive approximation.
               This program can also calculate a power of a number by using an indicated root (x) of
               of (1/x).  The same function was modified to create a power function.
               The functions created in this program use the standard C language pow() function,
               however a homemade pow() can be created and used instead.  A computer program
               called power.c, that is shown further ahead, will also calculate a power a number, and
               it uses the series sum method, and without using any of the standard C-programming
               language math functions to do so.

               Successive approximation will "zero-in" to the correct result, that is, each new or
               successive, intermediate or temporary result will have a greater numerical precision,
               hence more correct (decimal) digits to the right of the decimal point.

    (c) 2018 JPA
-------------------------------------------------------------------------------------------------------------------------------------*/
#include "stdio.h"
#include "math.h"   /* good to include when working with floats and doubles, etc.  It is
                        also needed for this program to work correctly for the C's standard
                        pow() that is used in this program. */

double  rootN(double index, double radicand);
 /* returns the index root value of the radicand
   Ex.    10 =  rootN(2,100);

This function, and specifically its arguments, can also be modified  to find powers:

  To find the second power of 10 = 10^x  = 10^2, the index of the radicand will be
  the reciprocal of this indicated power, here (1/x)=(1/2)=0.5.   100 = rootN(10,0.5);

   To calculate powers of (e), use 2.718281828459045235... as the radicand.  You
   can also make a specific  function(s) to solve for powers of (e).

The rootN() modified to more easily calculate powers is powerN();    */

double  powerN(double base, double exponent);

/* For both of these functions, generally, about 9 loops will usually give 9 or sometimes more
   decimal places of accuracy.  Both of these functions use the C-language pow(), but you can
   create or write your own pow() using the series for (e) and other mathematical steps.  */

};
/*-----------------------------------------------------------------------------------------------------------------------------------*/
```

The above program used the standard C language built in power of a value function: pow()
If you want to make your own power function, here are the main steps:

1. Within a new program, create a power function. For ex: double power(base, exponent);
2. In this power(), calculate the natural logarithm of the given base, and multiply it to the given exponent of that base. This will be equal to the exponent or indicated power of (e). You can call the LN2() as shown within this book, within this power().
3. Convert the indicated power value to the power of (e). You can call the epower() as shown next within this book, within this power().
4. Within the power(), when done calculating the power value, return the calculated power value.

Ex. Find 5^2 , as derived previously in this book:

b^x = e^(a ln b)
5^2 = e^(2 ln 5)   =   (2.71828182845904523536...)^(2 ln 5)

The computer program, shown further ahead, called power.c utilizes the method just described.

A COMPUTER PROGRAM TO CALCULATE A POWER OF (e)

```
/* -----------------------------------------------------------------------------------------------------------------------------------------------
    epower.c

    A homemade function to calculate any indicated power value of (e).

    (c) JA 2018
-------------------------------------------------------------------------------------------------------------------------------------------------*/

#include "stdio.h"

double epower(double exponent);

/*-----------------------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{                                        /*  a sample test program to use the epower()   */
double exponent=0.0;
double power=0.0;

for(;;){                        /* a loop to reuse or redo the following program code over and over  */
        fflush(stdin);       /* clear out any potential garbage from the keyboard (the standard input)  memory
                                  buffer input line */

        exponent=0.0;
        printf("\n\nEnter the exponent of (e):  ");
        scanf("\n%lf",&exponent);

        power=epower(exponent);

        printf("\n(e) to the %.16g power is %.16g",exponent,power);

      };    /* end of the loop, now go back to the start of the loop and let the user enter another value */

return;
};
/*-----------------------------------------------------------------------------------------------------------------------------------------------*/
double epower(double exponent)
{
/* Notes---     Here is the power of (e) series:

                 _n=infinity
                 \
     e^x    =    \       _x^n_              :  0!  =  1   and   x^0 = 1                              : (credited to Euler)
                 /        n!
                 /_____
                  n=0

Expanding the terms of this series:

e^x  =  1  +  x^1  +  _x^2_  +  _x^3  +  _x^4  +  _x^5  +  _x^6  +  _x^7_  +  . . .  : a derivation of this is shown
                        2!        3!       4!       5!       6!       7!               in the appendix section.

Simplifying the factorials:
```

$$e^x = 1 + x^1 + \frac{x^2}{2} + \frac{x^3}{6} + \frac{x^4}{24} + \frac{x^5}{120} + \frac{x^6}{720} + \frac{x^7}{5,040} + \frac{x^8}{40,320} +$$

$$+ \frac{x^9}{362,880} + \frac{x^{10}}{3,628,880} \ . \ . \ .$$

To use an exponent less than or equal to 1 for the series for (e), e^x can be factored to smaller powers of (e):

Ex. e^5.2 = e^(5 + 0.2) = e^5 e^0.2 = e^(wholepart) e^(fractionalpart)

The integer power of (e) can be found by repeated multiplication of e=2.718281829...

Here is another method:

Ex. e^5.2 = e^10 e^0.52

The calculation below is set to return 16 decimal places of accuracy.

```

A COMPUTER PROGRAM TO CALCULATE A NATURAL LOGARITHM

```
/* ----------------------------------------------------------------------------------------------------------------------------------------------
    LN.C    Natural Logarithm.c

    A computer program to calculate the natural logarithm of a number between 0 and <=2.  The program can
    be adapted  to build another natural logarithm program or function  to calculate the natural logarithm of
    higher values, and this is demonstrated below with the LN2() function which is based on the LN().

    In general, as the program is, it is very good for calculating the mantissa values of the logarithms
    on numbers that are less  than or equal to 1.

    (c) J.A. 2018
                                 _n=infinity
                                \
LN  N    =    LN (1+x)    =     \          (-1)^(n+1) .  _x^n_         :N<= 2 , x<=1        : A NATURAL LOGARITHM SERIES
                                /                          n             x=N-1                (Credited to Nicolaus Mercator)
                               /______
                                 n=1

Expanding some initial terms:

LN N  =  LN (1+x)  =   x^1    -   x^2    +   x^3    -   x^4    +  x^5    -   x^6   +  .  .  .          : N <= 2  ,  x <= 1
                        1          2          3          4         5          6                          x = (N-1)

A COMPUTER METHOD TO FIND A POWER OF A NUMBER

This method to find a power of a number utilizes the series of terms sum method, rather than successive approximation. This program and method does not rely upon any of the C-language pre-written standard math functions, and is completely homemade and may be modified if necessary. This program utilizes some of the homemade math functions shown previously in this book so as to create a power of a number function.

```
/* ----------------------------------------------------------------------------------------------------------------------------------------------------
    power.c

    A homemade function to calculate any power value.

    (c) JPA FEB 2018
-----------------------------------------------------------------------------------------------------------------------------------------------------*/
#include "stdio.h"
#include"math.h"

double power(double base, double exponent);
/* required for this function  to calculate any power value, are these two function: */
double LN2(double number);
double epower(double exponent);

/*-------------------------------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
double base=0.0;
double exponent=0.0;
double logarithm=0.0;
double x=0.0;
double N=0.0;

/*  printf("\n%.16g",pow(0.32,0.32)); getch();  just test to compare to, result is 0.6944612105965807, requires math.h */

for(;;){                          /* a loop to reuse or redo the following program code over and over  */
        fflush(stdin);      /* clear out any potential garbage from the keyboard (the standard input)  memory
                                 buffer input line */

        base=0.0; exponent=0.0;
        printf("\n\nEnter the base of the indicated power:  ");
        scanf("\n%lf",&base);
        if( base<=0.0 ){ printf("\a");  /* a beep sound */ exit(0);  };
        printf("\nEnter the exponent of the base: ");
        scanf("\n%lf",&exponent);

        N=power(base,exponent);
        printf("\n%.16g",N);

      };    /* end of the loop, now go back to the start of the loop and let the user enter another value */

return;
};
/*--------------------------------------------------------------------------------------------------------------------------------------------------------*/
```

```
double LN2(double number)

                /* can also program the loop to terminate when the difference between two successive
                    terms is a low value, for example: 0.000001, and this is shown and used right here:           */
                   if(term<=0){ term = -term; };  if(term<=0.0000000000000001){    break; };
```

```
            numerator=numerator*N;
            denominator = denominator+1;
        };    /* end of the for loop */

        logarithm=x+logarithm;

return  logarithm;
};
/*------------------------------------------------------------------------------------------------------------------------------------------------------*/
double epower(double exponent)
{
/* Notes---    Here is the power of (e) series:

                    _n=8_
                   \
        e^x   =     \       _x^n_              :  0!  =  1   and   x^0 = 1
                    /        n!
                   /____
                    n=0

Expanding the terms of this series:

e^x  =  1  +  x^1   +   _x^2_   +   _x^3_  +   _x^4_   +    _x^5_   +   _x^6_   +    _x^7_   +   . . .  : a derivation of this is shown
                          2!          3!         4!          5!          6!           7!                  in the appendix section

Simplifying the factorials:

e^x  =  1  + x^1  +  _x^2_  + _x^3_  +  _x^4_  + _x^5_  +  _x^6_  + _ x^7_  +  __x^8__  +
                       2         6        24       120       720      5,040     40,320

        +   _ x^9__   +     _  x^10__   . . .
            362,880         3,628,880

To use an exponent less than or equal to 1 for the series for (e),   e^x can be factored to smaller powers of (e):

Ex.   e^5.2  =  e^5  e^0.2    =   e^(wholepart)  e^(fractionalpart)

The integer power of (e) can be found by repeated multiplication of e=2.718281829...

Here is another method:

Ex.   e^5.2  =  e^10 e^0.52

The calculation below is set to return 16 decimal places of accuracy.

---------Notes */

A COMPUTER METHOD TO SOLVE EQUATIONS

```
/*--------------------------------------------------------------------------------------------------------------------------------------------
EQSOLVE.C          Computerized Equation Solving
                    (c) J.A. 2014

A minimal basic format for solving any single variable (N) equation by numerical computation using successive
approximation.

Given an equation, start by placing it into the form of this example:

    N = f(N)

, that is, where N is a function of N itself, algebraically, this (N on the left side) cannot be solved for since it is also part of
the solution (on the right side), the way to overcome this is to make the N's ever-so slightly different in value.  We can
identify these two values as something like:  N1 and N2:

   N2 = f(N1)

Ex:

    x^2 + 2x = 15            : a "quadratic" equation, after solving for x
                               (not using the quadratic formula):

    x = sqrt(15 - 2x)          and for the computer solution method below, this is transformed to:

   N2 = sqrt(15 - 2N1)       : sqrt means square-root

                               Or by factoring the common factor x on the
                               left side of the original equation:

    x (x + 2) = 15
    x = 15/(x + 2)             and for the computer solution method below, this is transformed to:

   N2 =  15/(N1 + 2)

The concept is that N2 will be a better approximation to the actual true result value of the equation than N1 is.  N1 is then
set equal to the value of N2, and then the process (ie. equation) is repeated.  Caution must of course be taken in selecting
a value for the initial value of N1. For example, division by 0 will yield in an error.  You can even write the function to
accept an argument that is an initial guess.  Note,  this method below, as of written, will only produce one solution per
equation.  For the example above, the solution for one equation is +3.0 and -5.0 for the other.  Though they are different in
value, they both satisfy the original equation.  Hence, its always a good idea to graph the equation by setting it equal to
zero, and then setting it equal to y, and then plotting points and connecting them with a smooth (true, accurate, without
using straight line segments) curve.  The solutions (of  (x) in the equations expressed this way) will be the points where
the curve crosses the x-axis, where y=0.

The user/programmer can use the function shown next that is called mysqrt( ) as a basic format or example to follow for
their own functions.  The format can even be used to solve for constants.

--------------------------------------------------------------------------------------------------------------------------------------------*/
```

```
#include "stdio.h"

double mysqrt(double X);          /* A homemade square-root math function.  */
                                  /* Here, we let X represent the radicand.      */

/*------------------------------------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
double radicand;                  /* doubles are 8 byte "floating" point data types in C */
double root;

radicand=2.0;
root = mysqrt(radicand);      /* call (transfer computer control or sends the program to) the
                                    mysqrt() function with the argument or variable identified as:
                                    radicand, and receive the "return(ed) value" (the numerical
                                    root) of the function and assign it to the variable identified
                                    as:  root.  The argument to the function can also be an
                                    explicit constant.  For ex.,   root  =  mysqrt(2.0)  */

printf("\nThe square-root of %.16g = %.16g",radicand,root);         /* display the result on the computer screen */

/*
   The output displayed on the screen will look something like:

   The square-root of 2.0 = 1.414213562...
*/

radicand=10.0;                /*  :Let's also find the square-root of 10.0, hence reusing the function already written. */
root = mysqrt(radicand);
printf("\nThe square-root of %.16g = %.16g",radicand,root);

return;
};
/*------------------------------------------------------------------------------------------------------------------------------------------------------------*/
```

```
/*-------------------------------------------------------------------------------------------------------------------------------------------*/
double mysqrt(double X)
{
double N1=1.0;            /* set to an initial guess for this function */
double N2;
double tempx1;
double tempx2;
double diff;               /* for the difference */

                           /* An infinite "for loop" (a program section that can
                              repeat endlessly until it's programmed to stop):   */
for(;;){

     /* - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - - ----------- - - - - - - - - - - - - - - - - - - - - */

                                                                       to, or compared to, the value shown is the
                                                                       mathematical condition (logic or truth) that
                                                                       will determine if the loop should break
                                                                       stop or terminate) right here.   */

    N1=N2;         /* : Preparing for the next iteration (instance or program execution or running) of the loop.    */
   };              /* : THis closing bracket signals no more loop statements to process, so repeat loop          */

return N2;         /* Return computer control back to the program code (the next statement just beyond where
                      the function was called) with the value of N2.  N2 is the square root of X.  */
};
/*---------------------------------------------------------------------------------------------------------------------------------------------*/
```

A COMPUTER METHOD TO SOLVE DIFFICULT EQUATIONS

/*--
EQSOLVE2.C

This program demonstrates a way to solve a **single variable equation** (ie., an equation with just one variable within it, however there may be several instances of it in the equation), and it is very useful to solve difficult equations when there is no known or simple algebraic solution (ie., an equation to do so). This program contains an algorithm I made called a **Fast Algorithm To Solve Equations**. There is a alternative version of this algorithm placed in the **Extras And Late Entries** section at the end of this book that you may prefer. After making a study of this discussion and program, please then check the topic of "An improved algorithm to solve difficult equations", and which is similar and was based on this discussion, but with a slightly better algorithm. The program there with this algorithm is called there is called FESA.C

The relatively short C-language program given below solves for (x) in an example equation that is a multiple term exponential equation of the form:

N1^x + N2^x = N3 or even with more terms such as: RESULT = N1^x + N2^x + N3^x + ...

, and gives about 10 decimal places of accuracy of x. It is a difficult equation without an algebraic solution.

The example below solves the hard coded (set, but can be changed) and specific equation of:

5^x + 6^x = 61 : the solution is x = 2.0 , checking: 5^2 + 6^2 = 25 + 36 = 61

This method below does not use recursion. Its more of a fast "trial and error, precision method" so as to "zero in" (ie., find) the result quicker than simply incrementing it by only a very small amount after each loop. Requires only ten loops max. per correct digit position. Ex. For 9 places, instead of 1,000,000,000 loops for a net increment of 1 in (x) when incrementing by just 0.000,000,001, my process in the worst case requires only 100 loops, and on average (ie. digit 5 of 10 possible digits) of only 50 loops will be required to solve for (x). The program assumes that (x), the variable being solved for is positive. (x) is initially set to 0.0. Following the program are other code samples for other equations.
(c) J.A. 2014
--*/

```
#include "stdio.h"
#include "stdlib.h"
#include "math.h"
#include "float.h"
/*---------------------------------------------------------------------------------------------------------------------------------*/
void main(void)
{
double N1=5.0;              /* a value used in the given equation.  Can make this and other values a user input value. */
double N2=6.0;              /* a value used in the given equation  */
double RESULT=100.0;    /* right side of the given equation      */

double x=0.0;                /* to be found, this can set to a low positive value such as
                                    0.0000000001 if division by 0 error is to be avoided in the algorithm */
double TEMP=0.0;        /* ie. left side of equation */

int n2=0;                     /* outer loop counter variable */
```

```
int n=0;                        /* inner loop counter variable */

double a=1.0;                   /* (variable) increment to be added to current value of the variable (x) */

/* Below is the main algorithm for a fast method to solve an equation.  It is short with only a few lines of code statements,
   but  it is very powerful in terms of what it does.  It is just two loops, and one loop is an inner loop of the outer loop.  It is
   a "brute force" or "trial and error"  type of algorithm, but rather more of a "calculated or fast trial and error" algorithm.*/

/******************************  FAST ALGORITHM TO SOLVE EQUATIONS  *********************************************/

for(n2=0;n2<=15;n2++){     /* outer loop, get 15 digits of the result.  Can adjust this value for other computer systems. */

    for(n=0;n<=9;n++){                          /* inner loop, find a correct digit from 0 to 9 */
          TEMP=pow(N1,x) + pow(N2,x);    /* pow(N1,x) is a function for solving and returning:  N1^x  */
          /* printf("\nTemp = %.15g",TEMP);   optional, display the intermediate temporary result(s) */
          if(TEMP>RESULT){ x=x-a; break; };       /* halt, stop, break from the inner loop */
          x=x+a;   /* increment (x) by (a), so as to have a more accurate value of (x)  */
       };

   if( (TEMP - RESULT) <= 0.0000000000000001){ break; };   /*  break from the outer loop */
    /* if(TEMP==RESULT){ break; };  */       /* optional, break or halt the loop or repetition early if these are already equal */

    a = a/10.0;    /* (a) is essentially the weight of the next digit to find */
  };
/****************************************************************************************************************************/

printf("\nx = %.15g",x);             /* display the value of the independent variable (here, x) solved for */

printf("\n\nChecking the equation with the solved value for x:  ");
printf("\n5^x + 6^x = %.15g + %.15g = %.15g",pow(N1,x), pow(N2,x), pow(N1,x) + pow(N2,x));  /* should = RESULT */

printf("\n\nPress A Key To Exit");  fflush(stdin); getch();

exit(0);
};
/*----------------------------------------------------------------------------------------------------------------------------------*/
```

Here is the output with the hard coded values:

```
x = 2.28768427762655

Checking the equation with the solved value for x:

5^2.28768427762655 + 6^2.28768427762655 = 39.7212301043361 + 60.2787698956639 =100

Press A Key To Exit
```

```
/*--------------------------------------------------------------------------------------------------------------------------------*/
```

Here is code that can be substituted above for finding Square Roots.
For cube roots, the formula is almost identical:

```
   for(n=0;n<=9;n++){
        if((x*x)>N){ x=x-a; break; };       /* where N = root * root = radicand  */
        x=x+a;
```

```
        };

    if((x*x)==N){  break; };
    a=a/10.0;
   };
/*------------------------------------------------------------------------------------------------------------------------------------------------*/
```

This code below will work for cube roots, even when written in a form that cannot be solved with standard iteration:

For the cube root of 10 (or set 10 equal to a variable such as N):

```
for(n2=0;n2<=14;n2++){

    for(n=0;n<=9;n++){
        if(x>(10.0/(x*x))){ x=x-a; break; };              /* : Here N is "hard-coded" to 10.0,  */
        x=x+a;                                            /*   only for this example code.        */
       };

   if(x==(10.0/(x*x))){  break; };
   a=a/10.0;
  };
/*---------------------------------------------------------------------------------------------------------------------------------------------*/
```

Here is the loop code for solving the Cubic equation of: x^3 + x^2 + x^1 + C = 14

For this example here, C is arbitrarily set to 0, but should be coded into the program.

```
   x=2.0

   for(n2=0;n2<=14;n2++){

       for(n=0;n<=9;n++){
          if( (x*x*x + x*x + x)>14.0){ x=x-a; break; };              /* : 14 was "hard-coded" as a constant; best to use a variable */
          x=x+a;                                                     /*   so as to reuse the function for other values.              */
         };

       if((x*x*x + x*x + x )==14.0){  break; };
       a=a/10.0;
     };
/*--------------------------------------------------------------------------------------------------------------------------------------------*/
```

Extra notes on the above fast algorithm for solving a single variable equation:

If solving something such as: 100 = 10^x and using the above method to solve for (x), the indicated power, it will actually be solving for a logarithm value: x = log 100.   You can use any base and number as needed, perhaps (e)=2.718281828 as the base if you need to find a natural logarithms: logarithm = ln Number

If solving something such as: 0.5 = sin(x), it will actually be solving for: x = arcsin 0.5 , and note the value found will be a radian angle because it is natural, rather than the man-made values of degrees. The standard C language function for sin(x) considers the argument, here (x), as a radian angle.

For a dynamic equation or user input equation, such as a text string, after parsing it, perhaps the hard coded equation in this algorithm can be replaced by a hard coded equation such as::   result = term1 + term2 + ... term20 , and where each term is initially set to 0.0

A COMPUTER PROGRAM FOR A SIMPLE MULTI-FUNCTION CALCULATOR

```
/*-----------------------------------------------------------------------------------------------------------------------
calculator.c

    A scientific calculator program.  This program can be improved to
    implement any math function desired into this calculator program.
    Use the examples of the operations shown in this program to
    implement new operations into the calculator.  Look up C's
    prewritten math functions to use, such as in the math.h file.

   This type of calculator program is often called a "line calculator".
   There are various methods to input the desired expressions using
    the standard keyboard as the input mechanism, and the "syntax"
    or proper way to enter them for this program is perhaps the simplest.

    For some computers, you can run multiple instances of this program.

```

SUMMING CONSECUTIVE TERMS OF AN ARITHMETIC SERIES

Given (N) consecutive terms of an arithmetic series, here is how to find the sum of those terms:

Algebraically, the terms of an arithmetic series can be expressed or noted as:

Term (N):	1	2	3	4	5	6	. . .
	F	F+d	F+2d	F+3d	F+4d	F+5d	. . .

Where (F) is the first considered term, term 1, and (d) is the constant difference between each terms value. Consider for example that the third term is the sum of the second term and the difference (d):

(term 3) = (previous term) + d = (term 2) + d = (term 1 + d) + d = (term 1) + 2d = F + 2d

Algebraically summing up the terms:

Term	Term Value	Total Sum Of Terms (A Running Or Continuous Sum Of This Term and All Previous Terms)	
1	F	1F	
2	F + 1d	2F + 1d	: since: (this term) + (previous sum) = (F + 1d) + 1F = 2F + 1d
3	F + 2d	3F + 3d	: since: (this term) + (previous sum) = (F + 2d) + (2F + 1d) = 3F + 3d
4	F + 3d	4F + 6d	
5	F + 4d	5F + 10d	
6	F + 5d	6F + 15d	

Notice in the sum expressions that the first term of each expression can be easily predicted to be NF, however the next term is awkward since the numerical coefficients (C) of (d) appear to be that of some unknown series. There is one "observable formula" for the value of C that will be shown ahead, and can you possibly guess it beforehand? Below is a method of how these constants can be calculated so that the sum of the first (N) terms of an arithmetic series can be evaluated as:

SUM = NF + Cd : SUM OF N CONSECUTIVE TERMS OF AN ARITHMETIC SERIES (*)
F = value of first term, N = number of terms, d = difference, C = numerical coefficient of d

For this analysis, let's say an arithmetic series has a difference (d) value of 2.0, and the first term is 3. We can express the sum of the first 3 terms as:

$$\begin{array}{rcl} S &=& 3 + 5 + 7 \\ +\ S &=& \underline{7 + 5 + 3} \\ 2S &=& 10 + 10 + 10 \end{array}$$

Algebraically adding the sum to itself, using the commutative law:
(Or by multiplying each side by 2, and then distributing it.)

Notice that each term on the right hand side is algebraically equivalent to (F1 + FN), where F1 is considered as the first term, and FN is considered the "last" term considered. Since there are (N) terms in question being added, and each is the same value, we can express this repeated addition with multiplication:

$2S = (F1 + FN)\,N$ solving for S:

$$S = \frac{(F1 + FN)\,N}{2}$$

: **SUM OF N CONSECUTIVE TERMS OF AN ARITHMETIC SERIES**
F1 is the first term value , FN is the last term value, and the common difference (d) between terms is not needed and-or known.

Since $FN = F1 + (N-1)d$ using algebraic mathematical substitution:

$$S = \frac{(F1 + F1 + (N-1)d)N}{2} = \frac{F1N + F1N + dN^2 - dN}{2}$$

$$S = \frac{2F1N + dN(N-1)}{2} = \frac{2F1N}{2} + \frac{dN(N-1)}{2}$$

$$S = F1N + \frac{dN(N-1)}{2}$$

: **SUM OF N CONSECUTIVE TERMS OF AN ARITHMETIC SERIES (based on the first term, and here, the last term is not needed and-or known)**

The first term in this expression above is equivalent to the first term of the expression for S shown previously: NF, (see the indicated * previously). Hence, the sum of the remaining term(s) must also be equivalent in value. That is:

$$Cd = \frac{dN(N-1)}{2}$$

Solving for C (the constant or numerical coefficient of (d)):
(ie., divide both sides by d)

$$\mathbf{Cn = \frac{N(N-1)}{2} = \frac{N^2 - N}{2}}$$

: **For Cn, n here is a subscript of C, that is equal to the term number N** We see that given a term number N, Cn is always a constant value associated with that term number and series, however since C changes in value from term to term, C in therefore not a constant in that aspect.

Checking, the constant of the 5th term should be 10 as indicated above:

$$C5 = \frac{5(5-1)}{2} = \frac{5(4)}{2} = \frac{20}{2} = 10$$

: checks

Checking, the constant of the 6th term should be 15 as indicated above:

$$C6 = \frac{6^2 - 6}{2} = \frac{36 - 6}{2} = \frac{30}{2} = 15$$

: checks

Here is an "observable formula" for C, the numerical coefficient of (d), however, it does not lead to a direct algebraic solution as shown above since it includes the previous value of C:

$Cn+1 = Cn + N$ Ex. $C6 = C5 + 5 = 10 + 5 = 15$

Here is a practical example of summing consecutive terms of an arithmetic series:

Ex. A checkerboard has a total of 8^2 = 64 squares on it. You are to place a (1) grain of salt on the first square, 2 grains on the second, 3 grains on the third, and so on. The grains of salt on each square will be equal to the square number. Each next square will have the number of grains as on the current square, plus one. How many grains of salt will you eventually place on the checkerboard?

This is an arithmetic progression type of problem. Clearly, the difference is 1, and there are 64 squares to consider, there is effectively 64 terms to mathematically consider. The first term is 1.

$$S = F1N + \frac{dN(N-1)}{2} = (1)(64) + \frac{(1)(64)(63)}{2} = 64 + 2016 = 2080 \text{ grains}$$

SUMMING CONSECUTIVE TERMS OF A GEOMETRIC SERIES

Given (N) consecutive terms, which can and will be considered as the first (N) terms of a geometric series below, what is the sum (S) of those terms?

Algebraically, the terms of a geometric series can be algebraically (mathematically, symbolically, generally) expressed as:

Term:	1	2	3	4	5	6	. . .	n
	F	Fr	Fr^2	Fr^3	Fr^4	Fr^5	. . .	Fr^(n-1)

Where (F) is the considered as the first term, and (r) is the constant ratio between consecutive terms. Each next term is found from: (term)(r) = next term. Mathematically , previous term = term = (next term) / r

An expression of algebraically summing up a total of (n) terms:

S = F + F^1r + Fr^2 + Fr^3 + Fr^4 + Fr^5 + . . . + Fr^(n-1)

Now, we can possibly derive a simple formula that is equivalent to the right hand side of this equation. Since each term has a factor of F in it, we can factor it from each term and get this equivalent expression:

S = F (1 + r + r^2 + r^3 + r^4 + r^5 + . . . + r^(n-1))

From the indicated factor to F as shown above within the grouping symbols, and considering just the first 4 terms of it, we can get:

1 + r + r^2 + r^3 factoring (r) out of the terms that contain it:
1 + r (1 + r + r^2)
1 + r (1 + r (1 + r))

The only observable possible formula is from the second term: For a total of (n-2) times, starting with (r) and add 1 to it, and then multiply this growing quantity by (r). This total value will be added to 1. The problem is that this is not a simple formula for the factor F as shown above, since it requires summing and multiplying almost the same number of terms as the series itself.

How about adding the series to itself, just like it was utilized during the derivation of the sum of an arithmetic series? This will not work here since the formula for the sum will simplify to the exact same series. However, rather than effectively multiply each side by 2 as in the sum of an arithmetic series, let's multiply each side of the equation by another value that is directly related to each term of the geometric series, specifically (r):

Let's try a geometric series where the first term is 4, r=2, and 3 terms are to be summed:

Eq. 1: S = 4 + 8 + 16 : r = 2, multiplying each side by (r) we get:

rS = 2(4 + 8 + 16) distributing:
rS = 8 + 16 + 32 which can be written or expressed as:

Eq. 2: rS = 32 + 8 + 16

Subtracting the first equation from the second we get:

rS - S = 32 + 8 + 16 - (4 + 8 + 16) = 32 + 8 + 16 -4 -8 -16 = 32 - 4 = 28

Notice that the only terms (always) left on the right hand side after the subtraction is the first term (F) of the original series and the last term (L) of the "multiplied" series which equals Lr. Noting this algebraically:

$rS - S = L - F$ using substitution for the value of the last term (L):
$rS - S = r^1 (Fr^{(n-1)}) - F$: $r^1 = r$, after distributing:
$rS - S = Fr^n - F$ factoring out common factors:
$S (r - 1) = F (r^n - 1)$ solving for S :

$S = \dfrac{F((r^n) - 1)}{(r - 1)}$: **SUM OF THE FIRST (n) TERMS OF A GEOMETRIC SERIES**
F is the term considered as the first term. (r) is the ratio between successive terms. (n) is the total number of terms.

Checking, the sum of the series shown (Eq. 1) should be 28:

$S = \dfrac{4(2^3 - 1)}{(2 - 1)} = \dfrac{4(8 - 1)}{1} = 4(7) = 28$: checks

If $(r < 1)$, the terms of r^n will approach to be a very small value of practically 0 for an infinite (or near infinite, large number for practicality) number (n) of terms, and the sum of this infinite number of terms will approach or converge to be a specific value of:

$S = \dfrac{F(r^n - 1)}{(r - 1)} = \dfrac{(-1)}{(-1)}\dfrac{F(r^n - 1)}{(r - 1)} = \dfrac{F(-1)(r^n - 1)}{(-1)(r - 1)} = \dfrac{F(1 - r^n)}{(1 - r)} = \dfrac{F(1 - 0)}{(1 - r)}$: as r^n approaches 0, $r^n \longrightarrow 0$

$S = \dfrac{F}{1 - r}$: Sum of terms when $r<1$ and the number of terms(n) approaches infinity

If the first term is F=1 we then have:

$$S = \frac{1}{1 - r}$$

Ex. If the first term is 1, and the ratio between each next or consecutive term is 0.5 (or 1/2):

$1 + 0.5 + 0.25 + \ldots$: in this example series, each next term is half of the previous. There is also an illustrative figure and computer program shown below for this type of series.
$1 + 1/2 + 1/4 + \ldots$

$S = \dfrac{1}{1 - 0.5} = \dfrac{1}{0.5} = 2$: note that the terms of this series are technically endless, yet this algebraic expression gives a definite or specific result.

Here's another observation of the above processes. The multiplying factor to (F) that was previously shown in the sum of (n) terms of a geometric series can be expressed as:

$\displaystyle\sum_{x=0}^{x=(n-1)} r^x$: simplest power series

Expanding the indicated series:

$$1 + r^1 + r^2 + r^3 + r^4 + r^5 + \ldots + r^{(n-1)}$$

Hence when the first term is F=1:

$$S = \frac{1}{1 - r} = 1 + r^1 + r^2 + r^3 + r^4 + r^5 + \ldots \qquad \text{:for this to converge} \quad -1 < r < +1$$

Or as:

$$1 + \sum_{x=1}^{x=(n-1)} r^x$$

Expanding the indicated series:

$$1 + (r + r^2 + r^3 + r^4 + r^5 + \ldots + r^n-1)$$

Equating the two sum formulas:

$$\frac{F ((r^n) - 1)}{(r - 1)} = F (1 + r + r^2 + r^3 + r^4 + r^5 + \ldots + r^{(n-1)})$$

By dividing both sides of this equation by F, or simply equating both of the factors to F, we get:

$$\frac{(r^n) - 1}{(r - 1)} = 1 + r^1 + r^2 + r^3 + r^4 + r^5 + \ldots + r^{(n-1)}$$

Transposing the (+1) term, and switching sides:

$$r^1 + r^2 + r^3 + r^4 + r^5 + \ldots + r^{(n-1)} = \frac{(r^n) - 1}{(r - 1)} - 1$$

If we add (r^n) to each side, we can get a formula (shown on the right side) for the sum of the first (n) integer powers of any value (such as r shown on the left side):

$$r^1 + r^2 + r^3 + r^4 + r^5 + \ldots + r^{(n-1)} + r^n = \frac{(r^n) -1}{(r - 1)} - 1 + r^n$$

Combing terms (ie., the fractions) on the right hand side:

$$r^1 + r^2 + r^3 + r^4 + r^5 + \ldots + r^n = \frac{r ((r^n) -1)}{(r - 1)}$$

: This is essentially the same expression previously derived, but here, r=F.

Another observation here is to note how a function such as on the right hand side of the equation above can be expressed as a sum of a specific series of terms.

Expressing this with summation notation, and letting the base = b = r :

$$\sum_{x=1}^{x=n} b^x = \frac{b((b^n)-1)}{(b-1)}$$

: **SUM OF FIRST (n) INTEGER POWERS OF A VALUE**
b = the base of the power = ratio (r) of the integer powers of it.
or= :

This sum can also be algebraically expressed as: $\mathbf{\dfrac{b^{(n+1)} - b}{b - 1}}$

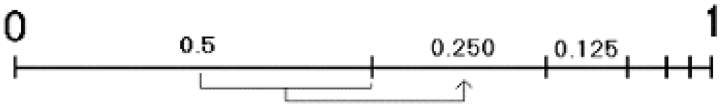
It may have not been apparent, but this is equivalent to the sum of the first (n) terms of a geometric series which has (F) and (r) set to the same value of (b).

Ex. If b=r=2 , and n=10:

$$2^1 + 2^2 + 2^3 + 2^4 + 2^5 + 2^6 + 2^7 + 2^8 + 2^9 + 2^{10} = 2046$$
$$2 + (2^1)2 + (2^2)2 + (2^3)2 + (2^4)2 + (2^5)2 + (2^6)2 + (2^7)2 + (2^8)2 + (2^9)2 = 2046$$
$$2 + 4 + 8 + 16 + 32 + 64 + 128 + 256 + 512 + 1024 = 2046$$

$$\frac{2(2^{10} - 1)}{(2 - 1)} = \frac{2(1024 - 1)}{1} = 2(1023) = 2046$$: the formula checks

Here is an illustrative example of a geometric series that is also a converging (to a specific value) sum of terms. It shows the remaining (fractional) values or terms after repeatedly dividing a value or length, here starting as a value or relative value of 1, by a constant value, here 2. This is the same as repeatedly multiplying the given value by the constant factor of r=0.5, (ie. (1/2) and resulting in "half" of a given value). The sum of all these remaining parts or quotients equals the original value, here 1 (or 100% of the initial value). In short and in a relative fractional or percentage manner, the sum of all the parts or fractions of the whole = 100% = 1. For starting values that are a multiple greater than 1, the terms and resulting sum will then be multiples as that shown for the series shown below that sums to 1: [FIG 214]



$$0.5 + 0.250 + 0.125 + \ldots = 1$$

$$1/2 + 1/4 + 1/8 + \ldots = 1$$

$$1/2^1 + 1/2^2 + 1/2^3 + \ldots = 1$$

$$1 = \sum_{n=0}^{n=\text{infinity}} \frac{0.5}{2^n} \quad \text{or} \quad \text{value} = \sum_{n=1}^{n=\text{infinity}} \frac{\text{value}}{2^n} = \sum_{n=1}^{n=\text{infinity}} \frac{\text{value } 2^{-n}}{1}$$

Note that above, 0.5 / 2^n = 1 / (2)(2^n) = 1 / 2^(n+1).

Note that the above could be expressed as: $x^1 + x^2 + x^3 + \ldots + x^n = 1$: where $x=0.5$ and $n \to$ approaches infinity.
And for just the first two terms: $x^1 + x^2 = x^2 + x = 1$: $x = GR = \sim 0.618$, Extra: $x^2 + x - 1 = 0$

By repeatedly dividing an object (ie., whole=100%) by two and making two pieces that are 50% of the original, it is the fastest way to create very small pieces of a certain size.

A COMPUTER PROGRAM SUMMING A CONVERGING GEOMETRIC SERIES

```
/* GeometricSeries.C     Displaying An Example Geometric Series With A Converging Sum Of Terms.c

   This is an example of repeatedly dividing a value by a value, and the resulting terms get less and less, and the
   sum of  those terms converge (gets closer and closer) to a specific value.  The classic example is repeatedly
   dividing 1 by 2, or multiplying 1 by 0.5, and the sum of all these (half, fractional, value) terms is 1.    Regardless
   of the denominator or (r), the sum is always 100% of the initial or starting value (numerator), and if 1 is used as
   the starting value, the sum is therefore 1.

   The sum of all the pieces or fractions (equivalent, or diminishing in value as for this series of terms) of a value
   is that value.  In general, the number of terms increase only slightly for a fixed denominator, or (r), as the
   numerator increases in value.  The higher the denominator, or the lower that the geometric ratio (r) is since
    (r)=(1/denominator),  the more terms required in the sum to the numerator or starting value since the fractional
    parts or successive terms will be smaller to continue working with.

    In the program below, if the input numerator is set to 1, and the input denominator is set to 2,  the series is the
    classic geometric series with (r) = 1/2 = 0.5 , and each fractional part and term is half of the previous.  This
    produces the terms, which always sum to the starting value, here 1, of:

      1/2  +  1/2^2  +  1/2^3  + . . .  =    0.5 + 0.250 + 0.125 + . . .  =    1      : sum of fractional parts = whole part or value

A DERIVATION AND UNDERSTANDING OF EPSILON (e)

This discussion is to provide some clarity of the constant (e) as found in many scientific, mathematical equations. If needed, please review the topic about Epsilon(e) previously shown in this book. The value of this constant is about: 2.718281828459045235. (e) is sometimes called Eulers number or (John) Napier's constant, epsilon or just plain (e) as seen in equations. (e) is an irrational constant like (pi), but (pi) can easily be described in a single sentence of the form: (pi) is the constant ratio of any, and all, circle's circumference and its diameter. (e) does not have a simple description, and hence its description is often omitted even though it is a very important value like (pi).

Values such as (e), (pi), and an angles trigonometric values are also called non-algebraic, or transcendental numbers, due to the fact that their values cannot be algebraically represented as a power (ex. n^x) value expressed with two rational numbers, that is, a rational base and rational exponent.

At the beginning of the year, say Jan. 1, you decide to deposit one (1) dollar (money) = $1 into a savings account at the First Simple Growth Bank in town. For this starting or "input" amount, the bank claims it will give you money that is one (1) dollar of interest (I) or "growth" at the end of a one year time period, hence doubling your money from 1 dollar to (1 + 1) dollars = 2 dollars. (starting input money + interest money) = $1 + $1 = $2. This is an increase of 100% from the initial starting or input value of $1, hence you can say that the banks interest rate (I) is 100% (or 1 = 1/1 in decimal).

Total = Original Deposit + Interest

$Mt = Mo + IMo$: Mo = original deposit of money. Since the interest rate (I) is 100%, and 100% = 1.0:

$Mt = \frac{Mo}{1} + \frac{(1)Mo}{(1)}$: Mt = total money in the account. Since the original deposit is $1, Mo = $1 = 1:

$2.00 = 1 + \frac{(1)(1)}{(1)(1)}$

You decide to split the total time period of 1 year into n intervals of time. If you let n=2 intervals, then at half the period or end of the first interval within that total time period, you should also receive half the interest since:

I% = (100% / n) = (100% / 2) = 50% or= 0.50 in strict decimal numeric form or= 1/2 in a proper decimal fraction form.

Half of the 1 year time period is: (total time period) / (n time periods) = (1 year) / n = (1 year) / 2 = (1 year)(0.5) = 0.5 years = 12months / 2 = 6 months

Half of the $1 dollar total interest for the year is: ($1 x 0.50) = $0.50 dollars or 50 cents. Your "net worth" or total money (Mt) at the bank at this point or time (6 months) in the total time period of 1 year should be $1.0 + $0.50 = $1.50. We are also considering that the bank allows this method of (partial) interest payment, and for this example, bank or system, we will assume it does. You decide to verify the above calculations using above formula:

$Mt = Mo + IMo$

$Mt = Mo + (50\% \text{ of } Mo) = Mo + 0.5Mo = \frac{Mo}{1} + \frac{(1)(Mo)}{(2)(1)}$

$Mt = \frac{Mo}{1} + \frac{Mo}{2}$ after substitution of values:

$1.50 = \frac{1}{1} + \frac{1}{2} = 1 + 0.5$: which verifies your claim

In general, if you split the interest total time period into N intervals, the (simple, non-compounded) interest you should receive per period is:

$\frac{100\% \text{ of the total interest}}{n} = \frac{1 \text{ (interest)}}{n}$: in decimal form

If n was 4 intervals:

time of each interval = (total time period) / (n time periods) = 1year/4 = 12months/4 = 3 months = 0.25 years

Since if n = 4 intervals, the (simple) interest to expect per interval period of 0.25 years or 3 months is also 0.25 of the total interest: (I):

$\frac{\text{Total Interest}}{n} = \frac{100\% \text{ I}}{n} = \frac{100\% \text{ I}}{4} = 25\%$ of the Interest, and expressing this mathematically:

$Mt = Mo + 0.25$ (Total Interest). Since: (Total interest) = 100% (Total interest) = 100% (1) = 1 = Mo :

$Mt = Mo + (25\% \text{ of } Mo) = Mo + 0.25Mo = \frac{Mo}{1} + \frac{(1)(Mo)}{(4)\ (1)} = \frac{Mo}{1} + \frac{Mo}{4}$

Notice the correlation to the number of time intervals chosen (n) and the denominator of the fractional value of the interest the bank will give you. If a time interval is a certain percentage of the total time period, the partial interest will be the same percentage of the total interest. Rewriting the formula, we get:

$Mt = Mo + IMo$: Here, initially considering the interest as: I = 100% = 1 , that is, as undivided.
For each and every interval of interest payment, I is now calculated to be:
I = 100%/n = 1/n :

$Mt = Mo + \frac{(1)\ Mo}{(n)}$ Factoring out Mo from each term:

$Mt = Mo + \frac{Mo}{n}$ or * $Mt = \frac{Mo}{1} \left(\frac{1}{1} + \frac{1}{n} \right)$: * (more will be said about this further ahead)

For this example where n=2, Mo=\$1, and It = \$1, at the end of the first interval of the 2 total intervals :

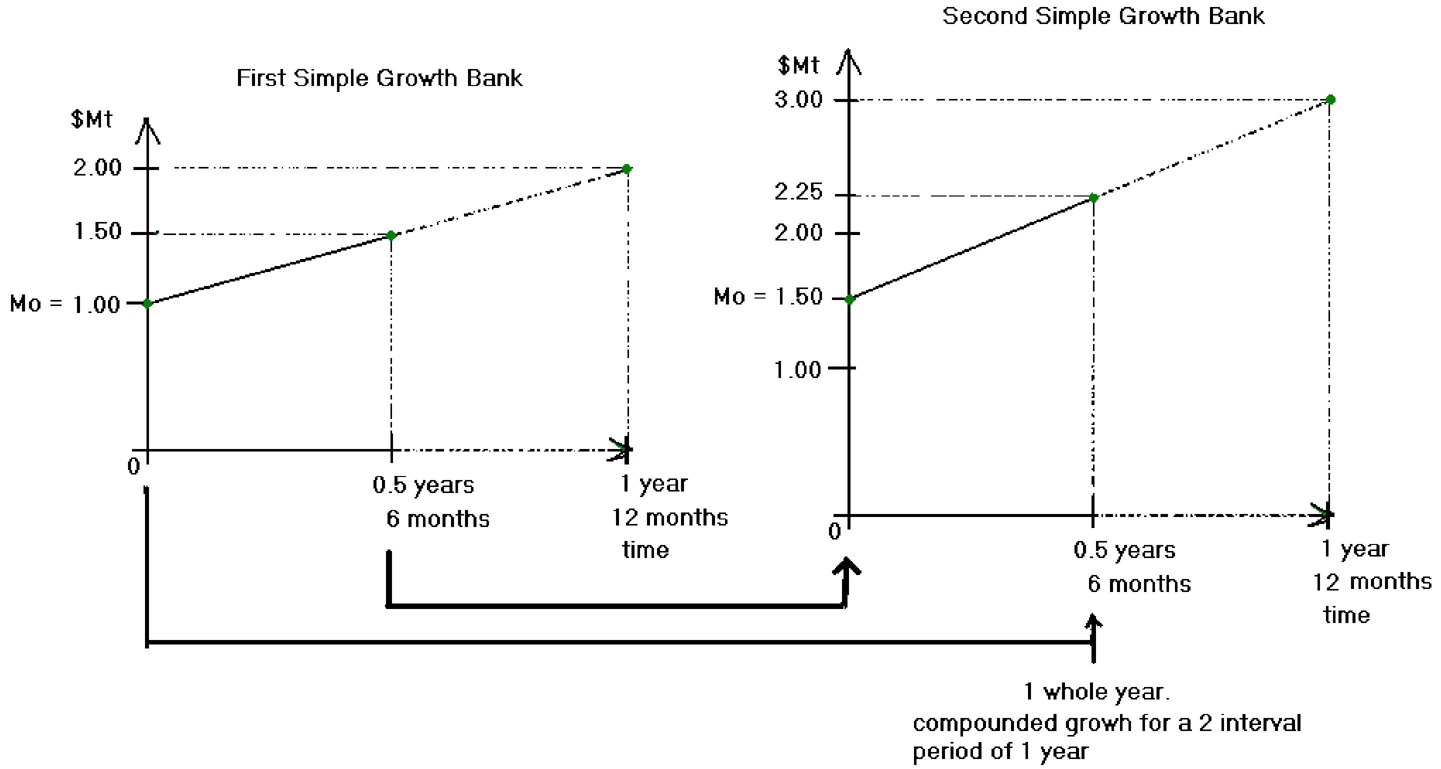
$Mt = \$1 + (0.50)\ \$1.0 = \$1 + \$0.50 = \$1.50$

If you then withdrawal this total money value of \$1.50, which can be expressed as just 1.50, at the end of the first interval (of a year divided into two intervals) and deposit it at a similar bank called: Another Simple Growth Bank, they will recognize your initial savings deposit as Mo = 1.50 instead of 1.00 as the First Simple Growth Bank did. Then at the end of the first interval (of a two intervals per year period, hence after 6 months) of one total time period (here, it's a year also), you should again receive 50% or half of the interest of \$1.50. Since I = 100%Mo, It =100%(1.5) = 1.5.

$In = \frac{It}{n} = \frac{It}{2} = \frac{1.5}{2} = (1.5)(0.5) = 0.75$

$Mt = \frac{Mo}{1} + \frac{Mo}{2} = \frac{1.5}{1} + \frac{1.5}{2} = 1.5 + 0.75 = 2.25$: By Dec. 31. Here at this bank, Mo = 1.50

This is certainly larger than the 2.00 you would of received if you kept your money in the First Simple Growth Bank after 1 year. The above "process" you have done is essentially known as compounded growth (due to interest being added to the (stepped, intervals or completely continuous with an infinite number of intervals) growing total value) which is growth based on, or with respect to, the current total or net growth value. The total growth in this example is growth based upon any and all previous growth (here, 1.50) of the total value in the bank which includes the initial deposit (Mo) and all the previous interest already added to the total value (Mt) in the bank. The value of Mt (or even the initial deposit) is then said to grow compoundedly after each interval of the total time period. [FIG 215]



1 whole year.
compounded growth for a 2 interval
period of 1 year

After each interval (n) of the total time period of growth, the new net value is calculated using the total value (Mt, or better yet, a subscripted variable like Mn which indicates which interval) or the entire growth from the previous interval (where the interest or growth was also added on to produce a new entire growth or growing value), and that the new value for this discussion about (e) is (as indicated above at *, as a multiplying factor to Mo):

* $\left(\frac{1}{1} + \frac{1}{n}\right)$ times larger than the previous interval value.

Algebraically:

$Mt = \frac{Mo}{1}\left(\frac{1}{1} + \frac{1}{n}\right)^1$: after the first interval of the time period

$Mt = \left[\frac{Mo}{1}\left(\frac{1}{1} + \frac{1}{n}\right)^1\right]\left(\frac{1}{1} + \frac{1}{n}\right)^1$: after the second interval, and simplifying this we have:

$Mt = Mo\left(\frac{1}{1} + \frac{1}{n}\right)^2$: after 2 intervals per period

At the end of a third interval (n=3), the total value of the growth would again be $\left(\frac{1}{1} + \frac{1}{n}\right)^1$ times larger:

$$Mt = \frac{Mo}{1}\left(\frac{1}{1} + \frac{1}{n}\right)^2 \left(\frac{1}{1} + \frac{1}{n}\right)^1 = Mo\left(\frac{1}{1} + \frac{1}{n}\right)^3$$: after 3 intervals of the total time or period

Clearly, an obvious pattern or correlation is that the value of the exponent of the expression for Mt is equal to the total number of intervals (n) in that total time period. Reflecting this correlation into the formula:

$$Mt = Mo\left(\frac{1}{1} + \frac{1}{n}\right)^n$$:Total Compounded Growth Formula of a (total time) period divided into n (compound growth) intervals.

We already know that for two (2) intervals of compounded growth that Mt = would be 2.5 times greater than the original or starting value of Mo. That is, mathematically:

$$\frac{Mt}{\text{The initial starting value of Mo}} = \frac{2.5}{1} = 2.5$$

$$Mt = Mo\,(2.5)$$

Increasing the intervals (n) of this compound growth process to see how many more times greater the total value (Mt) can be due to various compounded growths with an increasing number of intervals (n) :

$$\left(\frac{1}{1} + \frac{1}{100}\right)^{100} = 1.01^{1,000} = 2.70\underline{5}$$: after 100 intervals of compounded growth in the period

$$\left(\frac{1}{1} + \frac{1}{1000}\right)^{1,000} = 1.001^{1,000} = 2.716923932$$: after 1,000 intervals of compounded growth in the period

$$\left(\frac{1}{1} + \frac{1}{1,000,000}\right)^{1,000,000} = 1.000001^{1,000,000} = 2.718280469$$ This can also be expressed as:

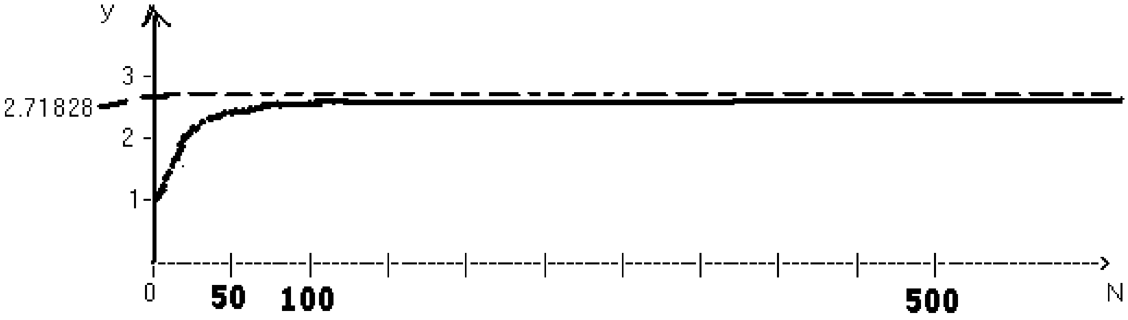
$$(1 + 0.000,000,1)^{1,000,000} = (1.000,000,1)^{1,000,000}$$: This clearly shows the base of the indicated power is only slightly greater than 1. A value of 1 raised to any indicated power greater than 1, including very high values, is only, and equal to 1. If 1 is increased by a very small , seemingly negligible, value, the result of that value raised to a very high value is significant. 1 will increase or grow by a factor slightly greater than 2.7

$$\left(\frac{1}{1} + \frac{1}{1,000,000,000}\right)^{1,000,000,000} = 1.000000001^{1,000,000,000} = 2.718281827$$

Rather than being some vary large value (as might be intuitively expected due to the large exponent) we see that this value is actually only approaching, converging to, or reaching a maximum limit (final value) of about 2.71828 as n approaches a (endlessly, infinitely) very high value. Here is why the value is not actually larger:

Given the power of: $y = \left(\frac{1}{1} + \frac{1}{n}\right)^x$

Note that when n approaches a value of infinity that the fraction (1/n) gets less and less, approaching a value of 0, and therefore, the base of this power actually approaches a value of 1. When n is approaching infinity and the indicated exponent x=n, the rate of change of this power value with respect to n is approaching a value of 0. That is, the slope of the curve is approaching 0, and it not rising much at all as n increases. In short, this is because any power of 1 is still 1 (ie. does not change in value), and any other higher power of a value only slightly larger than 1 will still be about the same power value. This all does seem a bit odd given a value of 1 with the smallest fractional portion possible, practically equal to 1.0, and raised to a very high power value is equal to 2.71828..., and is not so near to 1 or some very large value at all. The graph of the relationship of (y), and (n=x) somewhat resembles a logarithmic curve where slope of the curve eventually becomes very low, practically 0, and remains there for the remainder of the curve: [FIG 216]



This constant value (that the expression eventually becomes) is given the identifier symbol (e) or epsilon. This infinitely compounded growth concept is sometimes known as natural growth.

$$\frac{\text{Mt at the end of period}}{\text{Mo at start of period}} = (e)$$: ratio due to natural (infinitely compounded, with an infinite number of intervals) growth

Hence mathematically, given a value (Mo), it will be (e) times the original value at the end of one period of compounded growth where the number of growth intervals (n) approaches infinity. For example, if you deposit an initial value of $25.00 into a "Natural Growth" bank, this value will grow to (at the end of one period of total time, say 1 year):

Mt1 = (Mo)(e)
Mt1 = ($25.00)(2.71828)
Mt1 = $67.96

After two periods, your original value would grow to:

Mt2 = (Mt1)(e)
Mt2 = (Mo e)(e) = ($67.96)(2.71828) = $184.73
Mt2 = Mo e^2

Notice the pattern or correlation between the exponent of (e) and the period in question. Hence to calculate the total value at the end of 3 periods, you would simply make the exponent of the constant (e) equal to three (3):

Mt3 = (Mt2)(e) = Mo e^2 = Mo e^3

Hence, whenever you see an expression of the general form such as: ce^x , you will know that the value of (c), any constant value, will undergo (go through, be affected by) natural growth for (x) periods (and each single period has an infinite number of growth intervals) of time, and that the value that (c) will grow to is the value of this expression:

ct = ce^x :natural growth, ct = the total (t) value that the constant (c) will grow to.
Note, if you see e^x by itself with no multiplying constant (c), this actually means c=1 and e^x = 1e^x.
A value of 1 (ie. c=Mo=1) will undergo continuous compounded growth for (x) periods of time.

Ex. Let: $ct = n = e^x$ hence:

$n = 1e^x$: The constant of 1 will undergo continuous compounded growth for x periods.
Solving for x by taking the natural logarithm (ln) of both sides of the equation:

$\ln n = \ln 1e^x$
$\ln n = x \ln e$ since $\ln e = 1$ and switching sides:
$x = \ln n$ hence also, the expression $n = e^x$ could be written as: $n = e^x = e^{(\ln n)}$

Ex. $5 = 1e^x = 1e^{(\ln 5)} = e^{1.60948}$: for 1 to grow to a value of 5, 1.60948 periods are needed

Ex. $10 = 2e^x$ Here 2 will undergoing continuous compounded growth for x periods. Solve for x.
After dividing both sides by 2 for some simplification:

$5 = 1e^x = e^{(\ln 5)} = e^{1.60948}$: $x = \ln 5 = 1.60948$

In general, given: $n = ce^x$ dividing both sides by (c):

$n/c = e^x$ taking the logarithm of both sides:

$\ln (n/c) = \ln e^x$
$\ln (n/c) = x \ln e$: $\ln e = 1$

$x = \ln (n/c)$ also, according to the basic definition of a logarithm:

$e^x = \ln (n/c) = x$

Ex. Find x in: $37.6 = 1.6e^x$

$x = \ln (37.6 / 1.6) = \ln 23.5 = 3.157$

Ex. Find c in: $37.6 = ce^{3.157}$

$37.6 = ce^{3.157} = c\ 24.5$, $c = 37.6 / 24.5 = 1.534\underline{7}$

When (c) is not multiplied by a power of (e), but divided by a power of (e), the value of (c) will undergo natural decay:

$ct = \dfrac{c}{e^x} = ce^{-x}$: a common natural decay expression. Remember that $e^0 = 1$, ie.$x=0$, and $x<1$.
With ce^{+x} , there is a natural growth, even if $c<1$and is a fractional value.
With ce^{-x} , there is a natural decay

For example, when a heated object naturally cools down to any temperature, it's temperature will undergo natural decay and these facts will be included in a given formula relating the objects temperature with respect to time.

A derivation of the reciprocal of (e) is nearly identical to that for (e), except that instead of adding a value, a value is subtracted per interval of the period:

$e^{-1} = \left(\dfrac{1}{1} - \dfrac{1}{n}\right)^n = \left(\dfrac{n-1}{n}\right)^n = 0.367879441 = \dfrac{1}{e}$: as n approaches infinity

After one period of natural decay, a value will decay to about 0.368 = 36.8% of its original value, hence about (100% - 36.8%) = 63.2% of the original value is decayed or removed.

For calculating negative powers of (e), and as previously mentioned in this book:

$b^{-x} = 1 / b^x = (1^x / b^x) = \left(\frac{1}{b}\right)^x$: and since the base being considered here is (e):

$e^{-x} = 0.367879441^x$: an advantage of this method is that a reciprocal does not need to be taken

Since we have an algebraic-like expression for $e = e^1$, here is an expression for e^x:

In deriving the formula for (e), we used $x\%/n = 100\%/n = 1/n$, and essentially evaluated e^x where $x=1$, hence e^1. If (x) is some other value, then this changes the formula to:

$e^x = \left(1 + \frac{x}{n}\right)^n$: as n-->inf , (inf = infinity) , : Powers Of (e) , and:

This is also the same as the following which is perhaps more understandable at this point:

$e^x = \left[\left(1 + \frac{1}{n}\right)^n\right]^x$: as n-->inf , (inf = infinity) , Powers Of (e) , and:

You may view the topic of: DERIVATION OF THE SERIES FOR POWERS OF (e) to help understand this.

One other fact that was implied, but not discussed much above, is the fact that the time, time length or duration of each interval is mathematically inversely related to the number of intervals (n).

Expressing this in mathematical form:

time of each 1 interval = 100% total time / number of intervals = 1 / number of intervals or:

$t = 1 / n$: for a naturally compounded growth process, as n approaches infinity, (t) approaches 0.

If the total time is 100% = 1 for a relative analysis, and if this amount of time is equal to one complete period (P, or T) time, we can substitute this for the value of 1:

$t = \frac{P}{n}$ or= $\frac{T}{n}$: The higher the number of intervals (n), the "faster", "shorter", "quicker" or lower the time length of each interval. (t) and (n) are inversely related. T or P is the period or time length where the value undergoing natural growth will increase by a factor of (e) = 2.71828...

As an extra advanced consideration, if the number of intervals was considered as the frequency (ie. number of similar times or occurrences) of calculation or reckoning during the one complete period of time, and where new growth will be added on to the previous growths, then this has the standard form of:

t = time = 100%/ frequency = 1/ frequency : Each cycle or wave of a certain frequency has a a corresponding time value or duration needed to complete that cycle or wave. Frequency (f) and corresponding time (t) value are mathematical reciprocals of each other. $(f)(t) = 1$

PERT , The PERT formula

"Pert" or Pe^(rt) is a common formula for a bank that offers continuously compounded interest. It will be shown below how Euler's Number (e) comes into use at the bank and in other formulas elsewhere. Below, P = Principle (similar to Mo=initial money amount) is the starting amount that will be grown by the growth formula applied to it. Variable (I) = the interest rate.

Total Value = Starting Value + Interest

$Pt = P + PI$ Pt = total principle after interest is applied to it. Factoring P from each term:
$Pt = P (1 + I)$ If interest is to be calculated again after another period:
$Pt = Pt + (Pt)(I) = Pt (1 + I) = P(1 + I) (1 + I)$ Which can be expressed mathematically as:
$Pt = P (1 + I)^2$

If there are several intervals (n) in the period, the interest for each interval will be the total interest for that period divided by that number of intervals, and the exponent will also be equal to that number of intervals (of interest calculation) in the period:

$$Pt = P \left(1 + \frac{I}{n}\right)^n$$

Now in relation to Euler's Number (e) where the number of intervals approaches infinity for naturally compounded growth:

Letting interest rate = I = 100% = 1 = r , and n=x to express this as the classic power of a binomial expression for (e) which can be expressed with some grouping:

$$Pt = P \left(1 + \frac{1}{x}\right)^x$$ If the interest rate was not 1, but another value, this can be expressed as:

$$Pt = P \left(1 + \frac{r}{x}\right)^x$$ And this is equal to the following expression.

$$Pt = P \left(1 + \frac{1}{x}\right)^{xr}$$ We see that the rate (r) essentially becomes a power to (e). This is verified below at (*) and (**). This can be expressed as a power to a power:

$$Pt = P \left[\left(1 + \frac{1}{x}\right)^x\right]^r$$ As the number of intervals (x) in the period approaches infinity, this is equivalent to:

$Pt = P e^r$ If there are several periods (t) of time of this growth calculated, then the formula will include a power of (t) due to repeated multiplication, and which (t) could even be a fractional value.

$Pt = (P e^r)^t$ which can be expressed as:

$Pt = P (e^r)^t$:this is a power (of e) raised to another power, and this can be mathematically expressed as:

$Pt = Pe^{(rt)}$ **: the PERT formula.** P=starting principle amt., (e) is epsilon or Euler's Number, about 2.71828, r = interest or growth rate per time period of calculation , t = number of time periods being considered. For example. if the (infinitely compounded growth) time period is 1year = 12 months, and 6 months of time has elapsed: t = (6 months/12 months) = 0.5

A helpful way to understand this formula is to consider that when the interest or growth rate doubles, for example, that it will essentially have the same result as doubling the number of periods of (infinitely compounded) growth. The interest rate effectively becomes as like a multiplier value to the period of growth reckoning. Also consider:

* Given the basic growth formula:

$P\left(1 + \frac{I}{n}\right)^n$: I = interest rate (r), n = number of intervals of growth within the time period

When I=1, and n is very high, say n=1,000,000, we get:

$$P\,(1.000001)^{1,000,000} = 2.718280\underline{5} = e^1$$

If interest (I) (or the rate=r) doubles, from 1 to 2, and n is very high, this can be represented as:

$$P\left(1 + \frac{2}{1,000,000}\right)^{1,000,000}$$

$$P\,(1.000002)^{1,000,000} = P\ 7.3890413\ldots = P\,e^2$$

We notice that the power of e, is equal in value to the interest rate. A more generalized formula for all values of interest (r=rate) is then:

From: $P\,e^r$ or = $P\,(e^r)^1$, if the number of growth periods (t) is more than one (1), the generalized formula is:

$$P\,(e^r)^t = Pe^{(rt)}$$

As some extra verification, you can consider all of the following:

ce^1 represents the infinitely compounded growth of (c) for 1 period or time interval. $(ce^1)\,e^1 = ce^2$ represents the infinitely compounded growth of (c) for 2 periods or time intervals. Since the exponent of (e) corresponds to the time interval. After (x) time intervals, (c) will grow to a value of: ce^x. (c) can have any value including 1.

$$ce^x = ce^{(\text{time periods})}$$

If something, such as (c) was to grow (infinitely compounded) for 2 time periods, it is mathematically the same (equal to) as it growing at twice the rate, or twice as fast for just one time period or half of that total time of 2 time periods. That is, at half the time period specified, it essentially already grew by a factor of e^1.

$$c\,(e^x)^2 = c\,(e^x\,e^x) = ((ce^x)\,e^x)) = ce^{(x+x)} = ce^{(2x)}$$

$c\,(e^x)^2 = ce^{(2x)}$ and in general terms, for various rates and time:

$ce^{((\text{rate})(\text{time periods}))} = Ce^{rt}$ which is identical to the "Pert formula"

Also consider that mathematically, for example:

(e^x)^2 = e^(2x)

$$\left|\left[\left(\frac{1}{1}+\frac{1}{n}\right)^n\right]^x\right|^2 = \left[\left(\frac{1}{1}+\frac{1}{n}\right)^n\right]^{2x} = \left(\frac{1}{1}+\frac{1}{n}\right)^{2nx} = \left(\frac{1}{1}+\frac{2}{n}\right)^{nx}$$

as shown below:
(x can be 1 also)
When n--> infinity, that power of the binomial is defined as e=2.718...

e^2 = e^1 e^1 = (1/1 + 1/n)^n (1/1 + 1/n)^n = ((1/1 + 1/n)^n)^2 = (1/1 + 1/n)^2n = e^2 : when n is a very high value

If interest rate (I = r) doubles, say from 1 to 2 we would find this expression for the value of growth after (n) periods of time.

(1/1 + 2/n)^n when n is very high, this is equal to:

(1/1 + 1/n)^n (1/1 + 1/n)^n = e^2 = (1/1 + 1/n)^(n+n) = (1/1 + 1/n)^2n = ((1/1 + 1/n)^n)^2 = e^2

(**) We see a pattern that the indicated power; the exponent of e is equivalent in value to the interest rate. Also consider when n is a very high value:

e^2 = ((1/1 + 1/n)^n)^2 = ((1/1 + 1/n)^2)^n = [(1/1 + 1/n) (1/1 + 1/n)]^n

[(1/1 + 1/n) (1/1 + 1/n)]^n = [1^2 + 1(1/n) + 1(1/n) + (1/n)^2]^n

[1^2 + 1(1/n) + 1(1/n) + (1/n)^2]^n = [1 + 2(1/n) + (1/n^2)]^n : as n--> infinity, this last term approaches 0 very quickly, and is practically of no effect

e^2 = [1/1 + 2/n]^n , and if this is multiplied by [1/1 + 1/n]^n = e , the result is:

(e^2) (e^1) which can be expressed as:

[1/1 + 2/n]^n [1/1 + 1/n]^n = ([1/1 + 2/n] [1/1 + 1/n])^n = ([(1/1) + (1/n) + (2/n) + (2/n^2)])^n =

([(1/1) + (3/n)]^1)^n = [(1/1) + (3/n)]^n = e^3 as n---> infinity

A DERIVATION OF THE SERIES FOR POWERS OF (e)

The derivation of the series for powers of (e), or e^x, requires that you first know about the Binomial Theorem. Rather than perform repeated multiplication to "expand" a binomial (a two term expression) that is raised to an indicated power, a general formula has been developed and it is called the **Binomial Theorem**. The Binomial Theorem, as we know it today, was discovered in about the year 1665 by Sir Isaac Newton who also discovered many other properties, relationships and formulas, such as the basic formula for force: (force = mass x acceleration), and gravity (a force). The derivation of this formula begins with the following basic form of any binomial raised to an indicated power:

(a + b)^n

Since we are dealing with algebra, (a) and (b) can actually be or represent expressions, but for most practical cases, they just represent a simple numeric value. If the binomial is a difference of terms: (a - b)^n, you can perform this simple algebraic manipulation to place it into proper form, or just consider it in this form: (a + (-b))^n. The terms of the expansion of this binomial (a - b)^n are almost identical to those of a binomial with two positive terms except that now they will alternate in sign from positive to negative. Also note that regardless of the values (ie., signs) of (a) and (b) in the expression (a - b)^n, the result is always positive when (n) is even, and negative when the base is negative and (n) is odd. This can easily be verified by the rules for squaring or multiplication, for example:

(5 - 2)^2 = (3)^2 = 3^2 = (3)(3) = +9 : base is positive (here, +3), and n is even

(2 -5)^2 = (-5 + 2)^2 = (-3)^2 = (-3)(-3) = +9 : base is negative (here, -3), and n is even

Note that it is incorrect to simplify (-3)^2 above by removing the parenthesis before performing the squaring since:

-3^2 = - (3^2) = - (9) = -9 :since powers and roots have a higher precedence than summation

(5 - 2)^3 = (3)^3 = 3^3 = (3)(3)(3) = +9 : base is positive, and n is odd

(2 -5)^3 = (-5 + 2)^3 = (-3)^3 = (-3)(-3)(-3) = -9 : base is negative, and n is odd

Using repeated multiplication, expanding and simplifying some powers of the general algebraic form of a binomial:

(a + b)^1 = 1a^1 + 1b^1

(a + b)^2 = 1a^2 + 2ab + 1b^2 ex. 7^2 = (1 + 6)^2 = (1)^2 + 2(1)(6) + (6)^2 = 1 + 12 + 36 = 49

(a + b)^3 = 1a^3 + 3a^2b + 3ab^2 + 1b^3

(a + b)^4 = 1a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + 1b^4

Now, let's note the similarities or patterns in each expansion:

The total number of terms for the expansion will be one more than the indicated power of the binomial.
ex. (a + b)^2 , here the indicated power is with exponent n=2, so there will be (n+1) = (2+1) = 3 terms in the expanded form of that binomial.

The sum of the exponents of both the (a) and (b) variables in each and every term is equal to the indicated exponent (n) of the binomial.

If (n) is even, there will be (n+1) terms, hence an odd number of terms. The exponents of the (a) and (b) variables in the "middle term" will be equal to (n/2), and the sum of those exponents will be equal to (n).

The first term is: $a^n b^0 = a^n(1) = a^n$. For each next term, the exponent of (a) will be one less, and the exponent of (b) will increase by one. The last term is: $a^0 b^n = (1)b^n = b^n$.

The (numerical) coefficients of the (a) and (b) variables are symmetrical (ie. the same value) on each side of the middle of the sum of all the terms.

For the example above, the coefficients of the variables in each consecutive term are: 1, 4, 6, 4, 1, and note the similar value (here, 1 and 4) at both ends. Here is a formula for the numerical coefficients (c1, c2, c3, **. . .** cn+1) of those variables:

1. The first and last coefficient is 1.

2. The second coefficient is (n)

3. The next term's coefficient (ct+1) is found from it's previous term's coefficient (ct):

$$ct+1 = \frac{ct\ (\text{exponent of variable (a)})}{t}$$

: t = term number. All values on the right side correspond to term (t) which is essentially the previous term used to find the constant of the next term (t+1).

Any constants past the (n+1) term are 0, and therefore all those terms will have a value of 0. Here is a (non-standard) formula for these constants that does not rely upon the previous constant. This may be skipped over (to: *****) if its excessive to the reader, and since its non-standard:

Notice that for the first term of each expansion, the exponent of (a) is equal to (n). For the next term, the second term, the exponent of (a) is one less or (n - 1) and for the next term, the exponent of (a) is two less than (n) or (n-2), and so on:

$$c3 = \frac{c2\ (n-1)}{2} = \frac{\frac{n\ (n-1)}{1!}}{\frac{2}{1}} = \frac{n\ (n-1)}{(2)(1!)} = \frac{n\ (n-1)}{2!} \qquad : 2! = (t-1)! = (3-1)!$$

$$c4 = \frac{c3\ (n-2)}{3} = \frac{\frac{n(n-1)\ (n-2)}{2!}}{\frac{3}{1}} = \frac{n\ (n-1)\ (n-2)}{3(2!)} = \frac{n\ (n-1)\ (n-2)}{3!} \qquad : 3! = (t-1)! = (4-1)!$$

Summarizing the results:

$$c1 = \frac{1}{0!} = 1 \quad , \quad c2 = \frac{n}{1!} \quad , \quad c3 = \frac{n(n-1)}{2!} \quad , \quad c4 = \frac{n\ (n-1)(n-2)}{3!}$$

To be consistent with (t - 1)! , 0! is shown above and it is formally defined as: $0! = 1$.

The formula resulting from these expressions for the constants is:

1. Starting from the second term, each numerator has (t - 1) factors.

The first factor is (n).
Each next factor is 1 less:
The second factor is: $n - 1 = (n - 1)$
The third factor is: $(n - 1) - 1 = n - 1 - 1 = (n - 2)$, and so on.

In the last factor, the second term (the one being subtracted) is (t - 2).

2. Each denominator is (t - 1)!

* When these expressions for the constants are placed into the Binomial Theorem, the entire expression is formally known as the Binomial Formula:

(a + b)^n = c1a^n + c2a^(n-1) b^1 + c3a^(n-2) b^2 + . . . + c(n+1) b^n : **Binomial Formula**

Note that the first term that does not express the (b) variable since: c1a^n b^0 = c1a^n(1) = c1a^n
The last term does not express the (a) variable since a^0 = 1, however you can indicate (a^0, and b^0) it you want to be more formal in the ascending and descending powers of these variables.

Still, there is yet a pattern in these expressions for the constants, and the reader may skip this (to: *****) if it is excessive, and since its non-standard:

Each numerator essentially contains part of the most significant or leading portion of n!, and the denominator is (t-1)!. If the numerator is expressed as n!, some of the least significant or trailing portion of this factorial must be removed, and this can be done with division by that value that must be removed. Here is this formula:

$$ct = \frac{n!}{(t - 1)!\,(n - t + 1)!}$$

As a check, the sum of the indicated numerical coefficients (and not the value of the factorials themselves) of the two factorials in the denominator is always equal to (n).

* In the Binomial Formula shown above, when (n)<1, or a proper fraction, an infinite series of terms will be produced where the terms get smaller and smaller, and therefore, the sum of these terms (which get smaller and smaller in value) will converge or "zero-in" to a specific value.

The value of the exponent (n) need not be an integer, in fact, any value, such as a whole number (consisting of an integer or whole part, and a fractional part) for (n) can be used. Hence various roots and powers can then be found. Variables (a) and (b) can also be any value. Here are some of the results to expect using the Binomial Formula:

When (n) is an integer, the number of terms is fixed at (n+1).

When (n) is not an integer, or when (n) is negative (ie., the reciprocal of that power), the number of terms becomes infinite. Consider for example that a value raised to a negative power is the reciprocal value of the equivalent positive power. Still, the sum of the series of terms will converge to a specific value. As an illustration to why the expansion of this binomial is an infinite series of terms, imagine finding the square root of 2 with the Binomial Formula:

$\sqrt{2}$ = 2^(1/2) = (1 + 1)^(1/2) or (1 + 1)^0.5 : in this binomial, a=1, b=1, n=(1/2) = 0.5

The result to expect is the irrational value about 1.414213562**...**, and its' digits will not terminate or repeat at some point. To calculate any more digits for increased accuracy, you will need to do more calculations, hence there can never be a fixed number of terms for such a situation with "endless digits". Unlike when the exponent is an integer, here, the last coefficient (of the n+1 term) is not 1, and the exponent of (a) is not 0, so the process of adding more terms will continue.

Fewer terms are needed when one variable (a or b) is greater than 1 and when the other variable is less than 1. For example, instead of using (2 + 2)^1.5 for evaluating 4^1.5, you can use something like: (3.5 + 0.5)^1.5

When one of the variables, or terms, of the binomial is equal to 1, the Binomial Formula can be simplified or reduced to what is commonly called the **Binomial Series**. If (a) = 1, all of the powers of it are equal to one, and it can essentially be eliminated or removed as a factor in each term. Expressing this:

$$(1 + b)^n = c_1 + c_2b^1 + c_3b^2 + \ . \ . \ . + c_{n+1}b^n \qquad : \textbf{Binomial Series}$$

Even though the (a) variables were eliminated from the expansion, the same concepts and expressions for the constants are the same.

The results of using the Binomial Series are somewhat, but not exactly similar to that of the Binomial Formula:

Expect (n + 1) terms if (n) is an integer.

When (n) is not an integer, the expansion of the binomial becomes an infinite series of terms. The value of variable (b) must also be less than 1, otherwise, the terms will become larger and larger (since its' exponent is becoming larger and larger), and therefore, the series will not converge to a specific value. The lower (b) is, the fewer terms required for a specific number of (most significant, higher numeric weight, leading) accurate digits in the result.

The binomial series can be used for general mathematical calculations such as for taking powers or roots of values. Below, the binomial series is used to find a series for powers of (e):

The core or fundamental expression for (e) is a binomial raised to an indicated power (ie., indicated with an exponent). Since the first term (a) in the binomial is equal to 1, the binomial series can be utilized to "expand" it so as to find its value.

$$e = \left(\frac{1}{1} + \frac{1}{n}\right)^n \quad \text{or} = (1 + 1/n)^n$$

: (e) is defined where (n) is very high (infinite) in value. Raising each side to the (x) power:

$$(e^1)^x = \left[\left(\frac{1}{1} + \frac{1}{n}\right)^n\right]^x$$

using the power to a power rule on the right hand side:

$$e^x = 2.718281828^x = \left(\frac{1}{1} + \frac{1}{n}\right)^{(nx)}$$

To find any power of (e), this binomial can be expanded into a (power) series of terms by using the Binomial Series, where the exponent will be (nx), and (b) will be (1/n). Since (a)=1, it will essentially not be needed in this expansion since all powers of 1 have a value of 1, and 1 as a factor does not change any value of a term. Showing this algebraically, we will arrive at a simplified formula for finding powers of (e):

$$e^x = c_1 + c_2b^1 + c_3b^2 + c_4b^2 + \ . \ . \ . \qquad : e^x \text{ expressed as a power (of b) series}$$

$$e^x = c_1 + c_2\left(\frac{1}{n}\right)^1 + c_3\left(\frac{1}{n}\right)^2 + c_4\left(\frac{1}{n}\right)^3 + \ . \ . \ . \qquad \text{distributing the power to the num. and den.:}$$

$$e^x = c_1 + c_2\left(\frac{1^1}{n^1}\right) + c_3\left(\frac{1^2}{n^2}\right) + c_4\left(\frac{1^3}{n^3}\right) + \ . \ . \ . \qquad \text{simplifying:}$$

$$e^x = c_1 + \frac{c_2}{n^1} + \frac{c_3}{n^2} + \frac{c_4}{n^3} + \ . \ . \ .$$

$c_1 = 1$

$$c2 = \frac{nx}{1!}$$

$$c3 = \frac{nx\,(nx - 1)}{2!} = \frac{(nx)^2 - nx}{2!} = \frac{n^2x^2 - nx}{2!}$$

$$c4 = \frac{nx\,(nx - 1)\,(nx - 2)}{3!} = \frac{(nx)^3 - 3(nx)^2 + 2(nx)^1}{3!} = \frac{n^3x^3 - 3n^2x^2 + 2nx}{3!}$$

Now substituting the expressions of the constants:

$$e^x = 1 + \frac{(nx)(1)}{(1!)(n^1)} + \frac{(n^2x^2 - nx)(1)}{(2!)(n^2)} + \frac{(n^3x^3 - 3n^2x^2 + 2nx)(1)}{(3!)(n^3)} + \ . \ . \ .$$

$$e^x = 1 + \frac{(nx)(1)}{(1!)(n^1)} + \frac{(n^2x^2 - nx)(1)}{(n^2)(2!)} + \frac{(n^3x^3 - 3n^2x^2 + 2nx)(1)}{(n^3)(3!)} + \ . \ . \ .$$

$$e^x = 1 + \frac{x}{1!} + \left(\frac{x^2}{1} - \frac{x}{n}\right)\left(\frac{1}{2!}\right) + \left(\frac{x^3}{1} - \frac{3x^2}{n} + \frac{2x}{n^2}\right)\left(\frac{1}{3!}\right) + \ . \ . \ .$$

When (n), the number of intervals per period approaches infinity as for the definition of (e^1) and its corresponding value (about 2.718), all the fractions containing (n) in the denominator will rapidly approach a value of 0 and are therefore insignificant, "meaningless" or negligible in value, and those terms can be removed from the sum of terms:

$$e^x = 1 + \frac{x}{1} + \left(\frac{x^2}{1}\right)\left(\frac{1}{2!}\right) + \left(\frac{x^3}{1}\right)\left(\frac{1}{3!}\right) + \ . \ . \ .$$ simplifying:

$$e^x = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \ . \ . \ .$$

: **SERIES FOR POWERS OF (e)**
(The derivative of (e) is also the same series)
This was found by the profound Swiss scientist
Leonhard Euler (1707-1783AD), and it is why (e),
"epsilon", is often called "Euler's Number".

When x = 1 we can find the value of e = e^1 = 2.71828 . . . :

$$e^1 = 1 + \frac{1}{1!} + \frac{1^2}{2!} + \frac{1^3}{3!} + \ . \ . \ .$$

$$e^1 = 1 + \frac{1}{1} + \frac{1}{2} + \frac{1}{6} + \ . \ . \ .$$: this is essentially 1+ (sum of reciprocals of the factorials)

$$e^1 = 1 + 1 + 0.5 + 0.16666666\underline{7} + \ . \ . \ .$$

: these four terms of the expansion sum to about 2.6$\underline{7}$
The specific value of each term will be less and less,
till the value of any new terms added in are nearly
meaningless since they will have a value close to 0.
The sum of all these terms will approach, "zero in", or
"converge" to have a certain or specific value, and here it is:
2.71828**...**

DERIVATIVE OF e^x

We can find the derivative of the function: e^x by taking the derivative of the expansion of e^x. To do this, take the derivative of each term and sum the derivatives. The result is amazing since the derivative of this function is actually the same function. That is, the derivative of e^x is e^x. Given (x), the derivative (dy/dx = de^x/dx) or slope of the curve at that point is equal to e^x = f(x) = (y) which is the corresponding coordinate of (x) on the curve. Obviously, the greater (x) is, the greater the value of e^x = slope at that point on the curve.

Since the first term is a constant, its derivative is 0.

The derivative of the second term is: $\frac{1\,x^{(1-1)}}{1!} = \frac{1x^0}{1!} = 1$

The derivative of the third term is: $\frac{2\,x^{(2-1)}}{2!} = \frac{2x^1}{(2)(1!)} = \frac{x^1}{1!}$

The derivative of the fourth term is: $\frac{3x^{(3-1)}}{3!} = \frac{3x^2}{(3)(2!)} = \frac{x^2}{2!}$ therefore:

$$\frac{dy}{dx} = \frac{d\,(e^x)}{x} = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \;.\;.\;. = e^x$$

: **Derivative of e^x , series expression**
The derivative of e^x is e^x.

By knowing that the derivative of e^x is e^x, and that e^0 = 1, you can also write a Maclaurin series for e^x which will produce the same results as shown above for the series for powers of (e).

As another advanced verification to the derivative of e^x:

From: y = a^x : an exponential equation, and it's derivative is:

$$\frac{dy}{dx} = \frac{d(a^x)}{dx} = a^x \ln a$$

, if a=2.718281828... = (e), we have:

$$\frac{dy}{dx} = 2.718281828^x \ \ln 2.718281828$$

$$\frac{dy}{dx} = e^x \ \ln e = e^x \ (1) = e^x$$

We see that the derivative equals the original function. For other values of (a), lower or higher than 2.718281828 = (e), the derivative of a^x will not equal just the same function of a^x because it will also include the factor of (ln a). Since (e) is a valid value for (a), it gives a verification to the formula for the derivative of an exponential equation of the form: (a^x).

A similar formula for (e) is: e = lim n-->0 of: (1 + n)^(1/n)

Euler's Formula or Equation is: e^(ix) = cos x + i sin x : i is the imaginary unit or number of: sqrt(-1) = i

For example $\sqrt{-7} = \sqrt{(-1)(7)} = \sqrt{-1}\,\sqrt{7} = i\,\sqrt{7}$

In the series for (e), if you substitute (ix) for (x),
you can obtain this expression for Euler's Formula.

Besides the MOD operation, we have seen that only the trigonometric functions are periodic or cyclic (will repeat over and over with the same output, which can be seen on a graph of these functions). Euler's Formula above shows a relation of a standard algebraic equation and the periodic (an irrational) ones. It is derived from the combining of the series for (cos x) and (i sin x) term by term (which is very similar to combining of the series for (cos x) and (sin x)). Its two-dimensional graph has two curves on it, one for cos x and the other being an imaginary curve of (i sin x) that looks identical to sin x. In a three-dimensional graph, the curve looks like a spiral shape since the imaginary part (i sin x) causes a periodic rotation. When there is a rotation due to the imaginary part, the "curve or locus movement" is always perpendicular (at a right angle) to the current real (number) location.

Euler's Constant, or Euler's Number (e) has many strange properties associated with it, for example, of all the values of (x) for: $y = \sqrt[x]{x} = x^{(1/x)}$, y will have the maximum value when x = e. And that maximum value is about: 1.4446678610 . As x increases, the same value root of it will approach 1.0 in value as x approaches infinity. I have found that $(e)(\ln \sqrt[e]{e}) = (e)(\ln e^{1/e}) = 1$, and this 1 value also indicates that the two factors are reciprocals, hence the second factor equals (1/e) and-or e^{-1} , and that: $e^1 e^{-1} = e^{(1-1)} = e^0 = 1 = (e / e) = (e)(1 / e)$.

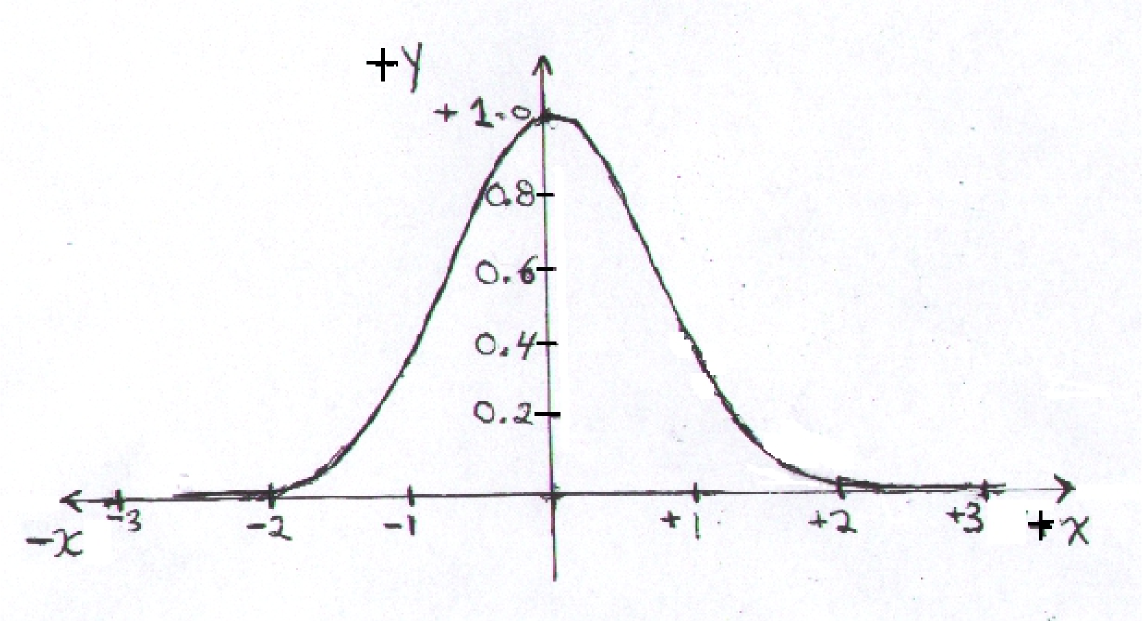
Another constant related to (e) is the "omega' constant" which is about 0.567143290. When (x) is this value, the equation below and other similar basic types of (e) and natural log equations are solved:

For example: $e^x = 1/x$: this equation is true when (x) equals the "omega constant" = ~ 0.567143290

If you want to draw the classic "bell (shaped) curve", try this:

$y = e^{-(x^2)} = \dfrac{1}{e^{(x^2)}}$: note, $e^{(x^2)} \neq (e^x)^2 = e^x e^x = e^{(x + x)} = e^{(2x)}$

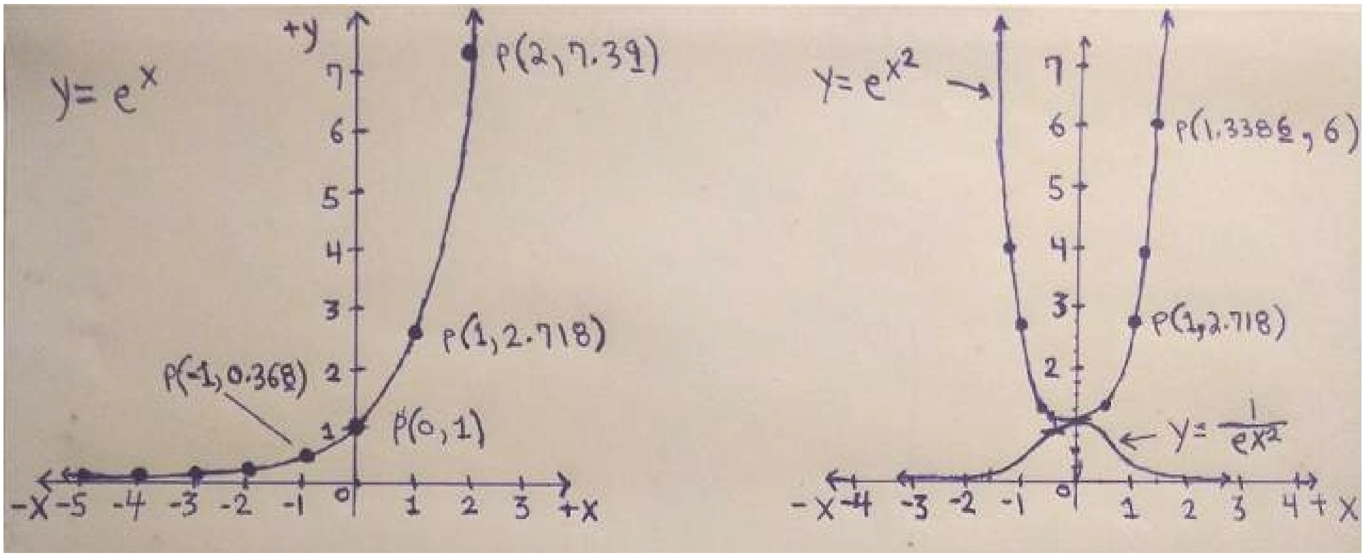
The maximum (y) value is 1 when x=0, the lowest absolute or signless value of x. This is due to the inverse mathematical relationship between a quotient (here, as y) and the divisor (here, as $e^{(x^2)}$). Points such as this are sometimes called the vertex of the curve. For this equation, the value of (y) approaches, but never is actually a value of 0. [FIG 217]



bell curve

In the above equation, variable (x) is squared, and the result besides a steeper curve shape, is that the values of the (y) and the equation are always positive in sign, regardless if (x) is positive or negative in value, and due to the rules for multiplying signed values . Here, the squaring of the variable creates the curve ("mirror") symmetry about the (y) axis.

Below are some examples of typical curves which involve (e) as a base of a power in an exponential equation, and the results are similar for values other than (e). In general, the greater (e) and-or (x) is, the steeper the slope of the curve.
[FIG 218]

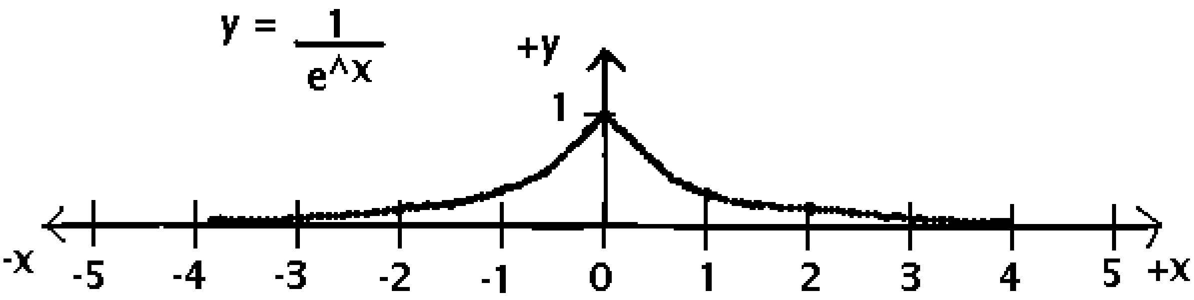


For curve above for y=e^x, notice that the values of (y) when x<0 (ie., negative in value) are reciprocal in value to the (y) values when (x) is positive, and that their product is therefore 1. For example: when x = 1, y = 2.718, and when x = -1, y = 0.368. The product of (2.718) and (0.368) = 1. (e^x) (1 / e^x) = 1 = (e^x) (e^-x) = e^(x-x) = e^0 = 1 . For this curve, when (x) is negative in value: y = e^(-x) = 1/e^x, and this curve is shown further below below.

On the right side is the bell curve of: y = 1/e^(x^2) , and the reciprocal of this equation and curve is: 1/y = 1 / e^(x^2) = e^(x^2), and this curve is also shown. Here, the corresponding values of (y) for the same value of (x) on each curve, are reciprocal in value.

The reciprocal curve, equation and values of: y = e^x is 1/e^x = e^-x , and this curve is shown below:

[FIG 219]



Note that: y = e^x + 1/e^x = e^x + e^-1x Is the catenary curve. This curve could be described as the natural sag or bend of a suspended (supported at its ends) line that is perpendicular to a field of attraction such as gravitational force.

For electronic circuits, the current and voltage within a capacitor (basically, 2 closely spaced metal plates acting like a battery or charge holder ("condenser", "accumulator"), or inductor (basically, a coil of wire that has the effect or temporarily impeding or resisting changes in charge or current) component will increase or decrease in value according to their respective and fairly similar equations which contain **Euler's constant (e)**. While at this topic, and briefly, a resistor component in series with a capacitor can reduce current to it and therefore increase the time it takes for that capacitor to fully charge up with current (electrons) and reach it's specific supplied or maximum possible voltage. Capacitors constructed to store more electric charges are said to have a greater "capacity" or ability to store charge, and will naturally take longer to charge. This is all helpful when designing and experimenting with electronic timer (ie., delay) and-or oscillator (periodic, cycled or repetitive signal pulses) circuits such as for radio [rf, radio frequency]. Radio waves are invisible waves of (electro-magnetic) energy at any frequency from 0 hertz to trillions of hertz or repeating cycles per second. Modern scientific studies have found that radio wave energy is composed of both an electric field and a magnetic field that is transmitted and received. These fields are transmitted together and having the same polarity, however they are at right angles to each other since this is how they were first created in the wire and-or transmission antenna. Many consider these fields as being composed of energy particles called photons, albeit many frequencies of it are not visible to the human eye, but they can be sensed by other electronic sensors and-or radio antennas. These sensors, including our eyes, convert this electro-magnetic energy into electrical energy (such as for a radio or solar-panel) and-or heat energy (such as for a green-house).

A DERIVATION OF THE NATURAL LOGARITHM SERIES

This derivation for the natural logarithm series stems from the facts that the derivative of e^x is itself, and from the derivative of the natural logarithm of (x) as will be explained here:

Given: $e^y = x$: taking the logarithm of both sides of this equation

$\ln e^y = \ln x$ by the log rules, this can be expressed as:

$y \ln e = \ln x$: since ln e = 1, this simplifies to:

$y = \ln x$ according to the basic logarithm definition, we then have:

$e^y = x$ taking the derivative (with respect to y) of both sides of this equation:

$\frac{d(e^y)}{dy} = \frac{dx}{dy}$: since the derivative of a power of (e) is equal to that same power of (e), for example, given: e^x , $d(e^x)/dx = e^x$. We now have:

$e^y = \frac{dx}{dy}$ since $e^y = x$, and $y = \ln x$ as shown above, and using substitution, we have:

$x = \frac{dx}{d(\ln x)}$ taking the reciprocal of both sides of this equation, and switching sides:

$\frac{d(\ln x)}{dx} = \frac{1}{x}$: **DERIVATIVE OF THE NATURAL LOGARITHM OF A NUMBER**

Note that the derivative of the natural logarithm of a number is equal to the reciprocal of that number. The higher the number (x), then the slope at that point on that log curve or graph approaches 0 which is the slope of a horizontal line. This is since given $y=\ln x$, and when (x) is high in value, changes in (x) will cause almost no effect or changes in the value of (y). Note also that while (1/x) is algebraic , (ln x) is not algebraic, but is transcendental in nature.

Now that we have the derivative of the natural logarithm of (x), we obviously cannot simply take the inverse (anti-) derivative of (1/x), which results to: (ln x), so as to find a usable expression (such as a series) for the natural logarithm of (x). Even if we tried taking the inverse derivative of $(1/x) = (x^{-1})$ using the method shown previously, it will also not produce a usable result since according to that method: increasing (adding) the exponent of (x), here -1, by 1 is 0, but then the division by this value of 0 is not mathematically allowed:

$\frac{1}{x} = x^{-1}$ taking the anti-derivative: $\frac{x^{(-1+1)}}{0} = \frac{x^0}{0} = \frac{1}{0}$: The quotient is undefined; has no specific value.

In order to find a usable expression for (ln x), we need more to work with, and this is an equivalent expression for (1/x). Perhaps then, there is a reciprocal series that is equivalent to (1/x) that we can use to find the inverse derivative of, and therefore have an expression for (ln x). As it turns out, the general reciprocal series is a bit more complex to work with than this "modified" reciprocal series shown below that we can use, but it will (only) evaluate the reciprocals of numbers (N) between 0 and 2:

$$\frac{1}{N} = \frac{1}{x+1} = \sum_{n=0}^{n=\infty} (-1)^n \, x^n = 1 - x^1 + x^2 - x^3 + \ . \ . \ .$$

: (modified) Reciprocal Series
: $0<N<2$
: $N = x + 1$
: $x = N - 1$
: $-1 < x < 1$

Unlike the general reciprocal series, there is no division required to evaluate the terms of this "modified" series. For this series to converge to a specific value, (x) must be less than 1, otherwise, the result would grow "without bounds" due to the increasing powers of it. More specifically (x) must be: $-1 < x < 1$. Remember, division by 0 is not allowed. The curve of this expression is actually the exact same curve as for the expression (1/x), the true reciprocal curve, except that it (all points) is effectively shifted leftward by 1 on the horizontal or (x) axis. Just the same, the curve of 1/(x+1) can be considered as being effectively shifted rightward by 1, or "one step ahead", with respect to the curve of 1/x. Consider this example data:

x	=	0	1	2	3	4	, . . .
y = 1/x	=	(undefined)	1.0	0.5	0.3333...	0.25	, . . .
y = 1/(x + 1)	=	1.0	0.5	0.3333...	0.25	0.1667...	, . . .

As an extra note, if N is greater than 2, you can still calculate its reciprocal using the above series by first factoring N (usually into a modified scientific notation form whose reciprocal(s) is already known). For example, to find the reciprocal of 4:

$$\frac{1}{4} = \frac{1}{10\,(0.4)} = \frac{1}{10} \cdot \frac{1}{0.4} = 0.10 \left(\frac{1}{0.4} \right)$$

: to divide a value by 10 or= multiply a value by 0.1, simply move its decimal point one position leftward.
$0.1 = (1)(0.1) = 1 / 10^1 = (1)\ 10^{-1}$

Then use the series to evaluate the reciprocal of 0.4, and then multiply it by 0.10. Here is the formula to determine the value of (x) for the terms of the series:

$N = 1 + x$
$0.4 = 1 + x$ solving for x:
$x = 0.4 - 1$
$x = -0.6$: use this value in the "modified" reciprocal series above

Don't forget that you can also use the log reciprocal formula:

$\ln N = -\ln 1/N$: for example $\ln 4 = -\ln 1/4 = -\ln 0.25$

The derivation of this reciprocal series uses the form of the binomial series shown previously:

$(1 + x)^n = c1 + c2x^1 + c3x^2 + \ . \ . \ . + cn{+}1\ x^n$: Binomial Series

To place $1/(x + 1)$ into a power of a binomial form, we will use its equivalent binomial form of: $(1 + x)^{-1}$

Letting n = (-1) and solving for the first four constants:

$c1 = \frac{1}{0!} = 1$, $c2 = \frac{n}{1!}$, $c3 = \frac{n(n-1)}{2!}$, $c4 = \frac{n(n-1)(n-2)}{3!}$

$c1 = 1$, $c2 = \frac{-1}{1}$, $c3 = \frac{-1(-1-1)}{2}$, $c4 = \frac{-1(-1-1)(-1-2)}{6}$

$c1 = 1$, $c2 = -1$, $c3 = 1$, $c4 = -1$

Substituting the constants:

$(1 + x)^{-1} = \frac{1}{x + 1} = 1 + (-1)(x^1) + (1)(x^2) + (-1)(x^3) + \ldots$ using distribution:

$(1 + x)^{-1} = \frac{1}{x + 1} = 1 - x^1 + x^2 - x^3 + \ldots$: checks , (modified) Reciprocal Series

Finding the inverse derivative of each term above to have the complete inverse (or anti-) derivative of this series, we have the following logarithm series which was developed by Nicolaus Mercator:

$$\ln(x + 1) = \sum_{n=1}^{n=\infty} (-1)^{(n+1)} \frac{x^n}{n} = +\frac{x^1}{1} - \frac{x^2}{2} + \frac{x^3}{3} - \ldots \qquad : x < 1$$

For this series to converge to a specific value, (x) must be less than 1. The terms will get smaller and smaller in absolute value. This series can evaluate the natural logarithm of values less than 2. This series is very important and-or useful, and a method has been developed as shown in this book of how to calculate the natural logarithm of numbers greater than 2.

For a simple formula for ln x , you can use the following, however without a computer or calculator, you will need to compute a power of (x) which for here, is actually a root of (x):

$\ln x = n(x^{(1/n)} - 1)$: as n-->inf , formula by Leonhard Euler
After simplifying, this is equal to:

$\ln x = nx^{(1/n)} - n$: as n-->infinity

A similar formula is:

$\ln x = \frac{x^n - 1}{n}$: as n --> 0

From the derivative of ln x, as shown previously, we mathematically have:

From: $y = \ln x$, $dy / dx = d(\ln x) / dx = 1/x$:

$\frac{d(\ln x)}{dx} = \frac{1}{x}$ from this equation, we mathematically have:

$d(\ln x) = \frac{1}{x}\,dx$ All the small parts or pieces of something considered as one whole thing will sum to that whole thing. This is called integrating. Each small part of (ln x) is noted as d(ln x), and all these will sum to the whole (ln x). Expressing the summation of all these small parts on both sides of the equation:

$$. \quad \int d(\ln x) = \int \frac{1}{x}\, dx$$ this results to:

$$\ln x = \int \frac{1}{x}\, dx$$

For an example of using the above, when the integral (of integrating or summing) is a definite integral, it is like an infinite area being defined, bounded or limited to a specific area or section that is below the curve (ie., between the curve of an equation and the x axis and where y=0). The result, the area in question, the bounded or definite area, is calculated as the difference of those two areas defined by upper and lower limits mentioned and-or indicated. With the above equation, the area beneath the curve of y = ln x, from the limits of x=1 to x=e =~ 2.71828 is:

$$\int_1^e \frac{1}{x}\, dx = \ln e - \ln 1 = 1 - 0 = 1$$

: The area beneath the natural logarithm of (x) curve between x=1 and x=e has a value of 1. This could also be said as the area between the curve and x-axis bound by the upper limit of (e) and lower limit of 1.

BASIC DEFINITIONS OF THE TYPES OF NUMBERS

Below are some of the various general types, categories, sub-categories, or classifications of numbers that you may sometimes see and-or read about, and it is would be helpful to at least know a basic or minimal definition of them. As you work more and more with numbers, you will obtain a natural, uncomplicated feel for what these numbers are.

natural number - Natural numbers are those used for basic counting and representing a quantity of whole (entire) things or units often found nature (plants, rocks, trees, stars). Ex. 1, 2, 3 , ...

counting number - Our man-made counting numbers are essentially the same as the natural or "natures numbers".

whole number - An integer value greater than or equal to 0, hence it is also positive in value. A whole number will also not have, include or indicate a fractional part (of 1). Ex. 0 , 3 , 7 , 1000 Whole numbers are used to enumerate complete or whole units, objects or entities. 0 is included since it numerically or symbolically represents an absence.

integer number - A signed counting number, hence can be positive or negative in sign. An integer also does not have, include or indicate a fractional part. Ex. -5 , 0 , +5 . The word "integer is rooted in the words: "wholeness", "complete", "integrity", "untouched" and probably; an "instance" or "next step" of. The word "integer" has some companion words such as: "increment" which means an "increase".

fractional number - A number that represents a value or quantity of something that is less than 1 or 1 whole entire unit or entity. A fraction of a thing is smaller piece or part of that entire or whole thing, hence it is not the whole thing. Its numerical value or representation of that part or quantity of the whole (considered as having a "relative" numerical value of 100% = 1), will therefore be less than 1.

Ex. 0.5 = 1/2 = 5/10, etc. , 0.5<1 , Ex. 0.1 = 1/10 = 2/20, etc. , 0.1 < 1

Although a fraction is always numerically less than, and only a part of the whole thing, if the whole thing is greater than 1, such as a group of things or units being considered, the actual or physical fractional part may then be numerically a value greater than 1. For example, if you have 100 bricks, a tenth (1/10 = 0.1, a fraction of 1 or the entirety) of those 100 bricks is 10 bricks, and this is more than 1 brick. These 10 bricks may also be said as being "ten percent" (10% = 0.1) of all the bricks. 10 bricks is still a fraction or part of all the 100 bricks considered as the 1 entirety, 100%, whole or all.

mixed number - A number containing a whole number part, and a fractional part or portion.
Symbolically: mixed number = whole number part + fractional part
or: mixed number = whole number part **.** fractional part
Ex. 5.2 , 5.2 = 5 + 0.2 , 5 is the whole number part, and 0.2 is the

fractional part that is less than 1.

positive numbers - Represent a value, quantity, or change of something that is greater than 0. Ex. positive 3 is written as +3 , + is the positive symbol

Increases (positive changes) are usually noted with a positive symbol. If the increase was 5, this would be noted as +5, and this will be combined or added to the reference value (0 is not indicated). If the reference value was +10, the resulting value is: +10 plus +5 = +15.

This positive number symbol (+) is also the same symbol for the mathematical addition, increment (ie., increase) or combine operation which is often called the "plus" operation and-or symbol.

negative numbers - Represent a value, quantity, or change of something that is less than 0. Ex.'s A negative temperature value such as -3°F, a debt (ie. a decrease, a loss), or a distance in the opposite (ie., by 180 degrees) direction than the positive, larger or increase direction.

negative 3 is written as: -3 , - is the negative symbol used to create or express a negative valued number or change which is for values less than 0 or some other reference value.

If you started with +7 and lost 3 (ie., a negative change, a decrease), the result is that: +7 and -3 combine or result to: +7 plus -3 = (+7) + (-3) = (+4) = +4

If you started with +0 and lost 3 (ie., a negative change, a decrease) the result is that: +0 and -3 combine or result to: (+0) plus (-3) = (+0) + (-3) = (-3) = -3

If you started with -3 and lost 1 (ie., a negative change, a decrease) the result is that: -3 and -1 combine or result to a bigger or larger negative number: (-3) plus (-1) = (-3) + (-1) = (-4) = -4 . Now consider the following:

If you started with -4 and gained or increased by 1 (ie., a positive change) the result is that: -4 and +1 combine or result to a lower negative number or toward the "(more) positive (values) direction".
(-4) and (+1) combined = (-4) plus (+1) = (-4) + (+1) = (-3) = -3

This negative number symbol (-) is also the same symbol for the mathematical subtraction, decrement (ie., decrease) operation and is often called the "minus" operation and-or symbol.

real number - A real number can be indicated (ex., a point) and-or located at a specific distance along a signed number line. A real number can be a rational or irrational number. In short, a real number is not an imaginary number.

rational number - A rational number is any number that can be expressed as the quotient or result of the division of two integer values. The fractional part of the result will be either 0, a number with fixed or certain number of decimal places, or a number which contains an "endless" repeating of the same decimal digits after a certain decimal position. All rational numbers are said to be "algebraic" (ie. can be produced (ie., a result) by a single variable polynomial equation).

Ex. 4/2 = 2.0 , 5 / 2 = 2.5 , 1/3 = 0.3333.... , 4/7 = 0.571428571428...

The word "(to) rationalize" basically means "to make (simple) sense or reason of".

irrational number - An irrational number cannot be expressed as the quotient or result of the division of two integer values. That is, it cannot be adequately expressed as a single fraction. The "expansion" or continuation of further decimal digits is endless and does not repeat (ie., have a constant pattern).

Ex. PI = 3.14159.... , e = 2.71828 .... , square-root 2 = 1.4142135.... , and the golden ratio = 0.618034.... are irrational.

The word "irrational" basically means: "does not make (simple) sense or reason", or is "beyond (simple or rational) reason and-or mathematical representation or expression".

Ex. (Pi) is the constant ratio of the Circumference of a circle to its Diameter: (Pi) = C / D = 3.14.... Even though (Pi) is a irrational number, it does not therefore mean that C and D are also irrational, and for example, it is very possible to have say a circumference equal to exactly 3, 5, 100 etc., a rational value. Here, mathematically: D = C / (Pi) , and D essentially becomes irrational in value since here it is being calculated by using an irrational value.

transcendental number - A transcendental number is a number that is "not algebraic", that is, it is not the root of a single variable polynomial equation with rational coefficients. A root is the solution of that variable in the polynomial equation that is set equal to 0. All transcendental numbers are also irrational (non-rational) numbers.
Ex. PI and Epsilon (e) are the best known transcendental numbers.
Note for example that squarer-root 2 is an irrational number, but it is not a transcendental number since the square-root of 2 is the "algebraic" solution of: $1x^2 - 2 = 0$.
The golden ratio (GR) is also irrational, but is not transcendental since it is the "algebraic" solution of: $1x^2 - 1x - 1 = 0$, and the solution here is found to be:
1/GR = 0.618033988749894 = 1.618004...
The equation shown can also be expressed as: $x^2 - x = 1$

The word "transcend" basically means "outside of" (such as standard mathematics such as basic algebra, or beyond "algebraic rationality"). "A number from out of the blue". "A number from out of nowhere". Transcendental numbers are real numbers. The trigonometric functions are considered as transcendental functions since the results take an infinite number of steps to complete, and therefore can't be represented or expressed as a ratio of two numbers or with a simple algebraic formula such as the angle or trigonometric value divided by some other value. In general, logarithm and exponential functions are to be considered as transcendental functions that generally result in a transcendental value, and especially due to how it may be calculated as a sum of an infinite series of terms that will eventually converge to a specific value after an infinite number of terms are utilized.

imaginary and complex numbers -

A complex number is a number that has both a real part and an imaginary part: complex number = real + imaginary
An imaginary number is a number that is imagined to have a numeric value, and is much like a theoretical concept. Whereas the negative of a number which can be symbolically expressed as: - (number) , and is like a reversal or 180° shift, opposite direction, or rotation of a (pos. or neg.) number, an imaginary number is preceded by the i or j symbol which represents the square-root of an effective 180° shift or rotation of a number, and which is therefore indicated as the square root of -1, and is often thought of as being a half, partial or 90° shift or rotation.

The imaginary part of a complex number is represented by the symbol of: j or i and is equal to the imaginary (ie., non-real) value of the square-root of -1.

Ex. $5 + 2i = 5 + 2(\sqrt{-1})$

Ex. $\sqrt{i}\ \sqrt{i} = \sqrt{-1}\ \sqrt{-1} = -1$: -1 is a real number

One possible way to possibly consider any real number is that they are all essentially found and-or already expressed in an equivalent digit form between 0 and 1 on the number line, hence all real numbers are effectively fractional values less than or equal to 1, and were effectively incremented by an integer value or multiplied by a power of 10. For example:

Given 0.5 , then 1.5, found between 1 and 2, is simply an increase of 1 integer step from 0.5 which is found between 0 and 1.

Given 0.314159265 , then 5.314159265 is simply an increase by 5 integer steps

Given 0.731 , then 7.31 , is simply 10 times higher

What can be said about some of the above examples is that it is essentially what also takes place when converting any value to scientific notation when the decimal point is shifted within a number.

Common Constants, Formulas, Equivalents And Conversions Within And Between Measuring Systems

SOME COMMON CONSTANTS:

pi = 3.14159265358979323846... : the ratio value of: (circumference / diameter) of all circles. (pi) = C / D

e = 2.71828182845904523536... : epsilon, Euler's number, base (of measurement) for natural logarithms

GR = 0.618033988749894... : Golden Ratio (GR), a ratio of two specially related lengths or amounts.
1/GR = GR+1 = 1.618033988749894... , GR^2 = 1 - GR and GR^2 + GR = 1 ,
GR^2 = 0.38196601

Vc = 186282.4... miles/1s = 299,792,458 meters/1s =~ 300000 km/s :speed or velocity of light (c).
(in empty space, hence a vacuum)

Using (300 million) m/s is only about 0.0692% =~ 0.07 = 7 hundredths of 1 percent greater than the true value of speed of light, and is also ~= 186,000 miles/s = 186000 mi/s (3600s / 1h) = 669600000 =~ 670 million mi / hr

Vs = 1125 ft/s = ~ 343 meters/s =~ 767.27 miles/h : velocity or speed of sound through air, at about room temperature
0.343 km/s =~ 1235 km/h ~1100 ft/s or= ~ 350meters/s . Thunder sound called "thunder" will travel about 1 mile in 5 seconds.

g = 9.807m/s^2 = 32.1752ft/s^2 : Earth's constant gravitational acceleration of an object due to gravity which is the attraction of masses (material, substances, matter), and is measured as a force. This specific value is due to the specific mass of the Earth, and is generally not the same value on the Moon or other planets since their mass is more or less than that of the Earth.

From: weight = force = (mass)(acceleration) = ma = mg :

g = weight / mass = a = f / m : force = weight is measured with units of newtons (N),
: mass is measured with units of kilograms (kg)
: 1gram of mass = 1kg/ 1000 = 0.001kg of mass
(g) and (weight) are directly proportional to each other for a given mass.

Ex. Using a known mass of 1kg, and if it was weighed on a force scale to be 9.8N, and on some other planet or moon, it might weigh 1.6N, then (g) can be calculated as:

$$ge = a = \frac{f}{m} = \frac{9.8N}{1kg} = \frac{((9.8kg)/1m) / 1s^2)}{1kg} = \frac{9.807m}{1s^2} \quad : \text{for Earth}$$

$$gm = a = \frac{f}{m} = \frac{1.6N}{1kg} = \frac{((1.6kg)/1m) / 1s^2)}{1kg} = \frac{1.6m}{1s^2} \quad : \text{for Moon}$$

The ratio: gm / ge = $0.1631\underline{5}$ =~ (1/6). A mass on the Moon will weigh about 16% or one-sixth as that of the weight Earth. Since weight is directly proportional to (g), the ratio of the weight of an object on the Moon to that of the Earth also has the same ratio value:

gm / ge = weight on Moon / weight on Earth ~= 0.16 , and from this we have:
(weight on Moon) = (0.16) (weight on Earth) = (weight on Earth) / 6

Because of the above facts, only (1/6) the energy is needed to lift a weight on the Moon as compared to that of the Earth. A person with the energy and strength who can lift 30 pounds on Earth for a short time, can lift the equivalent of (30lbs)(6) = 180 pounds on the Moon for a short time.

Fg = G (M1M2) / r^2 = Force of gravity or attraction between two masses. (r) is the distance between the centers of the two masses (M). (r) has units of meters (m), and M=mass has units of kilograms.
F will have units of Newtons = N . Note that (kg)(kg) = kg^2 , and (m)(m) = m^2
G = universal gravitational acceleration constant =
G = ((6.674)10^-11) m^3 / (kg)(s^2) or= (6.674)(10^-11) N m^2 / kg^2

This basic knowledge and formula is mostly credited to Isaac Newton, and who once said that he standing on the shoulders [ie., the knowledge] of giants [previous others and their own accumulated contributions to science].

G is mathematically a constant of proportionality. This equation for Fg has the form of an "inverse square law", since Fg is inversely related to the square of (r) and therefore rapidly decreases as (r) increases.

Using F=Ma , M1=Me=mass of Earth, and M2=Mo is the mass of an object close to Earth, re = (re) = radius of the Earth, g can be calculated as: g = a = F/Mo = G Me / (re)^2
G can be calculated knowing an objects acceleration g =32ft per second, per second =32 (ft./s^2)
The **mass of the Earth** has been calculated at about 5.973 (10^24) kg = about 6 (10^24) kg.
The radius of the earth = re = 3959 mi =~ 4000 mi =~ 6437 km =~ 6.4 (10^6) m
The mass of the Sun is about 2 (10^30) kg

Using the values given above, a force of 1N will be the force due to gravity upon a mass of 1kg on the surface of the Earth which has a distance = (r) of 6.4 (10^6) m from the center of Earth and the center of its gravitational attraction force. r^2 = (6.4 (10^6))^2 m =~ 41 (10^12) m.
. Note, here, at this value of (r): Fg = G(M1 M2) / r^2 = Fe = weight = ma = mg , and where a=g=9.8 m/s^2 .

Since the meters and kilograms are human made units and value, the specific value of G is technically or mathematically, also a human made value, and so as to have units of Newtons.

The above equation: Fn = G (m1 m2) / r^2 resembles the standard equation for force which is:

force = (mass) (acceleration) and with a dividing variable, here (r^2), that considers the inverse-square type of relationship between (gravity) force and the distance (r) between the two masses or objects.

The more massive (ie., mass) an object, the more gravity potential it will have, however due to equal and opposite forces, the actual gravitational force applied to both masses will be the same value, and it could perhaps be called their mutual force or gravity. If one or both masses change in value, their value of gravity will be different, and it is directly related to how much mass is involved in that system.

When force = f = ma = mg, the force is being directly applied to both

two masses with direct contact, and when considering forces that are not directly applied, such as gravity, and the fact that its strength is inversely related to the distance between those two masses, (r^2) is used as a divisor, and it is not equal (t), but analogous to:
force = mg / r^2   or= gm / r^2

Also, as a reminder, a given force can more easily move a smaller mass, and-or do more work (force x distance) with it due to that the more massive object has more inertia and will require more energy to move it, and-or accelerate it to change its velocity. Also of note is that if one mass is less than 1 kilogram, there will be no effective magnification or amplification in the resulting force. This leads to the question of whether a more massive object has that much more gravity, and due to this equation, it can only be said that a more massive object has more gravity force potential, influence or possibility upon another smaller mass. Note also that:
G = Fn r^2 / (M1 M2)

A basic derivation of the gravitational force equation:

First, the gravitational force Fg between two objects or masses (M1 and M2) is the same value (regardless of their amount of mass) due to the concept of equal and opposite forces, and this could be expressed as:

Fg = F1 = F2   : here the Force(s) is the gravitation force

Fg = (M1 a1) = (M2 a2)

The equation is also written in such a way that if the values of M1 and M2 are exchanged, then Fg is still the same.

We know that the more massive an object is, the more gravitational force or attraction to another mass it will have, and its value of (a) will depend upon the size of that mass, and is directly related to that value. On Earth, the specific value of (a) is (g) = 9.81 m/s^2, and for another object or planet with a different mass, the local or surface value of (g) will be different. Since Fg = F1 = F2 is the same between both masses, and that F = ma, the resulting kinetic acceleration and velocity will be higher of the smaller mass than that of the larger mass.

We know that M1 is generally not equal to M2. Given a mass having a weight or force, if that mass increased by a factor, its corresponding weight (ie., an effect or force due to gravity [force]) will also increase by that same factor.

Something having twice the weight will make a dent twice as deep in the ground when dropped from the same height, and this is due to that the force upon reaching the ground was also increased by that same factor.
From :   F = weight = ma   ,   multiplying both sides by a factor (n):   nF = (n) weight = (n)ma

This implies that the Fg between a mass and another will be a multiple or relative (in numerical reference) or factor the mass value, and a multiple can be expressed as a product. Each mass will have its own local gravitational attraction (g) upon another mass. This force (Fg) is like an effective or resultant force due to an effective or resultant mass value so that Fg between them is the same value, hence of an equal and opposite value. The two masses essentially amplify the force of each other and can be expressed as a multiple or product of each other.

In F = ma , both (m) and (a) can amplify a (force=weight) when those values are amplified (increased by a factor of (n), and if (m) is constant, then (a) determines that force and-or weight.   Since (a) can amplify the force or weight, it is as if the given mass rather was amplified instead. The effective result for a two mass gravity system is that each mass is essentially amplifying each other so as to have an amplified, equal and opposite force (Fg). An equivalent force (Fg = Ma) upon each mass implies an effective or apparent amount of mass, and at the same acceleration (a=G) and its value was first mathematically determined by Henry Cavendish using a torsion (ie.,twisting) balance and various masses to cause a gravitational attraction force on the masses, and then a twisting of the balance by an angle that is determined by the amount of their gravitational attraction. Note that (g) does not equal (G). Technically, (g) is the value of the gravitational acceleration at the surface of the Earth, and that it actually gets less (ie., g is not a universal constant like G is) as the distance from the center of the Earth becomes farther. (g) is rather associated with the kinetic energy of a single object. In 1687, Isaac Newton first proposed the formula for the universal law of gravitation, but it took till 1798 when Cavendish gave the constant (G) a specific value and verified Newtons proposal.

If two masses have different values, the smaller mass will actually have a larger gravitational acceleration towards the larger mass, and this can be seen when you drop an object, and it moves toward the Earth due to Earth's gravitational constant (g), and that the Earth will barely moves toward that smaller mass, and this is due to Earths inertia, and that it will take much more force or energy to accelerate and move it. Acceleration is inversely related to mass:
$a = F / M$, and $v = at$.

pi^2 = 9.869604401089358 $\sqrt{\text{pi}}$ = 1.772453850905516 2pi = 6.283185307179586

1/pi = 1 / 3.141592654 = 1 / (C/D) = (D/C) = 0.3183098861837907

1/ (2 pi) = 0.1591549430918954

e^2 = 7.38905609893065 $\sqrt{e}$ = 1.648721270700128 2e = 5.43656365691809 1/e = 0.3678794411714423

The cube root of 1 million = the cube rot of 1(10^6) = 1 (10^(6/3)) = 1 (10^2) = 100 or 100 units

[This space for edits.]

METRIC PREFIXES: [For multiples or fractions of a unit or reference of measurement. Here are some common [prefixes, and this topic was previously mentioned in this book.]

kilo means: (1000) = "a thousand of"
centi means: (1/100) = "one-hundredth" or "one-hundredth of" the units used, indicated or expressed
milli means: (1/1000) = "a thousandth of"

ABBREVIATIONS:

in=inches, m=meters, cm=centi-meters, km=kilo-meters
ft=feet, g=grams, L=liters, lb=pounds, oz=ounces, fl=fluid (ie., a [liquid] volume)
s= seconds of time, hr=hours, m=minutes

FREQUENCY AND TIME:

Time=1/Frequency = Ts=1/Fhz. hz=hertz = vibrations, cycles or waves per second. Time is the total time of each and every similar cycle or wave, and it is mathematically inversely related to the frequency of that vibration, cycle or wave. The higher the frequency of a wave, the lower or shorter (ie., "faster" , "quicker") the time needed to complete that 1 wave.

Wavelength (W or Wl) is essentially the physical distance or length between similar or corresponding points (such as the peak [maximum] amplitude value, "peak to peak") on the wave (of vibration, energy cycle or pulses) during its cycle as it travels outward from the source. The wavelength of a wave will be different for energy waves that travels faster or slower such as the speed of light and the speed of sound in air. Wavelength can also be calculated using the frequency of the wave.

Since wavelength is a length or distance, and distance = (speed of movement)(time of movement) = (speed)(time):

electromagnetic **wavelength** = (speed of light)(Ts) = **(Vc)(Ts)** = (Vc)(1 / Fhz) = **Vc / Fhz**

As a helpful thought experiment about wavelength and the speed of light (photons) and-or electro-magnetic waves, consider if the physical wavelength of an electro-magnetic signal was 5cm of length, and then imagine that distance segment and-or wave structure then moving at the speed of light of about 186000 miles per hour which is another distance.

Another helpful thought experiment is to consider a frequency (f) of 1 cycle per time = 1 cpt = (usually) cycles per 1 second = cps.

If you had a frequency of 4cps, then each cycle is less or quicker in time, and here it is one-forth (1/4) that amount of time (t) of one second. It will be shown below that cps and spc (or cpt and tpc) are reciprocals in value:

frequency = cycles per time = c/t = cpt , and t = **time = time per cycle** = spc = time per cycle = t/c

If frequency = f = 4 cps = 4 cpt = 4 (c/t) = 4 hz , and t = time per cycle = seconds per cycle = tpc = 1 / cpt = 1 / cycles per time = 1 / frequency = 1 / f = 1 / 4cps = 1 / (4c / s) = 1s / 4c = 0.25 s/c

frequency = 1 / time or **cycles per time = 1 / (time per cycle)**

W = d = v t , if v = c = the speed of light, and time of each cycle is t = 1s , then, W = c (1s) = (d mi / 1s) (1s) = c miles. Usually for electromagnetic waves, the time of each cycle is much less than 1s, and therefore d is much less than c miles = 186000 miles. Ex. If the time of each cycle is 1ms then: W = d = v t = c (0.001) = 186 miles.

Ex. For typical AM radio wave with a 1 Mega-hertz-cycle , the signals wavelength and basic antenna length is:
(300,000,000 m/s) / (1Mhz 1/s) = (300(10^6) m/s) / (1 (10^6) 1/s) = 300m
This leads to a simple and commonly spoken formula for radio wave wavelength in meters:
(300 / frequency in Mhz) = wavelength in meters

Frequency (F) and Wavelength (W) are inversely related as shown in the formula above. Also consider these inverse proportions: Vc = (W1)(F1) = (W2)(F2) , Therefore mathematically: (W1/W2) = (F2/F1) , and this is an example of what is described as an "inverse ratio (of values and units)".

As a simple example, if a given frequency is multiplied by 2, the resulting wavelength is divided by 2.
For example, for a typical FM radio wave of 100Mhz, the wavelength is: 300m/100 = 3m
For a 1Ghz radio wave, 1Ghz = 1000Mhz, the wavelength is: 300m/1000 = 0.30m = 30cm

Compared to low frequency, long wavelength signals such as for AM radio, a high frequency, short wavelength FM radio transmitter and-or receiver antennas are much shorter in length, and may even be shorter by using a half or quarter wavelength antenna which are very practical, but they will reduce the transmission efficiency of the input electrical energy. You may research a common antenna called a **dipole** (ie., two pole, here 2 half-wavelength segments, unconnected, but on the same imaginary line, and where each segment will alternate in polarity with the alternating RF alternating signal applied to it.). A horizontal dipole antenna is more directional than a vertical single pole ("omni-directional") antenna, hence it can be used to communicate farther in the two opposite directions perpendicular to it.

Wavelength And Frequency Of Visible Light: 1Thz = 1 terahertz = 1(10^12)hz=cps = 1 trillion hertz = 1000Ghz
1nm = 1(10^-9)m = 1 billionth of a meter , and:

(**RGB**) =: **R**ed = 700nm , 428Thz , **G**reen = 530nm , 566Thz , **B**lue = 470nm , 638Thz = 638 (10^12)hz

White light appears as the brightest color, and it is due to its **primary colors**: RGB and where their frequencies are overlapping or combining and effectively simulating a higher frequency when they are all received and sensed at the same time. It could be said that white light is composed of the RGB (Red, Green, and Blue composite or component parts) frequencies. A prism of clear glass can physically separate or "extract" the colors or frequencies within white light since each frequency has a certain wavelength and "diffraction (bending, or turning) angle" when it is slowed by the glass medium. When any two of the R, G and or B colors of light are combined, a third, and apparently slightly brighter color is effectively created of which can even be combined with the third primary color. The resulting colors and-or "shades" (ie., intensity) of color depends on the intensities of all the colors and-or their frequencies involved.

Radio waves are transmitted, radiated outward, or broadcast from a metal antenna such as a straight length of wire. The (invisible) radio waves are emitted from the antenna much like how (higher frequency) visible light is emitted from a light bulb that contains (electric) energy. Radio waves can be considered as like invisible (ie., not visible to the human) photons containing energy. Consider how a heated metal, either by flame or electric current, will have a dark red to white glow of light emitted. Our eyes can only see a small portion of the electro-magnetic range or spectrum of frequencies. Though an antenna is nearly an open circuit, charges can still move in an antenna due to the electric forces of attraction and repulsion. Moving charges such as electrons in a wire will create both an electric and magnetic field. When charges, such as electrons, have gained kinetic energy, and eventually fall back into the orbit of an atom, they will release and-or radiate that excess energy as a photon, and here, particularly the invisible type containing both an electric and magnetic field. The frequency of the radio's oscillator circuit will determine the frequency of the (invisible) photons and-or radio or "energy wave" transmitted.

To receive radio-waves, another metal antenna is needed. The transmitted radio-wave energy strikes the receiver antenna and induces (causes) a signal (voltage and current) to be generated in that antenna wire, which is then processed by other electronic circuitry so as to demodulate (extract) the desired information (audio, video, data) from it.

The received signal may also be amplified so as to be more usable. The specific length of the transmission and reception antennas is based upon the wavelength of the radio-wave frequency in use, and so as to be most efficient. Using the proper length for the antenna is said as "tuning" the antenna for best efficiency. **AM is Amplitude Modulation** (a form of signal combining, here, so as to vary the strength or intensity) of the transmitted radio-wave energy transmitted is done by first applying and combining the (voice, audio, image) low frequency input information signal's varying electric voltage (ie., the signals amplitude) to the main transmitted radio frequency. Specifically, the amplitude (ie., AM) of the input information signal is added to the radio wave signal, and this step then changes the amplitude (ie., amount) of the radio wave signal. The main or fundamental transmitted radio-signal and frequency is sometimes called the carrier (of the information) frequency or wave. In a radio receiver, the audio or information signal is extracted or "demodulated" out from the received radio wave, and the carrier radio wave is discarded. **FM is Frequency Modulation** of the transmitted radio-wave by applying and combining the information signal's frequency to it so as to slightly alter the frequency of the main carrier wave, and then transmitting it. Since (electronic, RF, radio-wave energy, signals) noise can alter the amplitude of a received AM signal, FM radio is often used so as to have much more clear communication since amplitude noise is not much of a concern. Generally, FM radio communication is usually assigned or permitted to have less distance for communication than AM radio communication, and each FM radio station or "channel" requires a much wider (ie., more) "bandwidth" or frequency range than AM does. FM communication is generally more complicated in terms of circuitry than AM is. **Continuous Wave (CW)** communication is somewhat like AM radio communication, but CW uses only brief pules of an input audio "tone" signal such as a 1000hz sine wave for the information, and this is how (binary, two states for each bit or particle of information) Morse Code signals are transmitted, and for very long distance, and requires a relatively low voltage power battery supply and-or current. CW requires only a very narrow frequency bandwidth, say about +,- 2000 hz, near the assigned **carrier frequency** (ie., the main RF transmission frequency), and thereby reducing station crowding and signal interference from other stations. It also allows the input energy to be concentrated near the main transmission frequency of which both the transmitter and receiver are tuned to, hence the pulses of input energy are not wasted as unwanted transmitted frequencies and energy such as in a wider (frequency) bandwidth (or range) radio signal.

An LC (inductor and capacitor) tuner (technically a type of selective frequency filter) has a natural resonant or center frequency as mentioned in this book, and a natural bandwidth. Bandwidth is a frequency range. Max. Bandwidth = (upper frequency passed by the turner) - (lower frequency passed by the tuner) = Fu - Fl. Since there is an extensive small amplitude, frequency range of signals that exist near the upper and lower limits, usually the (best, usable, practical) "bandpass" range is defined as where the frequency amplitudes are reduced to 70.7% of the maximum value at the resonant frequency (Fr), and these frequencies are called the upper and lower (practical , signal) cut-off frequencies.

Quality factor of a tuner = Qf = R sqrt (Cf / Lh) = (Fr / Bandwidth). Since I is proportional to V, this limited bandwidth range represents about at 50% of the input power value of the signal: From: Pw = VI , Here: P = (0.707V)(0.707A) = 0.5 VA = 50% (VI) = 50% Pw

Considering the speed of light and other electromagnetic energy waves moving at 186000 miles per second = 299792 km/s =~ 300000 km/s and which is the speed of light through a vacuum such as in outer space:

Distances	**Approximate time needed**	
Sun to Earth = 93 million miles	500s = 8.333 min	: 93 million miles = 1 AU of distance , 1 AU / 8.333 min
Earth to Moon	~ 1.3s	: 240,000 miles away
1 Million miles	~ 5.38s	: 1 million miles =~ 0.0107527 AU (=~ 1/100 AU = 0.01 AU)
1 Billion miles	~ 1.5h	: 1 billion miles =~ 10.753 AU. (=~ 10 AU) Saturn is almost a billion miles away.
1 mile	5.3763441 micro-seconds	
1 km	3.335641 micro-seconds	
1 m	3.335646 nano-seconds	
1 foot	1.01825 nano-seconds	

In 1 second, light will travel about 186000 miles = 0.002AU per second , and:
In 1 minute, light will travel about: (186000miles/s)(60s) = 11.16 million miles = 0.12 AU per minute

In 1 hour, light will travel about 670 million miles = 7.2AU per hour.
In 24 hours = 1 day, light will travel about 16.08 billion miles =~ 16 billion miles = 172.8 AU =~ 173 AU per day
In 1 year =1 light-year =~ 365 days, light will travel about: 5.870 trillion miles= (365.25 days)(173 AU per day)=~ 63188 AU

TEMPERATURE:

The temperature (ie., heat, thermal energy) of a substance (matter, mass) is a measure of its atoms or molecules average movement (vibration, motion, moving, or "kinetic") and its corresponding energy level. When this type of motion does not increase in value, it is considered that the substance or mass did not absorb or acquire any more external energy. When a mass with a higher temperature is joined to one with a lower temperature, energy, via the atomic movements or vibrations, the energy of the mass with the higher temperature will be transferred to the mass with a lower temperature until the temperature of the two masses are the same value. The mass with the higher temperature will loose some energy, and the mass with the lower temperature will gain that same amount of energy.

When all atomic or molecular vibration or motion stops, this temperature is defined as "absolute zero" and is the reference of measurement for the Kelvin (K), or "absolute" [scientifically true or natural] temperature scale, and each degree of temperature increase in this scale is identical to that of the Celsius scale. Water freezes at about 273K = 0°C = 32°F, and boils at about 373K = 100°C = 212°F. Kelvin values are always positive in value. Though water freezes at 32 °F, it still has some trace amount of (atomic, and-or environmental) thermal energy within it, and can get as cold as absolute 0 in theory.

If an object or mass is now twice its initial starting temperature of reference value, it is thought to have gained the same value of its starting atomic or molecular thermal energy. The (real, solid) matter or mass (technically, the measure of matter) is storing that energy.

"Absolute Zero" where all thermal energy is depleted and atomic vibration or motion stops or "freezes" is defined as:
0°K = -459.67°F = -273.15°C. The Kelvin scale is credited to William Thomson who was also the 1st Baron of Kelvin (a river and area) of Britain, and he is more commonly known as "Lord Kelvin". He conceived this absolute or true temperature scale in about 1848 and is actually based on and-or an extension of the Celsius temperature scale.

°F = (9/5) °C + 32 : Degrees Fahrenheit , and mathematically:
°C = (5/9) (°F - 32) : Degrees Celsius
°K = °C + 273.15 = ((°F - 32)) / 1.8) + 273.15 :Degrees Kelvin
(9/5) = 1.8 =~ roughly 2 and (5/9) = (1/1.8) = 0.555.... =~ roughly 0.5 = (1/2) : for quick estimations

Fahrenheit temperature = F° = 1.8C° + 32 : a derivation of this formula is shown in this book , 1.8 = 9/5
Celsius temperature = C° = (F° - 32) / 1.8 = 0.555... (F ° - 32°) = K° - 273.15 , 0.555 ... = 5 / 9 = 1/ 1.8
Kelvin temperature = °C + 273.15 = ((°F - 32) / 1.8) + 273.15 : 273.15 =~ 273 =~ 270
0 °C = 32 °F = 273.15 °K : **water freezes to ice at here or if less, or ice melts to water if greater** , and
100 °C = 212 °F = 373.15 °K : **water boils in a pressure of 1 atm (14.7 psi) if at here or if more. Higher pressure essentially means harder to boil, and will take more energy for the steam or water vapor to be released and "gas off" or be released from the water.**

Some selected temperatures and their converted values:

-28.88°C = -20°F
-23.3°C = -10° F : 10 below zero or= 10 less than a 0°F reference temperature
-17.8°C = 0° F : 0°F was defined as the freezing point (value) temp. of a special "brine" fluid.
This method allows the Fahrenheit scale to have values below freezing at 32°F
water freezes: 0°C = 32°F : Water freezing point at standard atmospheric pressure of 14.7psi , 273.15 °K
Flowing water has some kinetic and thermal energy and wont freeze in air 32°F
Water in higher pressure will be more difficult to crystallize correctly to ice

"a chilly day": 10°C = 50°F : a slightly warm day can be perhaps from ~ 45°F to ~71°F
"room temperature": 22.2°C = 72°F : this is a human subjective, average comfortable living or "room" temperature
"a hot day" : 30°C = 86°F : The air temperature measured in the shade. ~87° or greater.
A high humidity level can often make the air temperature feel much warmer,
especially when the temperature is above 72°F.
water boils: 100 C° = 212°F = 373.15 °K

For temperatures above 200°F, the equivalent Celsius scale temperature is approximately half. Likewise, for temperatures above 100°C, the equivalent Fahrenheit temperature is approximately double.:

100°F = 37.8°C =~ 38 °C
125°F = 51.7°C
150°F = 65.5°C
175°F = 79.4°C
200°F = 93.3°C
225°F = 107°C
250°F = 121°C
275°F = 135°C
300°F = 149°C=about half
325°F = 163°C
350°F = 177°C
375°F = 190.5°C
400°F = 204°C
425°F = 218°C
450°F = 232°C
475°F = 246°C
500°F = 260°C
525°F = 274°C
550°F = 288°C
575°F = 302°C
600°F = 315.5°C
1000°F = 538°C
2000°F = 1093°C
3000°F = 1649°C
: **rounded, approximate values**
4000°F = 2204°C
5000°F = 2760°C
6000°F = 3316°C
7000°F = 3871°C
8000°F = 4427°C
9000°F = 4982°C
10000°F = 5538°C

As a quick "rule of thumb", notice above that at about 175°F and greater, the numeric part of the equivalent C° value is about half. Likewise, for temperatures greater than 200°F, or about 80°C, that the equivalent numeric part of the F° value is about double the Celsius equivalent. The Celsius equivalent is about half that of the Fahrenheit numeric value. It still needs to be stressed that a even few degrees Celsius is equivalent to many degrees of Fahrenheit. For values between 100°F and 200°F, the equivalent numeric part of the corresponding Celsius value is about 40% of the Fahrenheit numeric value. For values between 50°F and 100°F, the corresponding Celsius value is about 30% of the Fahrenheit numeric value.

Materials made of elements that are more dense can both absorb and-or conduct thermal (heat) energy better than that of less dense materials. A layer of metal can conduct heat well, whereas a layer of cardboard, (steady, non-flowing or non-moving) air, plastic or foam does not absorb and-or conduct heat well. The atoms of metals have many electrons and the atoms are also more "packed" into say a cubic centimeter of volume, and therefore making it a denser material than say air or water. This density of atoms increases the probability and-or efficiency of (mechanical, vibration) heat transfer from one atom to another. Air is not as dense as a metal and therefore it does not conduct heat very well as compared to that of a metal, and air is considered as both an electric and heat insulator. Denser materials with more atoms and electrons can store more thermal energy.
Although (non-metallic, non-molten) fluids, such as water, are not as dense as metals, they can still absorb and easily carry (transfer) heat energy from a source to a destination at relatively large distances away and speed of travel. An example would be a hot water heater which heats water to a higher temperature which then gets sent or directed through a pipe so as to be available at a distant location where it is useful such as for a washing and-or showering.

Given two different elements of say each being 1 cubic centimeter in volume, the denser element will have more mass (amount of matter, atoms) in that same volume or space. If those two materials are subjected to the same heat source, it will take the denser element longer to heat up to the temperature of that heat source because the denser element can store more thermal energy. Because the denser or "more mass" element can store a greater amount thermal energy, it will retain that thermal energy longer when sitting in the air, and will take longer to cool-down or reduce in temperature to the surrounding air temperature.

For reference, and as mentioned in this book, if one pound (weight, = 454g = 0.454kg) of water is heated and it increases by 1 degree of Fahrenheit temperature, it is said to have gained **1 BTU** (British Thermal [measurement] Unit) of (thermal) energy which is equivalent to about **1056 joules of energy**, roughly 1000J = 1kJ of energy. This value does not included any inefficiency or energy losses (ie., wasted energy) heating that material, here water, but rather is the thermal energy needed and-or gained by the water.

1 Newton (N) is the (constantly applied) force needed to accelerate 1 kilogram of mass by 1 meter per second, per second. 1N = (mass)(acceleration) = (1kg)(1 m/s^2). 1N =101g of force (ie., weight) in Earths gravity = 101**gf** =~ 100 gf = 100 **g**ram-**f**orce. 1kg-m = 1N of force = 0.225 lbs of force , mathematically: 1lb = $4.44\underline{4}$ N , 10N =~ 1kg of force in (g)

1**Joule** of energy and-or work is expended applying a constant force of 1 newton through 1 meter of distance.
1J = 1 (force)(distance) = Fd = 1 Nm = (ma)(d) = 1 (Newton)(meter) = (1kg) (m/s^2) (m) = 1 kg (m^2/s^2) =
1J = 1 Nm = 1 kg (m/s)^2

The joule (J) is a unit of energy, and its named in honor of **James Joule** (1818-1889), from England, and who studied heat energy, such as that produced and-or wasted in a resistance when an electric current (ie., electricity, electron flow) is passing through it. Since heat is a form of energy, heat and-or electrical energy has an equivalent mechanical (Ie., "dynamic", and due to physical forces of matter with kinetic energy) energy such as (force)(distance) = work , and which can produce the same amount of heat. Essentially, any form of energy, and which can be converted to one form or another, including work, can and should have the same units such as **joules (J)**.

Power (P) is the (average) rate of using energy during a time interval, and has units of Watts. Power is therefore not the total amount of energy transferred and-or used during a length of time. Power is how much (average) of total amount of energy was needed, transferred, and-or used during a period or amount of time.

Power = (total energy / time) = (joules / time) watts. : rate of using energy or= doing work **,** Also: 1W = (1V)(1A).

1 Joule (J) of energy used for 1 second of time can be defined as 1 watt of energy:

$1W = \frac{1J}{1s}$, mathematically: **1J = 1W-s = 1 watt-second**

If 1 watt of power is applied or used for 1 hour = 3600 seconds of time:

Total energy used = (power)(time) : derived from the power equation above

(1W)(1hour) = 1 w-h = $\left(\frac{1J}{s}\right)$ (3600 s) = 3600J of energy : 3600Joules = 1W-h = 1 Watt-hour

Note the difference of the meaning of the units mentioned above:

watts is the energy used per an amount of time, hence watts is a rate of using energy , and
watt-hours is the total amount of energy used : Wh = (watt-hours) = (watts)(hours) = (J/s)(3600s) = J / 3600

If 1 watt is applied , used or converted for 1 hour, this can be expressed as: 1 watt-hours = 1w-h = 3.412 **BTU**/hour = (1056 joules/BTU) (3.412 BTU) = 3603 joules/hour ~= 3600J/hour. Consider that if 1watt-second = 1w-s = 1J/s, and if the time length or duration of using this energy is 1 hour = 3600 seconds, then the amount of energy would be 3600 w-s= 3600 J/hour = 3.412 BTU/hour. Note that 3600 w-s is not equal to 3600 watts per second, but is rather the total amount of watts used during the 3600 seconds = 1 hour of time, hence a total of 3600 watts (total) per hour. If 3.142 BTU/hour = 1 watt-hours, then after multiplying both sides of this equation by 3600, we have: (3600)(1) watts-hours = (3600)(3.142 BTU/h) = 12283 BTU/hour. Also from the above information, 1BTU/hour = 0.293 watt-hours =~ 0.3 Wh.

For electricity: 1J = 1 w-s = for example =: (1V)(1A) (1s) or for example =: (10V)(0.1A)(1s) :Joules = watt-seconds

A **calorie** (thermal) energy unit is defined as the thermal energy gained within a gram = 1g of water when its temperature is increased by 1 degree Celsius. **1 calorie = 4.185J (joules) of energy**, and it is roughly equal to 4.2J For a given temperature, it is not too difficult to conceive that when the mass of an object is (n) times more than that of a lesser mass object, then it can hold that many (ie., n) times more total thermal (heat) energy. This book discusses calories, specifically for food, and which is sometimes and more properly called as "food calories" or "dietary calories" in more detail later in this book. If you heat, say about 30 grams of water in an insulated container with a thermometer in it, and by using an electric resistor (here, effectively wastes and-or converts electric energy to thermal or heat energy) submerged in it, it will take an amount of seconds. The average amount of energy to raise 1 gram of water by 1 degree can then be calculated as: Total Energy / grams = (V)(A)(s) Joules / (grams of water) , and the result should be about 4.185J / 1 gram = 1 calorie or= 1 scientific calorie. 1 food calorie is equal to 1000 scientific calories.

Freezing Sea Water To Remove The Salt, and other related topics:

Because of the salt (sodium chloride molecule, table salt) in ocean or sea water, salt water is more difficult to freeze, that is, it takes a slightly lower temperature for it to freeze at about 28.4°F =~ -2°C. Pure water takes 32°F = 0°C to freeze. This difference in the freezing point is about 3.6°F or 2°C less. This is due to the interference of the salt molecule with the water (H20 molecule) ice crystal being formed. A pure **crystal** of a material has only atoms or molecules of the same type and they are physically arranged in a consistent, repeating order or array. When salt water freezes, the ice will not have the salt in it, and this is one method, called freeze desalination,so as to **desalinate** salt water. It is generally incorrect to think that freezing water is the best way to remove impurities and-or make it safe to drink. If very cold ocean water can be placed in a pond in a cold climate, it will be able to freeze naturally and more rapidly since there is (hopefully) less wind and no ocean wave movement giving the water some kinetic energy and preventing it from freezing faster into a nice crystal form. Sea or ocean water is about 3.5% salt by weight, hence 1kg = 1000g of salt water will have about 3.5g of sodium chloride which is table salt. Ice (ie., frozen water) can be melted to a liquid water form by using various solar heating methods such as a warm greenhouse.

Before modern electric refrigerators were available, various methods that used ice, cool water, and-or cool earth were used to refrigerate items. When water freezes it will expand slightly, and this can put much force and-or pressure (force per unit area) upon a container or region, and may cause it to crack, and this is why it is good to fill cracks on building structures, roads and sidewalks with a water resistance material, such as tar (a high percent carbon mixture), before freezing temperatures and ice occur in the winter. Running or moving water can also enter cracks and cause sever land or dirt erosion and which is more difficult to repair.

If the salt water is very cold, it will only take a few degrees less to make it freeze. During heat desalination, it takes much energy to heat water to its evaporation temperature where the phase of water changes from liquid to gas. Direct solar thermal (heat) energy can be used to help pre-heat large amounts of salt water. This type of (pure) water is called "evaporated water" and it is sometimes available in some stores, and it is used for cleaning, car batteries, and wounds, but it is generally recommended to not drink it as is without mixing in some trace amounts of certain minerals to replace those not in it.

A somewhat related topic to desalination of water is the disinfection or sterilization of water, so as to prevent illness and disease. Using various screens and-or cloth, visible debris should be removed from water, however, this does not mean small germs have been removed. Heating filtered water hot for several minutes will help disinfect (ie., neutralize germs) water. Most sources have also mentioned about **5 drops of household, plain, fragrant free bleach per gallon of reasonably clear, filtered of visible particles source water**. Since a drop is standardized at 0.050mL = 0.00005L of volume, we have: (5 drops)(0.050mL/drop) = 0.25 mL = 0.00025L , and since household bleach has a density of about that of water, this equates to about 0.25g = a quarter of a gram-weight. For 10 gallons, this would equate to 2.5g For 100 gallons, this would equation to 25g (ie., about an ounce of bleach). Before drinking any portion of this water, allow some time (several hours if possible) to let the chlorine disinfect germs, and to then "gas off" (evaporate) and-or heat it to speed up this process. **A simple or quick rule is to use 1 teaspoon of household bleach per 5 gallons of water**.

Extra: Note that :

1 ounce of weight = 1 dry ounce = 1 oz = 28.3495 grams , 1 oz = 1 pound / 16 = (1/16) lb = 0.0625 lb
1 Imperial or British fluid ounce of water = 1 oz of weight
1 US fluid ounce of water = 29.5735296 grams = 1.043176441 oz of weight =~ 29.574 cc water = 29.574 mL of water =
=~ 30 grams of water = 30mL of water = 30 cc of water =~ 1 ounce of weight . 1 US fluid "food ounce" = 30 cc

DISTANCE OR LENGTH

We commonly use units of meters, centimeters, feet and inches for distance. An object moving can travel a distance and the formula for this distance is: distance = (speed) (time) = (velocity) (time) = v t. Speed or velocity is how fast something is moving. Mathematically: v = d / t , hence it is the rate of change in distance traveled or moved, and divided by the change in time (t = d / v) it took to move that distance. The units of measurement for velocity or speed is a combination of units, and is the distance units used divided by the time units used. For example: v = 10 m / 1 s.

There are various instruments to measure distance. For example: rulers, both English and Metric gauged linear scales, rope and wheeled rotation counter gauges for long distances, and English and Metric micrometer gauges for small distances and with a high numeric precision and-or fractions of a unit of measurement.

1 in. = 1" = 1 **inch** = (1/12) of 1 ft = 0.083333.. ft = **2.54 cm (exact) = 25.4mm** = 0.0254m :slightly greater than 2.5cm

The key to converting between metric and English distance units is to know this equivalent length value: 1 in = 2.54cm

1 in = 3 (average sized, from the center area of the barley seeds) barleycorn (ie., barley seed) lengths ,
2 in = 5.08cm =~ 5 cm = 50mm , 1 in / 10 = (1/10) in = 0.1 in = 2.54 cm/10 = 0.254cm = 2.54 mm.
1 in = 2.54 cm = 25.4 mm . 1 in / 16 = (1/16) in = 0.0625 in = 2.54 cm / 16 = 0.15875 cm = 1.5875 mm =~ 1.5 mm
1 mil = (1/1000)in = 0.001 inch = a thousandth of an inch = 2.54 cm/1000 = 0.00254 cm = 0.0254 mm = 25.4 um ,
1in = 1000mils , 1000 mil = 1 in = 2.54cm = 25.4 mm = 25400 um

1 meter = 1m = 100 cm = 1000 mm = **3.28084 feet** , =~ 3.281 feet =~ 3.3 ft , = 1.09361 yards =~ 1.1 yd
1m = 100cm = 1000 mm = 1,000,000 um = 1,000,000,000 nm = 1,000,000,000,000 pm
1m = 39.37 in = 3 feet + 3.37 inches = 3 feet + 3 inches + 5.92128 sixteenths of an inch =~ 3ft + 3in + 6 sixteenths of an inch =~ 1 yd + 3in. 1m = 100cm , 1in = 2.54cm , 100cm / (2.54cm/in) =~ 39.37 in =~ 3.281 ft

1 cm = since **1 in = 2.54 cm** , mathematically: 1 cm = 1 in / 2.54 = 0.393700787 in =~ **0.3937 in**
1 cm = **1 centimeter** = (1/100)m = 0.01m = 10mm = **0.3937 inches** :**~ 0.4 = 40% of an inch** , **10cm =~ 4in =~ 100mm**
1cm =~ (3.1496 / 8) in =~ (6.3 / 16) in , (3/8) in = 0.375 in which is a good approximation if you have an English ruler.
1cm = 1m/100 = (1/100)m = a hundredth of a meter = 0.01m = 0.010m = 10mm
1cm =~ 0.393701 inches, (in) =~ 0.4 in or 40% of an inch , ~ (6.2992 / 16) in =~ (6.3 / 16) in ~= 3 eighths of an inch
10 cm = 3.93700787 in =~ very close to 3.937 in = (3 in + (15/16) in) =~ 4 in

By repeatedly dividing an inch unit by two, or in half:

1.0 in = 4 quarters of an inch = 8 eighths of an in. = 16 sixteenths of an in. = 32 thirty-two-seconds of an in.
(1 in / 10) = 0.1 in = "one-tenth" of an inch , Ex. 3.1" = 3" + 0.1"

1 nautical mile = arc length distance of 1 arcminute on Earth = 1min of arc ¢ from N. pole to S. pole. = 1.852km = about
= 6076ft = 1.15078 miles. Nau is an old word prefix for things pertaining to boats and navigation. Each degree of angle contains 60 minutes of angle, and each minute of angle contains 60 seconds of angle:
360° = 360 arcdegrees = 360 (60) = 21600 arcminutes = 21600 (60) = 1296000 arcseconds
From the center point of the Earth: A 360° arc = an arc length of 1 circumference of the earth =~ 25000 miles
1° or 1 arcdegree on the surface of Earth corresponds to: ~ 25000 miles / 360° =~ 69.44 mi = ~ 70 mi
1 arcdegree = 360°/360 = 1° = 1 degree , 1 arcdegree = 60 **a**rc**m**inutes = (60 **am**)(60 **as**/am) = 3600 **a**rc**s**econds
From horizon to horizon = 360° / 2 = 180° = 21600 arcminutes / 2 = 10800 arcminutes = 648000 arcseconds
1 arcmin = 1arcdegree / 60 = 1°/60 = 0.016666...° = 0.01666$\underline{7}$ arcdegrees , 1 arcmin = 60 arcseconds
The Moon appears to us on Earth as being 0.5° wide = 0.5° / (0.01667°/1 arcmin) = 30 arcmin = 1800 arcseconds
The Moon's diameter is about 2159 miles , 1800 arcseconds / 2159 miles =~ 0.83$\underline{4}$ arcseconds / mile
Or: 0.5° / 2159 mi. = 0.000231$\underline{6}$° / mile
1 arcsecond = 1arcmin / 60 = 0.0166$\underline{7}$° / 60 = 0.00027777...° =~ 0.0002$\underline{8}$° arcdegrees

For what each degree on the Earth's circumference length corresponds to, we can set up an equivalent ratio or proportion equation: 360°/ 25kmi as = 1° / x mi , x mi = 69.44mi , (1°/60) = 0.01667° = 1 arcminute angle = 1''
1° is to 69.44 mi as = 0.01667° is to x mi., **1 arcmin is about 1.15 miles = (1/60) arcdegree**
Or: (25000mi / 360°) =69.4444 mi / degree = 69.4444mi / 60 arcminutes =~ 1.15741miles / arcminute

The arclength of 1 arcdegree on Earth is about: 25000mi / 360° = 69.444 miles
The arclength of 1 arcminute on Earth is about: (25000mi/360°)/60 = 1arcdegree/60 = (69.444 miles)/60 = 1.15741mi
The arclength of 1 arcsecond on Earth is about: 1.15741mi/60 =~ 0.01929mi = 101.852ft =~ 100ft =~ 30meters

DMS = **D.M.S** = An angle measuring system = arcdegrees . arcminutes . arcseconds = D° + M' + S" = arcangle or "angle of arc". This system turns the fractional parts of a degree into units - much like how a fractional part of an inch is called a sixteen or an eight of an inch, and so on.

1 knot = 1 naut = 1 nautical mile per hour = 1.852km / 1 hour = about 1.151 miles / 1 hour , hence a speed or rate
1 furlong = 1/8 mile = 0.125 of a mile = 660 feet = 10 chains. 1 furlong was also used to define the side length of 1 acre of area. A stadion or stadia is 1/8 of a Roman mile, hence 5000ft/8 = 625ft. A furlong and stadion (or stadium) are nearly identical. Furlong ("furrow length") is based on the word furlang which is the length of the furrow (trough) or planting length of a 10 acre field. A furlong is the length cattle could typically plough (plow) before needing rest.
1 rod = (1/40) furlong = 16.5ft . 1 chain = (1/10) furlong = 66 ft = 4rod

1 foot = 1 ft = 30.48 centimeters = 0.3048 meters = ~ 30 centimeters = ~ 0.3 meters
In relation to ancient Greece units: 1 pous =~ 12.13 in =~ 1 foot
1 yard = 1yd = 3ft = 36 inches = 0.9144 meters = 91.44cm , slightly less than a meter, about 90% of a meter = 90cm
1 pace = 30.0 inches = 2.5 feet = 2 ft + 6 in. The pace is now an outdated unit, and is mentioned in older texts.
A pace is the average distance from the heel of one foot to the heel of the other foot when "distance walking". Surely this depends on the physical condition of the person. The value shown here is for a single step, and a full step is simply twice this value. A pace is a way to measure distances, such as on trails, and without standard measuring devices - perhaps a string of known length. A pace is sometimes used described how fast a person or thing is moving, such as 100 paces per minute = distance / time = velocity. Using this method, the walker would not have to count their "steady or constantly paced" steps, and the distance traveled can be found by the time taken, and is mathematically: distance = (velocity)(time) = (known or typical steps / minute) (time in minutes).
1 stride = 2 full steps or 2 paces. The word "pace" is sometimes used as a word for "speed" and-or "ability".

1m = 1 meter = was defined as 1/10,000,000 = 1(10^-6) the distance from the Equator to the North-Pole, hence this assumes that this distance is 10,000,000 meters or 10,000 km =~ 6214 miles, and multiplying this value by 4 so as to have the total circumference of the Earth, we have Ce = 40000km = 24855 miles, and this is very close to the modern accepted value of about 24900 miles. From these values, the "other side, or halfway around the Earth" is 2(6214 miles) = 24855/2 = 12428 miles. Here the meter is defined by what we can see in nature, and is much like defining a length based on the average seed length of a common plant. To make the meter practical it can be placed in terms of other known units. If 10000 km = 6214 miles, then after dividing both sides of this equivalence by 10000, we have 1km = 0.6214miles =~ 3281 feet , and after dividing both sides by 1000, we have 1m = 3.281 ft.

1m = 3.28084 ft =~ 3.281ft = 100cm , dividing both sides by 100, we have: 1 cm = 0.03281ft
(0.03281ft)(12in/ft) = 0.39372in = 1cm , solving for 1in by dividing both sides by 0.39372,
we have ~=: 1in =~ 2.54 cm , 1in = (1ft / 12) = 0.08333333ft
1m = 39.375 in = 1.09375yd

1 barleycorn (average barley seed length, from the center of the seed pod) = (1/3) inch = 0.3333 in
Barley is one of the ("cereal") grass plants (barley, wheat, oats, corn, rice) that produce edible seeds (or "corns") called grains. **Three average size barleycorn lengths from the center of the seed pod were used to defined an inch unit**. Surely, once this unit was defined, here naturally, wood and metal rulers of 1 inch were then rather used. Due to this natural definition, the length of the foot unit is based on the length of 1 inch, and 1 foot is defined as 12 inches, and then mathematically, 1 inch can then be "redefined" as (1/12) of a foot = 0.83333... ft.

The English shoe scale is based on the barleycorn = (1/3) in. For the length of the shoe, size 12 = 12 inches long, and each size lower is 1 barleycorn less in length, hence (1/3) of an inch less. Size 11= (12in - 0.33in) = 11.66 in. For some extra comfort, many will wear up to a size bigger (ie., longer) so as to have some extra toe ("wiggle room") space, and-or to consider a bigger size that may be usable for wide feet when wide-width shoes are unavailable.

1 cubit = 20.625" = 0.5236m (about 20" or half a meter) A cubit is an ancient distance or length measurement unit that was naturally defined as the length of an average man's arm from the elbow to the tip of the middle finger. Some cubit measurements vary from 18" (Bible) to 22", and 20in is an average = 50.8cm. **20.6 in = 1.71667 ft = 1 ft + 8.6 in = 52.324cm is the Egyptian Cubit; typically used**. This value is approximately half a meter = 0.5m. A cubit is an ancient measuring unit for length, and mentioned in the Torah, Old Testament book which is about 4000 years old at the current time of writing of this book. The Egyptian cubit was further divided into 28 (finger ("digit") sized widths) markings or steps. The cubit was often divided into steps of basic fractions (1/2, 1/3) of a cubit. A "palm" or "palm width" was "4 fingers wide". A cubit has 7 of these palm units, hence a palm unit is equal to a 1/7 fraction of a cubit unit. **As an example of expressing the difference and percentage between a measurement and a reference value:** If 20in is used as the cubit, then it is slightly less and in error of the 20.6in Egyptian Cubit by only: error = (value - reference value) = (20in - 20.6in) = -0.6in, and this error value as a percentage of the reference value is: (error value / reference value) = (-0.6in / 20.6 in) = -0.02913 = -2.913% =~ -3%. As a ratio of the two given measurements: (value / reference value) = (20 in / 20.6 in) = 0,97087 =~ 97%. That is, the average value is about 97% of the Egyptian reference value, and about: (1 - 0.97) = 0.03 = 100% - 97% = 3% percent less. Though this is a small percentage of error, it will become significant if may cubits are involved.

Mils. A mil is 1/1000 of an inch. A mil is sometimes used by a **machinist** when working with metal so as to be more precise than say a value with units of 32nds or 64ths of an inch. Since metric units are now common, the mil unit is not used much. The average human hair is 1 mil thick or wide. Mathematically, **1 in = 1000 mills**

1 mil = 1in / 1000 = 0.001 inch = a thousandth of an inch : note, 1" = 1in = 1 inch = 2.54cm = 25.4mm
1 mil = 0.001 in = 1 in / 1000 = 2.54 cm / 1000 = 0.00254 cm = 0.0254 mm = 25.4 um : um = micro-meters

1 mm = (1m / 1000) = 0.001m = 1000 um : mm = milli-meter
1 mm = (1cm / 10) = 0.1cm = "one-tenth of a centimeter" , 1 cm = 10 mm
1 mm = 0.03937000787 in =~ 0.03937 in =~ 0.04 in =~ 1.5 thirty-two-seconds of an inch = 1.5 (1 in/ 32) =
1.5 (0.03125 in) = 0.046875 in =~ 3 sixty-fourths of an inch = 3 (1 in / 64) = 3 (0.015625 in) = 0.046875 in
1 mm = 39.37007874 mils = about 39.37 mils =~ roughly 40 mils : derived from the above equivalence for mils
1 cm = 10mm = 10 (1mm) = 10 (39.37 mills) = 393.7 mils =~ 394 mils =~ roughly 400 mils
1 cm = 0.3937000787 in =~ 0.3937 in =~ 0.4 in , Note also that 1 cm =~ (3.15 / 8) in = 0.39375 and (3/8) in = 0.375 in
1 m = 100 cm = 100 (1 cm) = 100 (393.7 mils) =~ 39370 mils =~ roughly 40000 mils

1 inch = 1000 mils = 2.54cm (exact) = 25.4mm = 25400um : from this , the fractions of an inch can be found:
1/2 inch = (1/2)" = 0.5 in = 1.27cm = (1000mils / 2) = 500 mils = 12.7 mm
1/4 inch = (1/4)" = 0.25 in = 0.635cm = 250 mils : 1000mils / 4 = 6.35 mm
1/8 inch = (1/8)" = 0.125in = 0.3175cm = 3.175mm = 125 mils : = 1000mils / 8 =~ 3 mm
1/16 inch = (1/16)" = 0.0625 in = 0.15875cm = 1.5875mm = 62.5 mils =~ 1.5 mm
1/32 inch = (1/32)" = 0.3125 in = 0.079375cm = 0.79375mm = 793.75um = 31.25 mils =~ 0.8 mm
1/64 inch = (1/64)" = 0.015625 in = 0.0396875cm = 15.625 mils =~ 0.4 mm

1 inch = 1 in = 1" = 8 (1 inch / 8) = 8 (0.125 in) = 1 in
1 inch = 1 in = 1" = 16 (1 inch / 16) = 16 (0.0625 in) = 1 in
1 inch = 1 in = 1" = 32 (1 inch / 32) = 32 (0.03125 in) = 1 in
1 inch = 1 in = 1" = 64 (1 inch / 64) = 64 (0.015625 in) = 1 in

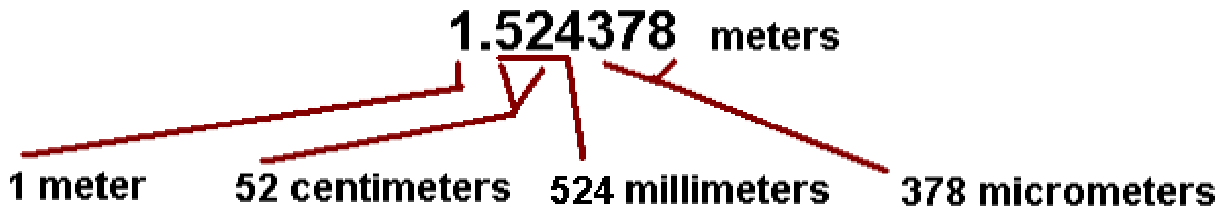
1 square-inch area = (1in)(1in) = 1in^2 = (1000mils)(1000mils) = (1000)(1000) mils^2 = 1,000,000 square mils
1 square mil = (1mil)^2 = (0.001 in)^2 = (0.001)^2 (in^2) = 0.000001 in^2 = a millionth of a square inch
= (0.0254mm)^2 = (0.0254^2)(1 mm)^2 = 0.00064516 mm^2
1 circular mil (CM) area has a diameter of 1 mil = 0.0254mm, and its area is: A =(pi)(r^2)= (3.14159265)(0.0254mm/2)^2 =
= 0.00050671mm^2 = (5.0671)(10^-4) mm^2

Wire diameter or "thickness" sizes may be expressed in mils (thousandths of an inch), or millimeters (mm, metric).

There are wheels, perhaps having a 2ft circumference, at the end of a rod which a user can push so as to measure long and-or awkward distances such as trails by the number of revolutions recorded on a counter, and then multiplied (ie., repeated addition) by the circumference of that wheel. Total Distance = (revs)(C distance)

1 fathom = 6 feet = 1.8288 m : a fathom is generally an old unit for water depth. Fathom is usually considered an old word for understanding, to make sence of.

How to comprehend a given value of meters. For example:



1m + 52cm + 4mm + 378um or:

1m + 524mm + 378um or :

1m + 52.4378cm

The decimal point in 1.524378 separates the number of whole meters from the fractional value of 1 meter:

number = whole meters + fractional value of one meter

number = meters + centimeters are hundredths of a meter + millimeters are thousandths of a meter +
+ micrometers are millions of a meter

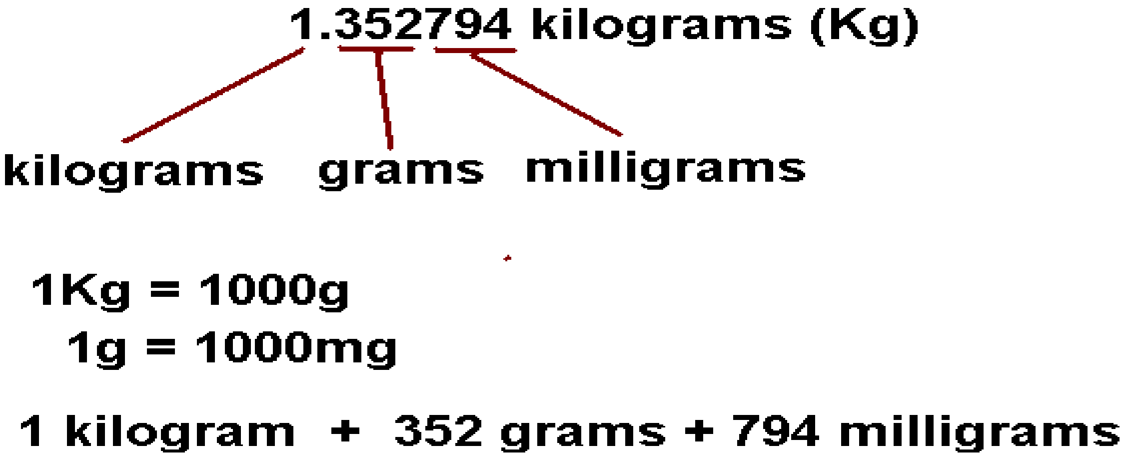
Ex. 52.4 cm = (52.4 cm)(1m / 100cm) = (0.542)(1m) = 0.524m

We see above that when we want to convert cm to meters, we have like units of (cm) in the numerator of one factor and (cm) in the denominator of another factors, and so as those units will cancel out and leave us with the units we want to have, and those are meters, and of which were placed in the numerator.

Ex. 52.4 cm = 52cm + 0.4cm = 52cm + 4mm
Ex. 1.542 m = (1.542m)(100cm/m) = 152.4 cm = 100cm + 52.4cm = 1m + 52cm + 0.4cm = 1m + 52cm + 4mm
Ex. 1.57347 km = 1 km + 573.47 m = 1 km + 573 m + 47 cm = 1 km + 573 m + 470 mm

For comparison: 1.43 ft = 1 ft + 0.43 ft = 1 ft + 0.4 ft + 0.03 ft = 1 ft + (4/10) ft + (3/100) ft : (1/10) ft = (12in/10)= 1.2 in

Here is an similar example of the above, but it is for how to comprehend a mass value with metric units such as kilogram (Kg) units. Note that 1 Kg = 1000g units.



Ex. 1.524378649 Kg = 1 kilogram + 524 grams + 378 milligrams + 649 micrograms =
= 1kg + 524g + 378mg + 649ug : here the value after the decimal point is less than 1 Kg
: micrograms may be expressed as **mcg** or **ug**

Ex. 0.003 Kg = 0 kilograms + 3 grams = 3g

Ex. 1.234 g = 1 gram + 234 milligrams = 1g + 234mg : here the values after the decimal point is less than 1 gram
Ex. 0.5g = 0 grams + 500 milligrams = 500mg
Ex. 0.001g = 0 grams + 1 milligram = 1mg

For a given amount of time, distance and velocity are directly related and proportional in value.

distance = (velocity)(time) = v t

From: d = v t , $\frac{d}{v} = t$, and if (v) changes by a factor of (n), then distance (d) will also change by that same factor of (n):

$$(n)d = (n)v\,t \quad , \quad \frac{d}{v} = \frac{d\,(n)}{v\,(n)} = t = \frac{d1}{v1} = \frac{d2}{v2}$$, and mathematically: $\frac{d1}{d2} = \frac{v1}{v2}$ and-or: $\frac{d2}{d1} = \frac{v2}{v1}$

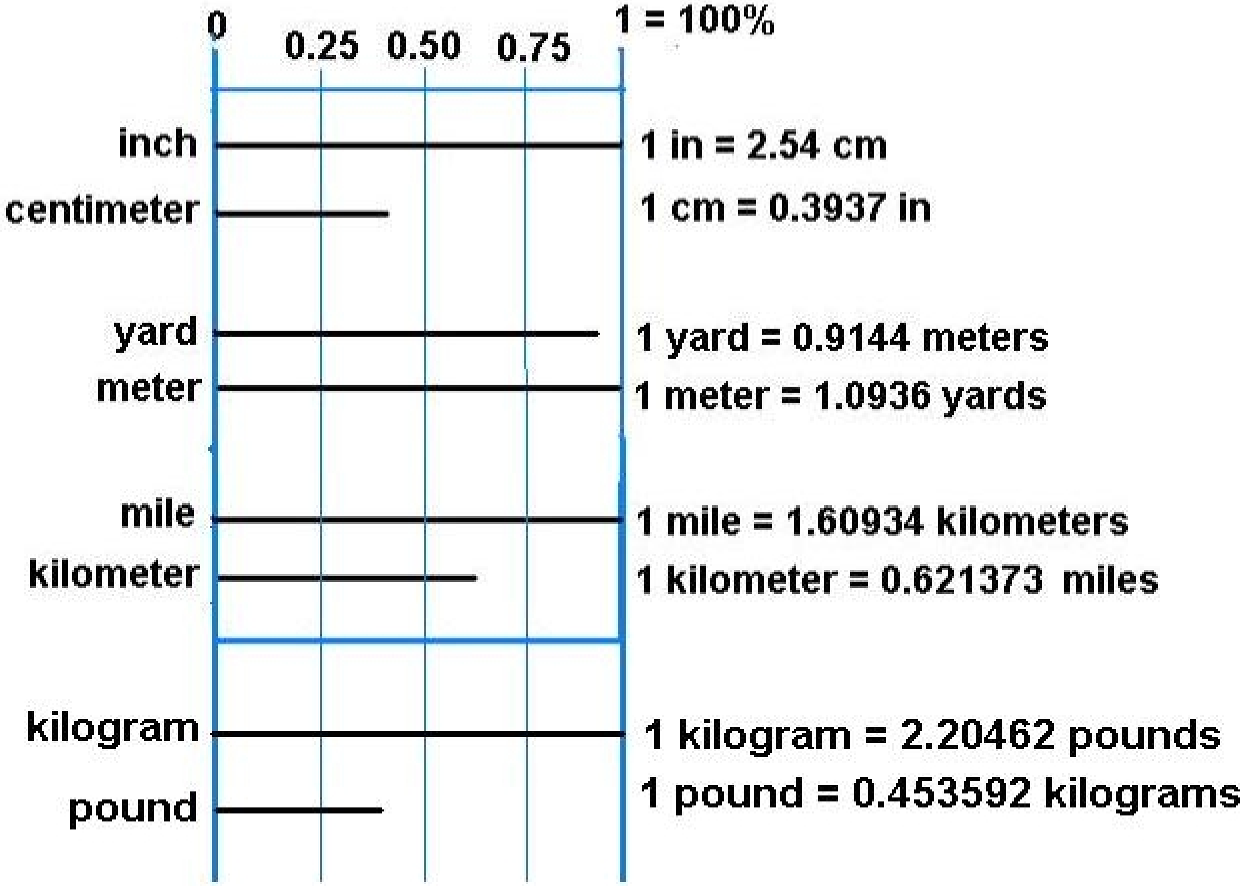
Note also that: d = vt is a linear or line equation of the form: y = mx , and $\frac{y}{x}$ = m = v = slope = a constant for a line.

Likewise, in a similar manner, if (v) is a constant value, (d) and (t) will be directly related and proportional in value:

d = v t , mathematically:
$\frac{d}{t} = v \quad , \quad (n)d = v\,(n)t \quad , \quad v = \frac{d}{t} = \frac{(n)d}{(n)t} = v = \frac{d1}{t1} = \frac{d2}{t2}$, and mathematically: $\frac{d1}{d2} = \frac{t1}{t2}$

Some Relative Sizes Of English And Metric Units

This figure is a quick and visual comparison of some length units. Also included is some mass and-or weight units The individual lengths are not drawn to actual size, but each set of two distances is rather drawn in relative or (fractional) percentage relationship to each other only. [FIG 219A]



SQUARE AREAS: (Some cubic units are also mentioned)

1 square inch = 1 in^2 = 1 in x 1 in = 2.54 cm x 2.54 cm = 6.4516 cm^2

1 square centimeter = 1 cm^2 = 1cm x 1 cm = 0.3937in x 0.3937in = 0.155 in^2
1 square centimeter = 1 cm^2 = 1 cm x 1 cm = 10 mm x 10 mm = 100 mm^2

1 square foot = 1 foot long by 1 foot wide = 1ft x 1 ft = (1)(1)(ft)(ft) = 1 ft^2 = 12in x 12in = 144 in^2 = 929.0304cm^2
1 square foot = (1ft)(1ft) = 1 ft^2 = (0.3048m)(0.3048m) ~= 0.092903 m^2 = roughly 0.1m or a tenth of a sq. mt.
1 square foot = 12in x 12in = 144 sq. in = 929.03 cm^2 =~ very roughly, ~ ~ 1000 cm^2 ~~ (1/10) m^2 ~~ 1m^2 / 10

1 cubic foot = 1 square foot x 1 ft. high = 1ft long by 1ft wide by 1ft high = 1ft x 1ft x 1ft = (1)(1)(1)(ft)(ft)(ft) = 1 ft^3
= 144 in^2 x 12 in = (base area of cube)(height of cube) = 1728 in^3 = 1728 cu. in

1 square yard = 3 ft x 3ft = 9 ft^2 = 36in x 36in = 1296 in^2 = 0.836127 square meters =~ 83.4% of 1m^2

1 square meter = 1m x 1 m = 1m^2 = 100cm x 100 cm = 10000 cm^2
1 square meter = 10000cm^2 = (10000cm^2)(0.155 in^2 / 1 cm^2) = 1550 in^2 = 1.196 square yards
1 square meter = 10.7639 square feet = 1550 square inches

1 square kilometer = (1000m)(1000m) = (3280.84ft)(3280.84ft) = 10763911.11 ft^2 = 0.386102 square miles
1 square kilometer = 1000m x 1000m = 1000000 m^2 = 1 million square meters

1 square mile = 5280ft x 5280ft = 27878400 square feet = (1.60934 km)(1.60934 km) = 2.589975 km^2 =~ 2.59 km^2
1 square mile = 2589998.11 square meters =~ 2.59 square kilometers
1 square mile = 640 acres , and if this is or was thought of as an actual square shape, it would be about 25.3^2 acres

1 acre, a unit of area, is defined as 660ft x 66ft = 1furlong x (1/10) furlong = 43560 square feet (ft^2) The square root of 43560 sq. ft. is about 208.7 feet, which is slightly over 200 feet long on the side of a square shaped area. An acre is therefore about 200ft x 200ft. = 40000 ft^2. An acre was defined as the average amount of land that an ox could till (plough, "plow") in a day, and the furlong was used for its dimensions, and the long length considers the plowing of a long (660ft) straight distance of 1 furlong along the typically narrow (66ft average) planting widths along rivers. The long furrow length meant fewer difficult turnings (reversing direction) of the oxen or horses. 1 square acre of land = 43560 square feet = 43460 ft^2 = (208.7 ft)^2 = (208.7ft / (3ft / yd))^2 = (69.567 yards)^2 =~ 4840 yards^2

1 acre = 63.612m x 63.612m = 4046.856 square meters = 0.004046866 square kilometers = 0.0015625 square miles

A square mile is 5280ft x 5280ft = 27,878,400 square feet , and 27,878,400 ft^2 / (43,560 ft^2 / 1acre) = 640 acres.
If each side of a given square area, say A1, is increased by the factor of (x), the total area increases by the factor of x^2 :
A2 = (xL)(xW) = x^2 LW = x^2 A1 , and A2/A1 = x^2

In the metric system, an area of: 10m x 10m = 100 square meters is called an "are" (based on the word for "area", the word "square" appears to be based on the word "are" or "area", and "square" then means "an e**q**ual **s**ided **are**a").

10m = 32.9701 feet ~= 11yds. 100 sq. m = (10m x 10m) = (10m)^2 = 100m^2 = (32.9701ft x 32.9701ft) =~ 1087 ft^2.
100 (= "hect") of these ares is called a hectare = (100 sq. meters / are) x (100 ares) = 10,000 square meters = (1/100)km^2 . 1km^2 = (1000m)(1000m) = 1 million square meters.
1 hectare = 2.47105 acres =~ 107639.104 ft^2 =~ 328^2 feet =~ 328 ft x 328 ft =~ (100m x100m)= 100 m^2 = 0.01 km^2

Extra: If something is said to be, for example: 0.75 square inches, this could be thought of as a square inch and then with a reduced dimension, such as its height being 0.75 inches long. If 0.75 square inches of total area was to have a square shape with equal side length dimensions, each side would be the square-root of this amount of area when it is considered as having a square shape with an area of 0.75 cu-in, and that value here is the square root of 0.75 in^2 which is equal to 0.86603 in. A square with sides = s = 0.86603 in will have an area of 0.75in^3.

In a square, L=H, hence its area is equal to A = L x H = L x L = L^2 , and the square-root of this area is L.

Surface Areas

The general formula for the area of a rectangle is : A = (length)(width) , if both dimensions increase by a factor of (n), the area will increase by (n^2): A2 = (n length)(n width) = n^2 (length)(width) = n^2 A1. If only one dimension increases by a factor of (n), then the area will increase by that same factor of (n); A2 = (n length)(width) = (n)(length)(width) = n A1

A cube has 6 square sides of equal sizes or areas. Each side is s^2, therefore, the surface are of a cube is:

Surface area of a cube = 6 (Area of 1 of the cube faces) = 6s^2 **: surface area of a cube**

For a rectangular prism, much like a stretched cube:

Surface area of a rectangular prism = Sum Of Area Of Its 6 Sides . There will be 3 pairs of 2 equal area sides.
Each area can be found from:
Any rectangular area = (length of side)(width of side) = (L)(W) sq. units

Arp = (areas of side pair 1) + (area of side pair 2) + (area of side pair 3)
Arp = 2(L1 W1) + 2(L2 W2) + 2(L3 W3) : terms with a common factor of 2:
Arp = 2 [(L1 W1) + (L2 W2) + (L3 W3)] :surface area of a rectangular prism

For the **surface area of a sphere**: A sphere structure can be created by rotating a circle or disk 180 degrees (half of a full rotation of 360 degrees) about its diameter line.

As = 4 (pi) r^2 = 4 (pi) (d/2)^2 = 4 (pi) d^2/4 = (pi) d^2 **: surface area of a sphere** = (pi) (area of a square)
r = radius , d = diameter. Also , **As = Cd or= CD**

For irregular and-or uncommon structures having flat and-or curved sides of various dimension, its total surface area can be found by the sum of each of those flat sides.

Smaller Objects, In Or Of A Larger Object, Will Have A Larger Total Surface Area

If you decrease the radius of a sphere, you obviously (by observing the formula for surface area of a sphere) will decrease its surface area. If you have a large amount of tiny spheres, say within another known amount of volume, such as that of a sphere or cube, their net or total surface area is greater than that of the largest possible sphere in that volume. A large value of surface area has some practical applications, particularly when trying to get maximum contact between substances and-or for more efficient processes. Consider a block or cube cut in half, there will now be more surface area.

The ratio of a spheres surface area to its volume is found using division of the two formulas, and is: (3/r). The smaller the radius (or diameter) of a sphere, the resulting value of (3/r) will increase, and this effectively means that the ratio of the surface area to volume, of a smaller sphere, is larger.

One way to help verify this is to imagine a unit cube or volume of 1 (unit^3)=cubic unit. If you divide its dimensions in half, each part, cube or smaller volume, will be only: (1/2)^3 = 0.5^3 = 0.125 unit^3 , but the total volume will remain the same. (1 unit^3 / 0.125 unit^3) = 8. There will be 2^3 = 8 smaller cubes if you divide a cubes dimensions in half. This is somewhat similar to dividing the radius of a sphere in half, but with a sphere, its surface area will decrease by 4, and its volume will decrease by 9. The total volume will be the sum of all the smaller segments of a certain volume. The total surface area will be the sum of all the smaller segments of a certain surface area. Dividing a volume up into smaller volumes will not result in a sum of those volumes being greater than the source volume.

The surface area of the cube with 1 unit, with 6 sides or surfaces, is: 6 (length x width) = 6 (1 x 1) = 6(1) = 6 (units^2).
The surface area of that cube divided up into 8 smaller cubes when its dimension are halved (divided by 2) is:

8 (surface area of one small cube) , and
8 ((6) (length x width)) = 8 ((6) (0.5 x 0.5)) = 8(6)(0.25) = 48 (0.25) = 12 square-units
Note the total number of (smaller) surfaces is 8 times more, and that the total surface area doubled.

For a thought experiment consider a circle, and all about that circle's circumference on the inside or outside of it are smaller half-circles side by side, and clearly, the (arc) length of each half-circle or semi-circle is longer than the portion of the larger circle's circumference it subtends or is on. This helps verify that the surface area is also larger for the smaller semi-circle(s) and theoretical smaller spheres. Consider a very large circle where the circumference is line-like for a small segment of it and the shortest distance is directly along its path, clearly an arc of a semi-circle placed on that segment is longer, and it has a larger surface area.

Some selected speed or velocity conversions:

1ft/second = (1ft)(3600) / (1s)(3600) = 3600 ft / hour = 0.681818 miles/hour = 1.097338 km/hr =~ 1.1 km / hr =!~ 1km/hr

1 km/s = 1000 m/1s = 0.621371 mi/s = 3280.84 ft/s = 3600000 m / 1h = 3600 km / 1h 1 hr = 60 s

1mile / 1s = 5280ft/s = (1mile)(3600) / (1s)(3600) = 3600miles / hour = (3600miles/hr) (1.609km/mile) = 5792.4 km/h
5 miles / 1s = 5 (1mile / 1s) = 5 (5280ft/s) = 26400ft/s = 5 (3600miles / 1 hour) = 18000 miles / 1hr = 28962 km/h

For angular velocity = w, and (linear) revolution velocity, see the section below titled: ANGLES AND ROTATION.

MASS: (The amount of real and-or physical matter, material or substance.)

Every object and-or (physical, real) substance will have mass (ex. grams), weight (depending on the local gravity, ex. Newtons, pounds), and volume (ex. cc, liters, cups. Mass and Weight are proportional to each other. An amount of mass can be determined by its weight. Two substances that weigh the same will have the same amount of mass, but then this does not determine the specific types of matter that the mass is, such as what element it is. Different elements have different densities or amount of matter per unit volume. Given a unit volume of two elements, their densities (= mass/volume) will not be the same, but different. Due to this, their weights per unit volume will also be different. An element or type of mass can be determined by its density (= weight / volume). Mass is independent of the gravity placed upon it, that is, mass is a universal concept, whereas the weight of an amount of mass depends upon the local gravity field and-or force upon it and giving that mass an acceleration: **Weight = weight of a mass = Force created due to gravity = force = (mass)(acceleration) = ma , in gravity, a mass will experience acceleration (g), hence: Weight = force = mg , and mathematically, m = weight / g**

The word "mass" appears to be rooted in the ancient Greek word "maza" and Latin word "massa", with a general meaning of "to mash and-or collect into a larger pile". Various words and-or spellings such as "make", "maker" and "massage" are rooted in those words and meanings. "Mass" has a general meaning of a large amount of a substance or material, hence the word "massive". Scientist use the word "mass" to usually mean the amount of physical substance(s) or matter, and which can be determined or measured by its corresponding and proportional weight (ie., the force due to gravity upon that mass).

In general, if the volume of a substance changes by a factor of (n), its mass and-or weight will also change by that same factor of (n).

gram is a word based on the ancient Greek word "gramma" which means a small weight, and may be related to the word "gravity" which has the general meanings of "seriousness" or "grave", weight, and matter which means the physical material or substance which has weight. It could also be rooted in the concept of a "**gra**in or **gra**nule [small piece] of **m**atter".

A gram is technically a unit of mass and not weight. The weight of an object is often expressed as the corresponding gram units of mass, and this is due to that the mass of an object is universal, whereas an objects weight depends on the local gravity of the planet. Weight is a unit of force and not mass. Weight = force = ma = mg. Mass = m = f / a = force / g = weight / g . (g) is the local gravitational acceleration. On Earth, g = 9.71m/s^2 = 32.2ft/s^2

1g = 1 gram of matter. Matter is real, physical material, and mass is the measure of it and has units of grams. This matter could be composed any substance, element, atoms, molecules, etc. Though having a different number of atoms or molecules, A mass of 1 gram of any substance(s) still has the same number of **atomic mass units** (**amu** or= "daltons" [in reference to John Dalton who studied such things]) which are protons and-or neutrons. The specific number of amu so as to have a gram of mass or matter is defined as 1 mol of amu. 1 mol of amu is 6.18 (10^24) amu. 1g of mass = 1 mol of amu, such as protons. Since a hydrogen atom only has a proton, 1g of mass = 1 mol of hydrogen atoms. 1g of any substance will also have the same weight since the number of amu in each gram of that substance is the same. A "common weight scale" is calibrated so as to show the corresponding weight as being 1g. Weight and mass are directly related and proportional. If something has twice as much matter or mass, it will weigh twice as much and vice-versa. The mass or amount of matter or material of an object can be found by weighing it. See the topic of WEIGHT shown below. 1 amu is sometimes called a **nucleon** since it is part of the nucleus of an atom.

1g = 1 gram. This was initially defined as the weight of 1 cubic centimeter volume of water due to Earth's gravity force. Anything that weighed 1g therefore had the same about of substance or matter. 1 gram of cotton has the same weight and mass (ie., matter, substance) as that of 1 gram of iron. Using volumes or containers to measure a true amount of substance has various problems such as randomly sized air gaps between the substance, such as between apples, grain, cotton, fabric, etc., and it creates a doubt as to what amount of matter or substance is actually in that volume. Surely a solid cube of gold weighs less than a hollow cube or box of gold that is the same size and looks exactly like the same volume. The way to avoid this problem of actual substance s to rather know the mass and-or weight of the item in question rather than its volume.

1g = the (corresponding) weight of 1cc of water or water mass = 1cm^3 volume of water = 1mL volume of water.

1g is also the base unit of the amount of mass, matter or substance, and without any influence of gravity.
1g of mass has 1g of weight displayed on a common weight scale, and this allows finding an amount of mass by using a common weight scale calibrated to display the corresponding mass value of an object or substance.
1g of mass, matter, material of any substance or element will have the same weight. This is since it will have the same total number of fundamental mass particles or atomic mass units (amu) which are protons and neutrons.
1g of water is actually 1 gram of water molecules which are composed of hydrogen and oxygen atoms, therefore, a fraction of that gram of mass or material of water is hydrogen and another fraction of that gram is oxygen.
Since atoms of different elements have different mass, the weight of those atoms is different. An atom of hydrogen does not weigh the same as an atom of oxygen. A mol count of hydrogen atoms does not weigh the same as a mol count of oxygen atoms. Still, a gram of hydrogen atoms does weigh the same as a gram of oxygen atoms.
A water molecule is composed of 2 hydrogen atoms and 1 oxygen atom. Hydrogen has 1 amu per atom, and oxygen has 16 amu per atom. 2 hydrogen atoms will have a mass of 1amu + 1amu = 2amu. A water molecule therefore has 2amu + 16 amu = 18 amu per water molecule. Since 16 amu / 2 amu is 8 times more, the weight of the oxygen atoms in any amount of water will be 8 times more than the weight of the hydrogen atoms, yet each water molecule has 1 oxygen atom per 2 hydrogen atoms, and that there is not 8 times more atoms of oxygen in a water molecule. Mass does correspond directly to the number of (amu) particles, but not to atom or molecule sized particles which contain various amounts of amu or mass depending on the specific element or substance such as a molecule, and therefore these particles will have a different (total) mass. An oxygen atom has more amu per atom than a hydrogen atom, and therefore it has more mass and weight than a hydrogen atom.

1g = 0.035274 oz = ~ 3.5 hundredths of an ounce , 1 oz = 28.3495g , 1 **Troy ounce** = 31.1034768g, 1 Troy ounce = 1 toz = $1.097\underline{1}$ oz = 1.097 oz =~ $1.\underline{1}$ oz in the (outdated, 1400's) English Troy mass system: 1 troy ounce = 20 pennyweights, and 1 pennyweight = 24 grains of the avoirdupois system. 1 Troy pound = 12 troy ounces. Troyes is one of the French towns of which many merchants went to buy, sell and-or exchange goods. The British Imperial units system replaced the Troy system in 1824. Troy ounces is still used for some precious metals.

A "**food ounce**" in the U.S.A. is standardized as simply being 30g of mass, and when in agreed use.

1g = 1(10^-3)kg = 0.001kg : a gram is 1gram / 1000 = "a gram is one-thousandth of a kilogram"

1g of mass actually weighs = force = (mass)(acceleration) = (0.001Kg)(9.81m/s^2) = 0.00981Newtons

1 milligram = 1 mg = one-thousandth of a gram = 0.001g.
1 microgram = 1mcg = 0.000,001g = one-millionth of a gram = one-thousandth of a milligram = 1mmg = 1 ug = 1mcg

A slug is a unit of mass in the (older, previous) US Customary or US Common, and British measuring systems. This unit has become outdated and is nearly obsolete, but it may be useful to know about for any possible reference and-or conversion needed. The word "slug" is from same word used in reference to piece of bulk-metal or "bullion" yet to be processed into smaller metal items. A piece of metal such as a coin yet to be stamped with a design is sometimes called a "blank" or "slug".

1 slug = 1 slug of mass = a mass of 1 slug

From: force = F = (mass)(acceleration) = ma

$$m = \frac{F}{a}$$

: extra, note that for a given force, if the acceleration is high, it is because the mass is low, and this is an inverse mathematical relationship. When a force is applied to a mass, more massive things are more difficult to change their motion and-or accelerate due to their inertia.

1 slug = (1lb of weight) : a slug of mass defined as a "gravitational pound" (GPound) due to a pound of weight.
(_1ft__) mathezation:
(1s^2)

(1lb of weight) = (1 slug)(_1ft_) = F = m a
(1s^2)

1 slug of a mass [matter, material atoms, real substance] has a weight [a force] of 32.17405 lbs due to gravity (= ~ 32.2ft/s^2), and this is 32.2 times more than (1ft/s^2). 1 slug =~ 143.1173 N

weight = force = (mass)(acceleration)
32.174 lbs =~ (1 pound-mass)(32.2 ft/s^2) : a (pound-mass) , (ie., a pound of mass) is the mass that will weigh 1 lb on a (force=weight) scale on Earth's surface and gravity (ie., g=acceleration due to the force of Earth's gravity) value there, hence it is said a being or correspondingly having
1 pound-weight = 1lb of wt = the wt of 1 lb or simply as = 1 pound : wt = weight

F = ma = (1 pound-mass)(32.2ft/s^2) = (1 slug)(1 ft/s^2)

From: mass = force / acceleration = weight / acceleration , we have from the above equation:

(1 pound-mass) = 32.174lbs weight / (32.2 ft / 1s^2) , mathematically:
(1 pound-mass) = (1lb-weight) / (1ft. / 1s^2) , from this we have:
(1lb-weight) = force = ma = (1 pound-mass) (1ft / 1s^2)

1 slug = a mass having a weight of 32.174 lbs = 14.59390312 kg of mass , dividing each side by 14.59390312 , we find:
1kg = 1000g = 0.068521765 slugs , dividing each side by 1000, we find:
1g = 0.000068521765 slugs = 6.85218 (10^-5) slugs

Since 1slug of mass will have a weight of 32.174lbs, after dividing each side by 32.174 we find:
1 lb of weight (a force due to gravity acting upon a mass) corresponds to matter having a mass of 0.031081 slugs

1kg = 1000g = 0.0685217659 slugs, and in the force of gravity, this will weigh 2.20462lbs.
1g = 0.0000685218 slugs = 6.85218 (10^-5) slugs

Note: A foot-pound = ft-lb is a unit of work and-or energy:

Work = Energy = (force)(distance) = (distance)(force) = (1ft)(1lb) = 1 (ft-lb) , with the units rearranged so as not to be confused with torque as mentioned below.

Ex. The Work or Energy required to move a 1lb weight object a distance of 1 foot is 1ft-lb. Applying a constant force of 1lb through a distance of 1ft, is 1ft-lb of work=energy.

In numeric value, work = energy used or required: f = ma =1lb = (0.454kg)(9.81m/s^2) = = 4.454 N , 1ft=0.305m , E=W = fd = (4.454N)(0.305m) **= 1 ft-lb = 1.35582 Nm = 1.35582 Joules**

Note: A pound-foot = lb-ft is a unit of torque or "twisting or rotating force" placed upon and-or applied to the rotational or pivot point at the center, and which is like an amplified input force when that force is transferred via a lever-arm and-or radius..
Torque = (force)(lever-arm) = (force)(radius distance from center) =
Torque units are (lb force)(ft) = lbf-ft. **1 lbf-ft** , and which is sometimes simply called a
1 lb=ft =~ (0.453592 kgf) (0.3048 m) = **0.138255 kgf-m = 1.355818 Nm** = **1 ft-lb** (see

1ft-lb mentioned above, ie., 1 (ft-lb) can be used to cause a torque of 1lb-ft = 1 (lbf-ft)

WEIGHT: Weight is equivalent to the downward force of a mass due to the influence or force of gravity (g) of the Earth being applied to and pulling downward on that mass and giving it acceleration, and even when the object appears still, and not in motion, and this can be observed by the constant weight value indicated for object on a weight measuring scale.

Weight = a Force caused by gravity = (mass)(acceleration) = F = ma or= mg

Some units of weight are outdated, but are still needed for past reference and conversions.

In the S.I. or Metric System, weight = force due to gravity = (mass)(acceleration) = (kg)(9.81m/s^2) Many modern "(metric) weight scales" will automatically convert the weight of the mass to just its mass value. For example, an object that weighs 9.8N = (m)(a), has a mass of 1kg and will be displayed on the scale as 1kg. This type of scale is actually a (user friendly) "mass scale" since for many people would rather have the (universal) mass value,rather than its corresponding force or weight value. 1Newton of force or weight is defined as = 1N = (1kg)(1m/s^2) = ma = f . A mass might have much kinetic energy KE= mv^2 / 2, but if it does not push or collide with an object, no force (the application or transfer) will be applied to that object, and therefore, no energy will be transferred to it. If a force is applied to an object, the mass that caused it will decelerate: F = ma , a = F / m.

1N = 1 Newton of force and-or it's equivalent weight = 1N = (1kg)(1m/s^2) = (mass)(acceleration) = force = ma. The velocity of a 1kg mass or object will change or increase by (1m/s) and for each 1 second of time if this amount of force (ie., the application of energy, inducing or causing a transfer of energy) is still being applied to that object and increasing its kinetic energy. In the presence of Earth's gravity force which applies a higher acceleration of 9.8m/s^2 near the Earths surface altitude (or practically less than a few hundred miles high), the mass would be less:

1N = force or= weight = (mass)(acceleration) =~ (0.1kg)(9.81m/s^2) = (100g)(9.81m/s^2) ~= 0.981N
1N = 101.97g =~ 102g :or equivalent gram-weight (force) on Earth = **roughly 100 g = 0.1 kg = 0.220462 lbs**
1N = 3.5969452724 oz =~ 3.6oz =~ 102g
1N = **0.22481 lb** : noted as about or roughly 0.25lbs = a quarter of a pound, shown above.
9.81N =~ 10N =~ the force of 1kg in Earth's gravity (a=g) = weight of 1kg of mass = **1kg weight** = 1kgw = 2.205lbs

1 lb = 1 pound of force. 1 pound of force or simply "1 pound". An amount of mass that happens to weigh 1lb on a weight = force scale, could be said as being the weight of a mass of: 1lb-mass = "1 pound of mass" = 1 mass-lb, or a mass having a force of one pound in Earth's gravity force and acceleration of about: 32.2ft / s^2 = 9.81m/s^2 Weight and mass are proportional, and if one changes by a factor, the other will also change by the same factor.

1 lb = 1 pound = 1 lb-weight = 1 lb-force = 1lbf = 1 one pound of weight in the avoirdupois system of weight = 7000 average center grains of barley. A barley grain is a seed of barley and is therefore called a "barleycorn". The corresponding mass which would weigh or have a force or weight of 1 lb in the influence of Earth's gravity is called a pound-mass = lbm. The pound is used in the US Customary and (British) Imperial Measuring system, however, the metric or SI (System International, or International System) measuring system use kilograms for mass, Newtons for force, and meters for distance are now widely used. The English word and unit of weight called a "pound" is based on the Latin word "poundus" which is a unit weight. A phrase sometimes still heard is "pound it down" or "pound it in", which basically mean to force or press something down or in. So that people do not have to have barley seeds and to count them all, equivalent or reference weights of 1 pound and other weights are available and are commonly used, such as for calibrating (checking, adjusting) weight scales so as to be accurate. The (previous in history, ancient) Roman libra (L) or pound (lb) was equivalent to about 0.75 pounds today.

1 lb = **16 oz. of weight or force** = **corresponds to a mass of**: 0.45359237kg = 453.59237 grams = about **454 grams** in the influence of Earth's constant gravity force causing an acceleration of (a=g=9.8m/s^2) and causing a force = weight = (mass)(acceleration) = ma = mg. 1lb =~ 45% of a kilogram, or vaguely as 0.5kg = half a kilogram

Since 453.59237 grams = 453.59237 cc of water, taking its cube root we have a side length of: 7.683432 cm. = 3.025 in =~ 3in + 1/32 in =~ **3 in** , and as a cube, this side length would then make:
(3.025 in)^3 = 27.68064063 in^3. 1 lb of water =~ 454 grams of water = 0.454L of water = 454cc = 454 mL vol

1 lb = 4.44822 Newtons. In other words: 1 pound of weight (a force) =~ 4.448 newtons of force =~ 4.54N
force = (mass)(acceleration) = f = ma =~ (0.454 kg)(9.81m/s^2) =~ 4.45N

1 lb = 1 pound (a weight) is defined as the weight of 16 fluid (a volume) ounces of water. 16 fluid ounces is defined as the amount of volume called a pint. 1 pint = 2 cups. 1 cup = 8 fl.oz of volume of any substance and regardless of its weight because the volume concept does not consider weight, and-or is a different concept than the weight concept. 1 lb of another substance other than water is still defined as 16 weight oz of weight of that substance.

In the United States customary system, mass can also have units of pounds, and it is more properly said as pound-mass (lb-m) as opposed to pound-force (lb-f). 1 pound of mass is defined as a mass which weighs (id., a force) 1 pound in the force of Earth's gravity. The usage of pounds (weight) is more common than using slugs (mass), particularly due to many scales are calibrated in pouinds of weight rather than slugs of mass.

Ton = "tun" = An English or short-ton=2000lbs. A long-ton = a metric ton = 2240lbs = 1.12 ton = 1000kg
A force that is said to be 1 million pounds of force can lift a maximum weight of 1 million pounds = 500 tons.
A ton of weight (ie., force) = (2000lbs)(4.448N / lb) = 8896 Newtons of force. 1 (10^6) lbs = 4.448 (10^6)N.
The word ton is derived from a certain container called a tun, of which when filled, it had 2000lbs of weight of a liquid substance, and may also be derived out of the word s**ton**e which was a certain unit of weight.

1kg = 1000g = 2.204622622 lbs =~ 2.2lbs = weight of 1L of water = weight of 1000cc of water.
1g = 1(10^-3)kg = 0.001kg = weight of 1 cc = 1mL of water , 1lb = 0.45359237 lbs

1kg = 35.27392 oz

A metric tonne is 1000kg = 2204.62lbs = with a "long" or English ton equivalent of 1.10231 English ton

1 English stone = 14lbs = 6.3503 kg , a very old unit of measurement that is not used much anymore.

1g = 15.43235835 grains (average sized center barley grains, hence a natural, non-made made, unit of measurement)
1 **grain** = (1/7000) avoirdupois pound = 0.06479891g =~ 65 mg =~ 0.0022857 oz

1g of mass in the influence of Earth's gravitational force field will weigh (a force) of 0.0098067N =~ 0.01N.
100g = 0.981 N =~ 1N.
454g = 4.45374 N =~ 4.54N = 1lb of weight
1000g = 9.81 N =~ 10N

1 pennyweight = weight of 24 average, center located grains of barley =~ 1.5552g

1 dram = (1/16) of an ounce in the common **avoirdupois** pound (lb) system = 0.0625oz = 1.772g. A dram is a also unit of mass and volume (fluid-drams) in the **apothecaries** (older, pharmacy) system where 1 dram = (1/8) fl.oz. = 0.125fl. oz. **The avoirdupois (bulk goods and weights) system was the English and European system just before the metric system.** In ancient Greece, 1 obol = 0.1g , In ancient Rome, 1 unus or ounce = 27.41g, and 1 libra = 329g

1 oz = 1 weight and-or "dry ounce" (and **not** a "fluid, volume ounce size"), = a fraction of a pound (= lb) unit = (1/16)lb = 0.0625 lb = 16 drams = 437.5grains of barleycorn = **28.34952313 grams** ~= **28.35 g** in the common avoirdupois system, and 480 grains in the apothecaries and-or troy system = 31.103g = 1/12 lb. A US **"food ounce"** is often rounded and simplified to: 1 US fl-oz =~ 29.57 cc =~ 30cc = 30mL and it could be said that 1 US oz of weight is about equivalent to the weight of 30g of mass. **The US weight ounce and British or Imperial weight ounce are equivalent in value.** There is a slight difference between US and British or Imperial fluid volumes. **Many**

countries are now using the equivalent Metric system: grams, meters and liters in place of any of older systems and their units. The United States is currently (2025) using both the older US Customary System and the modern Metric system, and with a future where the metric system is used mostly. Nonetheless, you may still encounter older and-or outdated measuring system units, and will need to make a conversion to the corresponding number of metric units, etc.. The word "ounce" is based on the ancient Roman words "unus" and "uncia", meaning "once" or an "instance of", and of where the words "unit" and "inch" (= 1/12 foot), come from.

1 oz =~ $0.0283\underline{5}$ kg = $28.3\underline{5}$ g :of mass , **This is a key to remember for converting English and Metric mass values**
1 oz = $0.27801\underline{4}$ Newtons of weight and-or force. : of weight or force = (mass)(acceleration) = ma = mg
1 toz = 1 **troy ounce**, a standard made in the city of Troyes, France, and of which is located in the central area of north-eastern France. 1tz ~= $31.1034\underline{8}$ g 1tz =~ 1.097143 oz ~= 1.097oz ~= 1.1oz

1 carat (ct) = 1 "carat weight" = 200mg = 0.2g = 0.007055 oz , hence 1g = 5 carats , such as for the mass of precious, rare minerals, stones and metals, such as a diamond. This word is derived from the word carob seed used as a common reference weight. 1 oz = 28.3495g = (28.3495g) (5 carats/g) = $141.74\underline{8}$ carats

A karat = a fractional (here equal to 1/24) measure and unit for the percentage of pure gold in a metal alloy. 1 karat means that the substance is or contains (1/24)% pure gold. (1/24)% = $4.16\underline{7}$% , 14 karat is (14/24) = 50% pure gold , 24 karat is (24/24) = 1 = 1.0 = 100% pure gold. 1 karat means that roughly 4% of the total mass and-or weight of a substance will be pure gold. 10 karat will mean roughly (4%/carat)(10 carats) = 40% of the total mass and-or weight will be pure gold.

Some commonly available reference and-or calibration weights and lengths:

When you do not have a known reference or calibrated weight or mass, such as 1oz or 1g, you can use some common items which are known to have a certain weight, mass or volume. You can use multiples and-or combinations of the known weights or masses so as to obtain or sum to a larger reference weight and-or mass. Many of the items listed below will require a fine (weight to equivalent mass) scale which can measure, say a gram to a high precision, say 2 decimal places such as (1/100) = 0.01 of 1 gram, and if you want to verify its mass and-or weight. If the item(s) you are weighing need a container to hold them in, be sure to first measure the weight of this container so as it can be subtracted (ie. to "tare", remove) from the total weight measured or displayed. Some electronic scales have a tare button which will set the scale to a value of 0.0, and to be pressed or activated after the empty container is placed on it.

1 **U.S. penny coin** = 1 cent = (1/100) of 1 dollar (1 USD $1 = 100 cents), monetary value, and base unit of the USA monetary system. If this coin was made in 1981 or earlier, it is mostly copper and with a mass of 3.11 grams = (3.11g)(1oz / 28. 349523g) = 0.109702 oz.. For 1983 and later, 97.5% zinc, weighs 2.5 grams = 0.0881855oz. The mass of two modern "zinc pennies" will be 5 grams. Its diameter is 0.75 in. = 3/4 in. = 12 sixteenths of an inch = 6 eighths of an inch = 19.05mm = about 19mm. Rim thickness is defined at 1.52mm. 4 of these penny coins side by side in a line, will have a total length of 3 in. 16 of these would have a total length of 12in = 1ft. 2 modern pennies would have a mass of: 2.5g + 2.5g = 5g = the mass of 1 U.S. nickel coin.

1 **U.K. pence coin** = penny coin = 1p = 1 cent or (1/100) of 1 pound monetary value. 1p = 0.01 GBP (Great Britain Pound). From 1992 and later, the coin is made with copper coated steel. mass = 3.56g, diameter = 20.3mm , thickness = 1.65mm.

1 **Euro cent coin** = (1/100) or 1 cent of a European Union dollar = E0.01 or $0.01E. Since 1999, it is composed of steel with a copper coating. Its diameter is 16.25mm, its thickness is 1.67mm, and its mass = 2.30g

1 **Rupee coin of India** = stainless steel since 1992 , mass = 3.76g , diameter = 21.93mm , thickness = 1.45mm,

1 **U.S. nickel coin**, 25% nickel, 75% copper, weighs 5 grams = 0.17637oz. , width is 0.835in = 21.21mm , rim thickness is 1.95mm This data excludes same sized nickel coins minted from 1942-1945 so as to conserve copper.

1 **Canadian nickel coin**, year 2000+, weighs 3.95grams = about 0.139oz , diameter = 21.2mm , thickness = 1.76mm

1 **Austrailian nickel or 5 cent coin** = 75% copper, 25% nickel. mass = 2.83g, diameter = 19.41mm , thickness = 1.3mm

1 **U.S. dime coin**, nickel clad, pure copper interior with a nickel-copper plate, 91.67% total copper, weighs 2.268 grams Diameter is 0.705 in = 17.91mm =~ 18mm = ~ 0.7 in. A pre-1965 silver dime weighs 2.5g. Also check the U.S. quarter coin.

1 **Austrailian dime or 10 cent coin** = 74% copper, 25% nickel, mass = 5.65g, diameter = 23.6mm , thickness = 2mm

1 **U.S. quarter coin**, nickel clad plate, 91.67% copper, weighs 5.67 grams = 0.2 oz. A 1932 to 1964 silver quarter is 90% silver and 10% copper, weighs 6.25 grams = 0.2205 oz. Diameter = 0.955 in = 24.26mm =~ 1 in. The mass or weight of silver in this quarter dollar (q) coin is 90% of its total mass or weight: 6.25g (0.90) = 5.625g . In terms of troy ounces this is: 5.625g / (31.1035g / toz) = 0.1808 toz of silver in 1 quarter (q).
1 **oz** = 28.3495g , 1 **Troy ounce** = 1**toz** = 31.1034768g =~ 1.1 oz , 5.625 g =~ 0.1809 toz
(0.1809 toz / 1q.) (5q) = 0.9045 =~ 0.90 = 90% of 1 Toz. (0.1809 toz / 1q.) (6q) = 1.0854 Toz =~ 1 Toz of silver
(0.1809 toz / 1q)(4q) = 0.7236 toz = the amount of silver in "$1 dollar "**face**" or "coin currency or money" **value**.
Note that "**spot price**" is the current price of silver, and the "sale price" is usually a few percent higher due to that the sellers handling and profit-business charge which is usually called the "(sellers) **premium**" price and-or is a percentage of the price of the total silver purchased, and which is usually **about 5%** added to the price per ounce.

1 **Euro dollar coin** = E1 or $1E, As of 2002, diameter = 23.25mm, thickness = 2.33mm, mass = 7.5g , various metals

1 **Austrailian dollar coin** = 92% copper, 6% aluminum, 2% nickel , mass = 9g , diameter = 25mm , thickness = 2.8mm

1 **U.S. Dollar Bill** = 75% cotton and 25% linen [flax plant] = 6.14in =155.956mm long = about 156mm, and 2.61in=66.294mm wide. Its diagonal length is about 6.912in long = 175.56mm = about 7in. Its weight is designed to be 1g, but could vary by a few hundredths of a gram depending on the moisture in it. This 1g defined weight is for the paper being in an environment that is said to have about 50% or a global average air humidity.

Craft wire, steel metal, ~0.5mm thick, ~35mm long = 3.5cm long = ~ (22/16)in = 1in + (6/16)in = 1.375in , weighed 0.1g
Since 0.1g is to 1.375in, we can express this as: 0.1g/1.375in , Multiply num. and den. by 10, we have 1g / 13.75in
3.5mm of this wire mathematically corresponds to a mass of 0.01g = a hundredth of a gram = 10mg

1 **Human hair width**, on average is about 0.1mm = one-tenth of a millimeter = 100um thick. 10 hairs wide =~ 1mm. The thickness of a common solarcell is about 125 um, and they are also brittle, and therefore will crack or break if bent a few degrees. For reference, a common soda or soft drink can has a wall thickness of about 100 um = 0.1 mm.

Width of an average adult **thumb** finger at the widest part is about 2 cm = (2 cm)(1in / 2.54 cm) =~ 0.7874016 in =~ 0.8 in

The mass of an average a **hard, air-dried yellow popcorn (corn, maize) seed or kernel** is about 0.1614545g=~ 162mg, and its length has an average value of about 7mm = 0.7cm . Therefore: 1g / (0.1615g / 1 kernel) =~ 6.2 average kernels / 1 gram, and 6200 kernels per kilogram (kg). This mass per kernel can be found from the total mass of a total sample size, and dividing by the number of samples. The **digital scale** used for small weights and-or mass had a precision (ie., position, and not necessarily accuracy, but very close to the rated precision) of one-hundredth of a gram = 0.01g, however when weighing a single kernel which is known to vary slightly in size and therefore weight, it usually does not represent the average weight of a single kernel. For example, one single (1) kernel was measured by this scale as only about 0.12g =120mg, but another kernel could measure as perhaps between 0.1g and 0.2g. The average expected kernel mass value from a large sample such as 220 kernels with a mass of 35.52g used for this measurement and calculation is: (35.52g total / 220kernels) =~ 0.162g = 162mg / 1 kernel.

A **steel metal bottle cap** used for a crimp (folded, mechanical) seal, often on a soft drink bottle, is about 2.02g =~ 2g

A solid, clear **glass sphere or glass marble** 13.7 mm in diameter weighs about 5.25g. Weight is proportional to volume. If the weight increases by a factor of (n), the volume increased by that same factor of (n) or vice-versa.

1L volume in a **cube shape** having sides that are almost 4 inches in length. 1L = 1000cc ~ (4in)^3 = 64 in^3 = 64 cubic inches. 1L of water is 1000g of matter and weighs 2.2046 lbs. You can make a homemade 1L volume by weighing out 2.2046 pounds of plain water and marking its height. 453.6g ~= 454g of water is equal to 1 lb of water.

A common **aluminum metal, soda, soft drink soda can** has a basic shape of a cylinder, and has a volume of 12 fluid ounces = 355mL = 355 milliliters = 0.355L, and is 2.13 in. = 5.4102 cm in diameter across the top rim. The main body cylinder has a diameter of 2.6 in = 6.604cm, and the total height of the can is 4.83in. = 12.27cm. The empty can has a mass of about 14g =~ 0.493835 dry ounces =~ half an ounce = 0.5oz. 32 of these cans would weigh approximately 1 pound-weight = 0.453592kg ~= 454g. Pound-weight = pound-force = "pound".

12 full of liquid soft drink cans weighs approximately: (12 cans x 12 fl.oz/can) ~= 144fl.oz =~ 144oz / (16oz / lb) = 9 lbs. The total weight of a "**12 pack of soda**" including the weight of the cans is therefore 9 pounds plus 6oz for the aluminum cans, and a total of: 9lbs + 6oz/16oz = 9lbs + 0.375lbs = 9.375lbs at minimum if considered pure water.

A (very near, metric) standard of **1s and-or 1m** can also be verified by a pendulum as discussed in this book. A pendulum that can define and has a swing of 1 second, is naturally called a "seconds pendulum".
1m = 100cm = 3.281 ft = 3 feet + 3.37 inches = 3 ft + (3.37in x 16 segments/in) =
3 ft + 53.92 sixteenths of an inch ~= 3 ft + 54 sixteenths of an inch =~ 3ft + 3in + 6 sixteenths of an inch =
3 ft + 3 in + (1/4) in + (1/8) in

[FIG 220]

The scale shown has units of millimeters. The coins, from left to right are: quarter, dime nickel, and penny. As an additional reference, a common AA size battery is typically a total of 50 mm = 5 cm long, and 14 mm = 1.4 cm wide. 1 cm = 10 mm. The image above has been magnified, and should not be considered as the actual physical size. The 4 reference coins shown in the image have a total width of about 81.5mm = 3.201in The combined width of the penny and the nickel is 40.25mm =~ 40mm = 4cm. A strip of paper 4cm long (L) can be folded in half so as to have 2cm = (L/2) or half-length, and that can be folded in half so as to have a 1cm = (L/2)/2 = L/4 or quarter-length. This 1cm length of paper can be divided into two 5mm= (L/4)/2 = L/8 or one-eighth-length. For a 1/3 length of a line or one-third of any length= L/3, one method to find this length is to cut a strip of thin paper that is the total length in question, and first bend it into an S curve shape, and then a Z shape, and then flatten this structure so as to have three equal lengths, and with each being (L/3).

1 fluid ounce volume of water weighs nearly 1dry or solid ounce of weight, and is about 1.040843 ounces.
1 U.S. fluid ounce volume of water weighs 29.57353 grams = 29.57353 cc of water ~= 30 "food, fluid, grams" = 30cc
1 fluid ounce of volume of water is about 29.57353 mL of water = 1.80469 in^3 =~ (1.2175 in)^3 : ~ 30mL
1 British or "Imperial" fluid ounce = about 28.41mL , and weighs 1 oz = 1/16 of a pound
1 cup volume of water = 8 fluid oz, volume, of water =~ 8 dry or solid ounces, weighs 236.588 grams = 236.588cc of water
2 cups volume of water = 16 fluid oz, volume of water =~ 16 dry or solid ounces = 1 poiund = 1 lb
1 cc volume of water weighs 0.033814 dry or solid ounces = 1 gram of mass
1 liter volume of water = 1000cc of water = 1000g = and weighs about 2.2 lbs = 33.814 dry oz of weight =~ 2.113375 lbs
1 U.S. gallon volume of water = 16 cups volume of water =128 fluid ounces volume of water weighs 8.326744 pounds

The size of a cube having a volume of 30 cc = 30 cm^3 =~ (3.1072 cm)^3 is roughly 3 cm

A much less common today, U.S.A. "customary measuring system" used the slug as the unit of mass, and a pound as the unit of force (such as weight). 1 slug = 14.5939 kg. A mass of 1 slug has a weight, due to the force due to gravity, of 32.2 pounds. 1 pound of constantly applied force can accelerate a mass of 1 slug by 1 ft/s^2. From: force = weight = (mass)(acceleration) , 32.2 pounds = (1 slug)(32.2ft/s^2). Hence 1 slug of mass of any substance(s) will weigh 32.2 pounds. In this system, which often uses Imperial (an older British system, before the metric system) units, the units of pressure is = force / area = pounds / ft^2 , and-or pounds / in^2. Torque in this system is torque = (force)(distance) = (force)(radius) = pound-inch = lb-in or in-lb. Here, the radius or "lever-arm" value is essentially a "force multiplier" value. Another common torque unit is the foot-pound or pound-feet.

Various units having pounds:

Modern science generally uses the metric system with kilograms (mass), Newtons (force), seconds (time) and meters (distance). Pound units are sometimes still used as in the United States of America and Great Britain. Conversions between old and modern (such as the metric system) measuring systems is often necessary.

Using the word "pound" for corresponding mass and weight seems like a good thing since mass and weight correspond to each other and are mathematically proportional to each other, however, it can be confusing to some people who are left in wonder if the topic is about mass or force. Weight is the force due to a mass when the constant force of gravity (causing acceleration = a = g) is applied to it. On another planet where (g) is not

the same, then a pound of force, and a pound of mass will actually (physically) have different values than those on Earth. Using mass or matter with units of kilograms is more practical and universal, and is the same physical value and measurement regardless of the value of (g) on that planet.

pound-mass = (lbm) = a measurement of mass (amount of real matter, material or substance) via its weight and giving it units of pounds. Note that a pound of mass will weight differently if the gravity is different than Earths gravitational force of acceleration (a = g).

pound-force = (lbf) = a measurement of force and giving it units of pounds. In the force of gravity (g), 1 pound-mass, or a mass of 1 pound has a weight (= force in gravity) of 1 pound-force or 1 pound-weight. Just the same, if given 1 pound-force, the corresponding mass to cause that force in gravity is 1 pound-mass.

foot-pound = (ft-lbf) = a unit of work = energy. Joules (J) is the unit of work = energy in the SI system.
Work = (force)(distance) = (pound-force)(feet) with units of "foot-pounds"

pound-foot = (lbf-ft) = "pound-feet") or= foot-pound = a unit of torque (twisting force) applied about a point.
Here: Torque = (force)(lever-arm distance) = (force)(radius) = (pound-force)(feet)

If a reverse manner, it could be said that the moment of this torque is that it can provide pound-force at a distance of feet from the rotation point.

For reference: 1L volume = 1000cc = 1000g mass of water = 1 kg of water and weighs 9.81N = 2.20462 lbs =~ 10N .
The dimensions of 1L cube are nearly 4in per side, hence 1L has a volume of about (4in)^3 = 64 in^3 = 64 cubic inches.

Some mathematical relationships of pounds and Newtons:

For mass: 1 pound-mass = 0.453592kg = 453.492g =~ 454g , after dividing both sides by 0.453592 :
1kg = 2.2046244 pound-mass = 2.2046244 pound-weight
1kg was defined in terms of distance and water as the mass of: 10cm^3 volume of water = 1000 cc

Force = (mass) (acceleration) , when (a)=(g = 9.81m/s^2 = 32.2ft/s^2), Force = Weight = force due to gravity.

A force of 1N that is constantly applied to 1kg of mass or mater, will keep increasing its velocity or speed by an acceleration of: a = F / m = N / m = (kg m/s^2) / kg = 1 m/s^2 or= 1m/s for each second of acceleration.

Force = weight = ma = (1kg)(9.81 m/s^2) = 1 Newtons = 1N = x pounds of weight

In the US Customary System: Force = (mass)(acceleration) , if (a)=(g = 32.17405m/s^2),
F = (slugs)(32.2 ft/s^2) = weight with units of pound-weight

Since 1m = 3.280804 ft , after dividing both sides by 3.280804: 1ft = 0.3048 m

If the acceleration is: $a = \frac{32.2\text{ ft}}{1\text{s}} = \frac{9.81\text{m}}{1\text{s}}$: = g , Here, this is the acceleration of a object due to the constantly applied force of gravity applied to it..

F = N = (m)(a) , and due to gravity, (a)=(g) and: F = N = weight = ma = mg

9.80665N = (1kg)(9.80665m/s^2) = (2.2046244 pounds-mass) = 2.2046244 pound-force = "pounds"
= weight in Earth's gravity force of: 32.2ft/s^2

Dividing both sides by 9.80665 , we find **1N =~ $0.22480\underline{9}$ pounds** of weight = pound-force or= weight-force

Force = 1 Newton = ma = $0.2248\underline{1}$ pounds ~= one-quarter of a pound =~ 0.25lb such as weight, solving for pounds by dividing each side by $0.2248\underline{1}$:

Force = **1 pound ~= $4.4482216\underline{2}$ Newtons** : a measure of force , 1 lb = 16 wt-oz =~ 454g of force = 454 gf
1 wt-oz =~ 28.375 gf , 1 gf =~ 0.0353 wt-oz

Work = (force)(distance) = (Newtons)(meters) = N-m Joules of energy , and since: 1m = $3.2808\underline{4}$ ft
0.3048m = 1ft:

Work = (force)(distance) = (($0.22480\underline{9}$) (pounds)) N x (($3.28\underline{1}$) (feet)) m Joules , when N=1, and m=1:

Work = (Newtons)(meters) = 1Nm ~= ($0.737562\underline{2}$)(pounds)(feet) = $0.737562\underline{2}$ lb-ft J = energy

Work = **1N-m = $0.737\underline{6}$ lb-ft** Joules of energy , dividing both sides by $0.737\underline{6}$:
: this can be thought of as lifting $0.737\underline{6}$ lb a distance of 1 ft,
or lifting 1 lb a distance of $0.737\underline{6}$ ft.:

Work = **1 lb-ft = $1.3558\underline{2}$ N-m** J : 1 pound-foot =~ $1.357\underline{6}$ Newton-meters

Finding mass and weight from each other. You can find the mass of an object by dividing its weight by (g).

From: force = (mass)(acceleration) = weight , we mathematically have:
mass = (force / acceleration) = weight / g : mass is essentially the weight value with the gravity factor and multiplier removed, and here its divided out

Force has units of Newtons (N). Weight (a force) is actually a measure of an object or mass in a gravitational field such from Earth. Gravity is constantly pulling (attracting) on the object with mass and causing it to accelerate. This will cause the object to have a force, and this force is called the weight of the object. Weight, being a force, is also measured with units of Newtons.

Mass (amount matter, and not its force) and weight (a force) are directly related and proportional to each other having a constant of proportionality of (g):

(g) = (weight / mass) = (force / mass) = (mass)(acceleration) / mass = (acceleration),

Mass and weight can be calculated from each other if the local force of gravity is known which causes an attraction and acceleration of a nearby mass. Technically, given two masses, their gravitational attraction or pull on the other mass is the same value for both, and this concept is called "equal an opposite (direction) forces".

A 1kg mass will have a downward force or weight equal to: (1kg)(9.8m/s^2) = 9.8N or weight.
Therefore, to find the weight or downward force corresponding to this mass with Kg units, simply multiply it by 9.8

The corresponding mass associated with 9.8N of weight is from: mass = (weight / acceleration) = (weight / g) = weight / (9.8m/s^2) = 9.8N / (9.8m/1s^2) = 1N / (m/s^2) = 1kg amount of matter. Therefore, to find the mass of a weight, simply divide the weight by 9.8 and assign the result as having kilogram units, and this is what most "weight scales" are actually calibrated to do, and the result displayed is actually the objects mass (in grams or kilograms units), rather than its weight (Newtons) force due to Earths constant gravity force. Mass is "universal" and a constant value, where as (g) of Earth is not, and it is just a local (specific location, or localized) value in the universe. The local value of (g) on each planet will cause an object to weigh (a force) different value.

1g weighs = (mass)(acceleration) = (0.001Kg)(9.81 m/s^2) = 0.00981N : a common scale is calibrated (ie., adjusted) to display the corresponding mass, and will display 1g.

Note that gravity is a force of attraction of two masses. The amount of force is determined by the sizes of the masses and their distance from each other since the "gravitational field strength" and its effect (of attracting other mass) is less as the distance between those two objects with mass increases. When a force is constantly applied to a mass, it will therefore cause that mass to not only be attracted, but to also accelerate and get faster and faster in speed as it nears the other object. As two objects get closer, their local (due to their masses) gravitational, "attractive" or "pulling" field strength or "force of gravity" is also stronger.

.
Mass in the presence of the constantly applied force of gravity near Earth's surface will then have an acceleration of (a) = g = 9.80665 m/s^2. =~ 9.81 m/s^2. Weight is a value of Force.

F = (m)(g) = the local, Earth "Weight" of that mass , therefore, Weight = (m)(g) , and mass = $m = \frac{\text{Weight}}{g}$

$F = (m)(g) = \frac{(\text{Weight})}{g}(g) = \text{Weight}$

[This space for edits.]

VOLUME: A measure of 3-dimensional (length, width, height) size or space, such as of containers and-or a size or an amount of a substance such as liquid or solids. A volume of something is essentially how much "room" something occupies within a container and-or will need.

1 fluid oz (a liquid, a volume) of water weighs 1.040843 oz =~ 1 dry oz for most practical purposes, therefore 16 fl. oz of water weighs about 16 dry oz = 16 oz = 1 pound = 1 lb : a dry ounce is essentially a non fluid, solid matter weight and not its volume, such as fluid ounces. In general, only 1 fluid volume ounce (1 fl. oz) of water equals 1 dry ounce (1 oz) weight ounce, and other elements or substances (such as mercury or oil) will weigh more or less per fluid ounce. In general, fluid ounces are a volume (3 dimensional space and-or shape having some length, width, and height) and not a weight. **1 fl. oz = 1 foz = 29.57353 mL of volume = 0.02957353 L =~ 29.576 cc**

The word "fluid" or "liquid" is not always indicated to distinguish it from a weight oz, and of which only 1 fluid oz of water actually weighs 1 dry oz. If the substance is not water, then this equal value (volume and weight) correspondence is not true, and should not be considered or used. When volume is considered, it is best to consider and-or indicate "oz" explicitly as "fluid oz", "fl. oz", "volume oz", "fluid volume oz". The Liter (L) is the common base unit for volume in the metric system. **1 fl. oz. = 1 volume oz :fluid ounces are not equal to weight ounces unless it is liquid water**

1L = 1000cm^3 = 1000cc = 10x10x10 cubic centimeters, (fluid) volume. 1 deciliter = (1/10)L = 0.1L =100cm^3 = 100mL
1in = 2.54 cm, therefore 1cm = 0.3937in., 10cm = 3.937in ~= 4in , 1L= (3.937in)^3 = 61.02334 in^3 = 61.02334 cu-in
A gallon volume has 231 cubic inches of volume. 1gal / 1L = 231 in^3 / 61.02334 in^3 = 3.7853447 , therefore:
1gal = 3.7853747 L and after dividing both sides by 3.7853747 , we have: 1L = 0.264170303 gal

1L = (1000 cm^3)(1000 mm^3/cm^3) = 1,000,000 mm^3
1L volume of water = 1000 cc water, and therefore its mass is: 10g x 10g x 10g = 1000 grams = 1 kg mass of water.
One-thousandth of a liter = 1L/1000 = 0.001L = 1mL = 1000cc/1000 = 1 cubic centimeter (which weighs 1 gram)
By filling a container with water, you can find the volume of it by the corresponding volume of water or the mass of it.
For example, if a contain was filled to some level by 400 grams of water, and knowing that there is 1g water / 1cc:
Setting up a proportional or equivalent fraction equation: 1g water / 1cc = 400g water / Xcc , Xcc = 400cc
1L = 1000 cm^3 = 1000 mL
1 liter = 1L = 33.814023 fluid ounces = 2.1133764 pints = ~ 2 pints = 1 quart = 1 qt.
The weight of 1L water at it maximum density at 4°C weighs 1 Kg = 35.274 dry oz = about 32 oz or slightly over 2lb =~ the weight of 1 quarter (ie., 1 quart = 2 pints) gallon of water
1 liter = 1/1000 of the volume of a cubic meter. (1m)^3 = 1m^3 = 1m x 1m x 1m =100 cm x 100 cm x 100 cm =
= (100cm)^3 = 1000000 cm^3
1 liter = 0.264172 gallons = roughly or slightly more than a quarter of a gallon.
1 gallon = 1 gal = 128 fl oz = 128 foz. and 1L / 1gal = 33.814 foz / 128 foz = 0.264172
1 liter =~ 1 quart (quart or quarter =1/4 of 1 gallon) ~= 2 pints ~= 4 cups =~ 32 fluid or volume ounces
1 liter = 1.05669 quarts (a quarter, one-fourth) of a US gallon. 1 quart = 0.94635 liters
1 liter = 61.0237 cubic inches ,and the cube root of 61.0237 in^3 gives a side length of about 3.9372 in = 10cm , or ~4in
1L =~ (4 in)^3 = 4^3 in^3 = 4^3 cu.-in. 3.9372 in = 3 in + nearly 15/16
1 liter = 4.22675 cups , =~ roughly 4.25 cups = 4 cups + 1/4 cup , and since 1 cup of water = 8 fluid ounces of water,
1L = (4.22675cups)(8oz/cup) = 33.814 floz
1L =~ 0.3058 chous units in ancient Greece =~ 10.3 fl. oz

1 cubic foot 1 cu. ft = 1 ft^3 = (12 in)^3 = 1728 in^3 = 28.3168667 Liters =~ 28L + 317 mL

1 fl oz = a volume defined as the volume corresponding to 1/16 of a pound of water, but is then used for any liquid
1 US fl oz = 1L/33.814 = 0.029573549 L = ~ **29.5735296mL = ~ 30mL** =~ 30cc which is how it is defined in the U.S.A. food industry as a "food, fl. oz". 1fl oz in the S.I. or British "Imperial" system is: 28.41306mL = 0.02841306L .
1 fl oz =~ 29.574 cm^3 = a cube having sides of the cube root of this value, and which is about: 3.1cm in length
1 fl oz = 591.471 drops =~ 600 drops and: (600 drops)(0.05 mL) = 30 mL = 30 cc of volume
1 fl oz = 1.8046875 in^3 , A cube of this volume will have a side length of ~ 1.2175 in =~ 1in + (7/32)in
Solving for 1 in^3 = 1 cubic inch by dividing both sides by 1.8046875:

1 cubic-inch of volume = 1 in^3 = 0.554112554 fl oz = slightly over half a fluid ounce of volume

1 dL = 1 deciliter = a tenth of 1L = 0.1L = 0.10L = 0.100L = 10 cL = 100 mL : the dL unit is not used much

1 cL = 1 centiliter = a hundredth of 1L = 0.01L = 0.010L = 10 mL : the cL unit is not used as much as the mL unit

1 mL = 1 milliliter = a thousandth of 1L = (1/1000) L = 0.001 L = 0.033814 fl oz = **1cc** = 1g of weight if the substance is water.

1ml = 1cc = 20 drops : here, the drop unit is scientifically defined or a standardized drop such as from a "eye-dropper"

3785.41178 mL = 128 fl.oz = **1 US gallon = 8.34 lbs of weight if water =~ 3.785 kg if water**

5 mL = 0.169070114 fl.oz. = 1 teaspoon of volume : 1 tsp is scientifically defined as slightly less than 5 mL
1 mL = 0.0338140227 fl.oz. = **1cc of volume = 1 cm^3 of volume = 1g if water**

1 cc = a cubic centimeter = 1 cm^3, and if in a cube shaped volume, it will have a length, width and height length of 1 cm
1 cc = 1 cubic centimeter = 1 cm^3 = **1 mL** = one-thousandth of a liter = (1/1000) Liter = 0.001L , 1cc of water will weigh 1 gram on an (equivalent mass) scale. 1 cm^3 = 1cm of length x 1cm of width x 1cm of height = 1cc = 1 cm^3 = 10mm x 10 mm x 10 mm = 1000 mm^3 . **1cc = 1mL = 20 drops**
1 cc = 0.0610237 in^3 , = and taking the cube root of this we have it being equal to: (0.393700692 in)^3 =~ (0.4 in)^3
1 cc = 0.033814 (US) fluid ounces =~ ((6.4/16) in)^3

1 drop = a volume = 1mL / 20 = (1/20) mL = 0.05 mL = "five, one-hundredths of a milliliter" = 1/20 cc = 0.05 cc = 0.05 cm^3 in volume. If this volume was a cube shape, it would then have a side length of the cube root of 0.05 cm^3, and that equals 0.3684 cm = 36.84mm = 0.145in = slightly over (1/8) in = 0.125 in. The volume of 20 drops would be equal to: (20)(0.05mL) = 1mL = 1cc. Since 1mL = (1/1000)L = 1 cc of water is 1g, 1 drop of water weighs = (1/20)g = 0.050g = 50mg = 0.0016907fl oz =~ 0.0017 fl vol. oz. Volume sphere, such as a drop = Vs = (4/3)(pi)(r^3) , r = cube-root of: ((3/4)Vs / (pi)) = cube-root of (0.2387324 Vs) = cube-root of ((0.2387324)(0.05 cm3)) =~ 0.22854cm = 0.09 in =~ 0.1 in =~ (1/10) in. =~ 2.3mm = (1.449 /16) in

1 drop = 1 mL / 20 = (1/20) mL = 0.050mL = 50uL , hence there are 20 drops / 1 mL = **20 drops / 1 cc**
1L = 1000 cc = 1000 mL , and the ratio of : 1L / 1 drop = 1000 mL / 0.05mL = 20000 ,
hence mathematically, there are **20000 drops / 1 L**

1 drop = 0.05 mL = 5 (10^-2) mL = 5 (10^-2)(10^-3) L = 5 (10^-5) L = 0.00005 L = 50 uL = 50 mico-Liters
1 drop of water = 0.05 mL = 0.05 mg = 5 (10^-2) mg = 5 (10^-2) (10^-3) Kg = 5 (10^-5) Kg = 0.00005 Kg
1 drop / Liter = 0.05 mL / L = 0.05 mL / 1000 mL = 0.00005L / L , if water: = 0.00005 Kg / L

1 pinch = a non-exact measurement of volume typically related to food. It is considered as an amount of a substance (ex. salt, sugar, spice) that can be picked up, pinched or contained between a persons fingers - typically the thumb and index finger. 1 pinch = 1/16 teaspoon. to 1/8 of a teaspoon. 1 pinch = 0.3125 mL to 0.625 mL

1 cup = 8 fluid (volume) oz = 14.4375 cubic inches (in^3) =~ (2.435 in)^3 cubic inches = (6.1849 cc)^3 = 236.59 cc
1 cup fluid volume is commonly considered as weighing 8 dry oz of weight if water (only), but is technically 8.3214oz of weight in the United States, U.S. customary measurement system = 236.59 grams of weight since 1 U.S. customary oz is 28.34952 grams =~ 28.35g
1 cup = 1/16 of a US gallon = 8 fl. oz = 0.236558 liters =~ 0.25L =~ about a quarter of a liter. 1 cup = 1/4 gal
2 cups = 1 pint = 16 fl. oz.
4 cups = 1 quart = 32 fl. oz = 2 pints = a **quart** is a **quart**er or 1/4 of a gallon =~ about 1 liter

1 pint = 1/8 gallon = 2 cups = 16fl. oz , and if it contains water substance, that water weighs: 1.04375 lbs = 473.437g ~= 1 pound = 1 lb = 473.437 cc = slightly less than half a liter = 1000cc/2 = 500cc . 2 pints can be thought of as roughly 1 Liter. 1 pint is defined as the (fluid) volume of 1 pound = 16 dry ounces, weight of water. Also by this definition, 1 fl. ounce = (1/16) of a (U.S. customary) pint.

1 quart = 2 pints = 4 cups = 0.94635 liters = 946.35 mL = 946.35 cc : a quart is sometimes approximated as ~ 1L
1 **quart** = 1/4 gallon = 0.25 gal = "a **quart**er of a gallon" = 32 fl. oz.
1 gallon = 128 fluid ounce. By this definition, 1fl. oz = (1/128) of a (American, U.S. customary) gallon
1 gallon = 4 quarts = 8 pints = 16 cups = 128 fl. oz = 3.785412 liters = ~ 3.785L =~ 3785ml =~ 3785cc = 3785g if water

1 gallon of water weighs 8.3454 pounds = 3.785412 kg = 3785.41 grams of weight : for water substance, mass only
1 US gallon has 128 fl. oz of volume and-or 231 cubic inches, and this is the American ("customary") gallon. A fl. oz is then (1/128) of 1 gallon. This makes (128 fl. oz / 231 in^3) = 0.5541126 fl. oz per 1 in^3, and it could be said as being roughly or about 0.5fl.oz = half a fluid ounce per cubic inch. Mathematically , 1 fl. oz = 1.804687351 in^3 , and if this volume had a cube shape, its side would be the cube-root of this value, and this is: ~ 1.2175 in = =~ 1in + 7 (1in / 32) = 1 in + (7/32) in. The dimensions of 1 gal would be the cube-root of 231in^3 = = ~ 6.1358 in = 6in + (1/8)in + (1/64) , and this is roughly equal to a cube of **~ 6 in.** per dimension (ie., L,W,H).

The **British** ("**Imperial**", standardized) gallon of which the American gallon is roughly based upon, has 277.4194 cubic inches, and is based on the volume of the weight of 10 pounds (weight) of water. 10 pounds of weight = 160 oz = 4.5359237kg = 4535.9237g. Since the substance is water, it was called a fluid ounce. 1 gal = 160 foz. Hence 1 fl oz = (1/160) gal = (4535.9237g / 160) = 28.349523g which corresponds to ~ 28.35 cc =~ 28.35 mL . This value seems to have been updated or redefined later as being slightly more as: 28.41306 mL
The physical dimensions of a British fluid ounce of volume is: (160 foz / 277.4194 in^3) = 0.576744 foz / in^3.
The British fl. oz. is also defined as (1/20) of a British pint, and there are 8 British pints in a British gallon, and

1 British pint = (160 fl oz / 8) = 20 fl. oz. A British quart or "quarter-gallon" = 2 pints = (160 fl. oz) / 4 = 40 fl oz.

1 British pint = 2 cups, hence 1 cup = 20fl. oz / 2 = 10 fl. oz = (160oz / 16) = 1gal / 16 = (1/16) gallon , hence 16 cups per gallon. Note that 10 lbs = (10)(16 oz) = 160 oz, and 1 Imperial gal = 160 fl. oz. , and therefore, 1 fl. oz weighs 1 oz of dry or solid weight. There are: 16 oz / 1 lb and 16 fl. oz / 1 lb , also, 16 oz / 16 fl .oz and 1 oz weight / 1 fluid oz water

1 British gallon = 1.20095 US gallons , 1 US gal = 0.832674133 British gal

As of the year 2022, the American gallon still has common use, however the use of the British gallon unit has faded more due to the more popular metric system with liters (L) as its base or reference unit of or for volume measurement. Nonetheless, the values and conversions between measuring systems is a problem to the average person, and therefore, there is still a significant effort for the world to adopt and use the metric system.

1 UK or Imperial **bushel** has the volume of 10 Imperial or British gallons of liquid water. An Imperial gallon is the volume of 10 pounds of water. 10 Imperial gallons of water is equivalent to about 9.61 US gallons. Today, a bushel of a product is associated with the weight of a (dry, non liquid) specific product that would normally be contained in that bushel sized volume. 1 bushel = 8 dry gallons (UK) = 32 quarts = 36.37L = 8.257 US gallons. 1 bushel = 9.3092 dry gallons (US) = 37.237 quarts (US) = 35.2393L. A bushel sized basket is often used for gathering and-or measuring produce such as fruits and vegetables from farms. A bushel is a unit of volume measurement, and therefore, it does not have a specific weight due to that various products, crops or foods to put in it will weigh differently due to their sizes, shapes, quantity or count, amount of water, etc, however for a single product or food, there will be a typical or average weight per bushel to expect. Crop pickers often use low-cost, lite-weight wooden baskets of various fractions of a bushel so as to gather crops. In good planting and growing conditions, an acre of **wheat** (ie., wheat grass, a tall grass, and with sprouts and seeds being edible) will yield (ie., produce) about 45 bushels of whole-wheat or even more for some wheat varieties, and where each bushel weighs abut 60 pounds. An acre can therefore produce about (45 bushels)(60 pounds / bushel) = 2700 pounds of ground whole-wheat (seed) flour (fine particles). 1 pound of whole-wheat can produce about 1 pound of whole-wheat (ground) flour, and about 0.65 pounds of white-flour.

1 Peck = a unit of volume for non liquid products, and is equal to 1/8 of a bushel, hence it is a volume of 4 quarts. 1 peck is equivalent to the volume of 2.3273 gallons = 9.3092 quarts (US) = 8.80977L. A bushel is equal to 8 pecks. The peck unit is not used much as of the writing of this book in the year 2022.

1 Barrel = US customary, such as for a variety of products, is 42 gallons =159L of fluid volume for the wooden (often with oak wood) ones created first, and then 55 gallons = "200L" (actually 208.2L) steel "drums" (oil) barrels which came later in 1905. Aluminum and plastic barrels, containers, "kegs" or "casks" of various volume sizes and shapes are also used and it depends on the product placed within it. Barrels are used to hold and protect goods during storage and shipment. The shape of a barrel often resembles that of a cylinder, and often with a height that is 1.5 times greater than its diameter. A US 55 gallon barrel has a 22.5 in. diameter and a 33.5 in height.

1 Cord = Usually a volume of cut and dried wood, and with pieces of it to be routinely placed in a stone and-or metal fireplace to heat a home. 1 cord is typically in these dimensions: 24 ft. long, by 4ft high, by 1.333 ft = 16 in deep. Multiplying these dimensional values together yields a volume of: 128 cubic feet = 128 ft^3. A solid cube of this size will have a side dimension of the cube root of this value, and which is: 5.04 ft =~ 5 ft. Since pieces of uneven wood will have spaces, this 5 ft value will average higher at perhaps 5.75 ft. Due to all the gaps (spaces) between each piece of stacked wood, it would be ideal to know the weight value of a cord of wood of a certain type of tree when dried sufficiently, and rather than the volume value. This is a large weight; several hundreds of pounds, and it is possible to construct a weight scale out of a floating container with a calibrated weight and-or depth scale on its side that corresponds to different weights within it.

1 Dozen = not a volume, but a (linear) count of 12 items. A **gross** (meaning large, huge, many) is twelve dozen, hence a dozen of a dozen, or a dozen dozen, and the number of items in a gross unit is (12)(dozen) = 12(12units) =

144 units or items. Food purchases from a store are sometimes often called groceries, and the seller is often called a grocer (ie. a large or gross amount wholesaler) . The words "gross" and "groceries" may be rooted in the words "grow" and "growth". A more generic and common word for edible groceries is food.

For fluids, such as water, a volume (ie. space or 3 dimensional size, and not a weight) measurement:

1 fluid or volume ("food") ounce = 30ml = 0.030L , a food (weight) ounce is also considered as 30g of weight = 30ml water
1 cup = 8 fluid oz (ounces) = 0.240L = 240ml = 240cc : = 240g = 1/2lb = 8 dry oz. of weight if the substance is water.
1L = 4.1667 cups : this considers fl. oz as "food ounces" with 30mL per ounce, and (8)(30mL) = 240mL per 8oz cup = 0.240L , otherwise, 1 cup = 0.23659 Liters and 1 Liter = 4.22675 cups

Fluid (fl) ounces, fluid or liquid measurement is actually a volume or space (as in size) measurement, however 1 fl. oz of water actually does nearly weigh, and is considered about 1 oz of weight or "dry weight" (non volume, but rather weight due to gravity). Consider that a cup full of plastic foam particles will weigh less than a cup of water, and that a cup of lead metal will weigh more than a cup of water. All these substances of matter can occupy the same volume, but these same volumes of the substances have different weights, and this is due to that their density (amount of mass per unit volume) each, has different value. Fluid or liquid essentially means having no discernible space between the particles, and can flow and fill any shaped volume. Fluid essentially means a flowing liquid or substance. or liquid or substance that can flow.

Here is a list of the common fractions of a cup, based on using: 1/8 cup = 30cc = 1fl.oz, = 30 gram "food ounce"

3/4 cup = 6 fl.oz = 180ml = 180cc , 2/3 cup = 5.33 fl.oz = 160ml = 160cc
1/2 cup = 4 oz fl. = 120ml = 120cc , 1/3 cup = 2.67 fl.oz = 80ml = 80cc
1/4 cup = 2 fl.oz = 60ml = 60 cc
1/8 cup = 1 fl.oz = 30ml = 30cc volume = 30g of weight if the substance being measured within is water only.
1/8 cup = 2 tablespoons (tbs) = 6 teaspoons (tsp) = 1 fluid ounce (oz) volume = 1 ounce of weight if water only

To find the basic equivalent amount of ml or cc given a volume of fluid ounces, multiply the fluid ounces by 30cc.

1 teaspoon of (fluid) volume = 5mL = 5cc (typical), substance weight could vary widely depending on the substance properties. Note that some "home teaspoons" may vary in the volume that they can hold, and may not be 5mL. **If possible, get some calibrated measuring (volume) spoons and scoops, so as to ensure better accuracy.**
1 teaspoon = 5ml / (0.05 ml / drop) = 100 scientifically defined drops
1 level teaspoon of water is 4.929cc ~ 4.93 grams weight = about 5cc = 5 grams of water weight = 1/6 oz = 0.1667 oz
1 teaspoon of water actually weighs ~0.17337 oz when not rounded to 1/6 "food ounces" = 30g / 6 = 5 grams
6 teaspoons =~ 1 US fluid ounce of volume
1 level teaspoon of water is equal to 1.33... fluid drams, which today is a unit of measurement that is not used much.
3 level teaspoons of water will equal the volume of about a 1 level tablespoon of water
1 level tablespoon of water is about 3 level teaspoons of volume ~ 15mL = 15cc = 15 grams if the substance is water
1 tablespoon volume of water weighs 0.52011 oz = about 1/2 fl oz, hence 2 tablespoons = 6 teaspoons is about 1 fl. oz
1 cubic centimeter = 1cc = 1 cm^3 = 1mL = 1milli-Liter = (1/1000) L = 0.001L = 0.0610237 cubic inches
1 cubic centimeter of water weighs 1 gram = 0.0352717 oz = 0.002204481 lbs
1 cubic inch = 1 cu. in^3 = (2.54 cm)^3 = 16.3871 cubic centimeters = 16.3871 mL , and would be 16.3871 grams of weight if the substance is water
1 cubic inch of water weighs about (8.345404lbs/gallon) / (231cubic inches/gallon) = 0.0361lbs/in^3 = 0.578oz/in^3 = 16.386 grams/in^3. A cubic inch of water weighs a little over half an ounce of weight , as shown next:
1 cubic inch = 0.554111786 US fl. oz of volume : slightly more than half a US fluid ounce
1 cubic inch of ice (frozen, solid water, a water crystal) weighs about: (0.578oz)(density of ice) = (0.578 oz)(0.9167) = 0.5298526 oz =~=~ 15.0210462g. Frozen water or ice, such as an icecube or iceberg) will float near the water surface.
1 cubic foot of water weighs about 62.427118 pounds, and is about 7.481 gal. Since iron is 7.874 times denser than water, a cubic foot of iron weighs 7.874 times more, hence: (62.43lbs/f^3)(7.874) = 491.57lbs/f^3
1 cubic foot = 1ft^3 = (12in)(12in)(12in) = (12in)^3 = 1728 in^3 = (1728 in^3)(16.3871cc / in^3) = 28316.9 cc = 28.317L
1 cubic foot of water would weigh: (1g/cc)(28316.9cc) = 28316.9 cc = 28.317L = 28317g if water = 28.317kg ,

and (28316.9g) / (453.6 g/ lb) = 62.437 lbs
1 cubic yard of water weighs: (62.4272lbs / 1 ft^3.) x (3ft. x 3ft. x 3ft) = 62.4272lbs x 27 = 1685.53lbs
1 cubic meter = (100cm)(100cm)(100cm) = (1,000,000)cm^3 , if the substance is water which is 1000cc / 1kg
= 1000cm^3 / 1 kg, then 1m^3 = 1,000,000cm^3 / (1000cm^3 / 1 kg) = 1000kg = 1000L of water
1m^3 of water = 1000kg of water = 1 metric ton = 2205lbs of weight if water = slightly over 1 ton of weight

Items that are "irregular shaped" and difficult to measure or calculate the volume of can be submerged into a liquid such as water to determine the change (due to the "**displacement**", "water displacement", moved to the side, essentially **the change in volume** caused by the submerged object) in volume of that liquid which is equivalent to the volume of the item. If the item is of a single and consistent (solid) material such as a flat or round piece of metal, it can be weighed, and then its volume can be calculated by the knowing weight per volume, or volume per weight of that material or substance:

Density of an element = d = (mass / volume) = (weight **/** g) **/** volume = (weight)(volume) **/** g
mass = (density)(volume) = (force **/** g) = (weight **/** g) :g = Earth's gravitational acceleration = 9.81m/s^2
weight = (density)(volume)(g) = (mass)(g) = ma = force
volume = (mass **/** density) = (weight **/** g) **/** (density) = (weight) **/** (density)(g)
g = weight / mass **=** force / mass = gravitational acceleration (due to gravitational force on Earth's surface)

Since ice (frozen, solidified water) floats on liquid water, ice has a lower density than liquid water. The density of ice is about 92% that of liquid water (1g/1cc): **Density of ice = 0.9167g/1cc** For a given volume, the weight of ice will also be 91.167% that of liquid water. Ice will float near the surface of water, but just barely float since it is not too much lighter than liquid water. Ex. Only the tip of an iceberg is above water.

Some Selected Volume And Weight Values (approximate values)

1L = 1 liter, of water substance weighs 1kg ~= 2.2046 lbs , 1L of volume = 1000 cubic centimeters = 1000 cc
1L = 0.264 U.S. Gallons = 0.0353 cubic feet = 61.0237 cu. in. , **1L of water is defined to weigh 1kg at 4°C = 39.2°F**
1 cc = 1mL water weighs 0.002205 lbs = 0.035oz = 1 gram of mass at 4°C and maximum water density (mass/volume).
1 fluid ounce of volume = 29.57cc. 1 fl-oz of water weighs 0.0651985 lb = 29.57g weighs 29.57g
1 U.S. Customary Gallon ~= 128 fluid-volume ounces = 231 in^3 / (1728 in^3 / 1 ft^3) = 0.133681 ft^3 ~= 3.7854 liters
1 US Customary Gallon is typically considered as weighing (128 fl. oz / (~16 fl. oz / lb)) = 8 pounds (actually 8.34 lbs wt)
1 Imperial Gallon (British) ~= 4.546 liters =~ 1.20093 US gal =~ 1.2 US gal
1lb of water is 16 fluid-volume ounces = 453.5924 cc of water = 0.4535924 L ~= 0.454 kg of mass if water

1 cubic inch = 1 cu = 1 in^3 = (2.54 cm)^3 = 16.387064 cc = 16.387064 mL = 0.0163872 L , Dividing both sides by 16.387064, we find:
1 cubic centimeter = 1 cm^3 = 1 cc = 0.061023744 cubic inches. 1 cm =~ 0.3937 in =~ 0.4 in = "4 tenths of 1 inch"
1 cc = 1 cm^3 = 1 mL volume =~ 0.033814 US fl. oz
1 US fl. oz = 29.5735296 mL = 29.5735296 cc = 0.0295735296 L . If water, it will weigh 29.574 g. 1 US fl. oz. of water weighs 1.04317556 wt. oz , therefore, 1 wt. oz of water = 0.95861142 fl. oz. =~ 0.96 fl. oz.
1 cu. in water weighs 0.03613 lbs = 16.3871 grams = the weight of 16.387064 cc of water indicated above
1 lb of water =~ 27.6778 in^3 of water, and taking the cube-root of this, we have a cube with a side of : **3.0249 in =~ 3 in**

Extra: If something is said to be, for example: 0.75 cubic inches, this could be thought of as a cubic inch and then with a reduced dimension, such as its height, of being 0.75 inches long. If 0.75 cubic inches of total volume was to have a cube shape with equal side length dimensions, each side would be the cube root of this amount of volume when it is considered as having as a cube shape or volume of 0.75 cu-in, and that value is: 0.90856 , and (0.90856 in)^3 = (0.90856)^3 (1 in)^3 = (0.75)(1 in^3) = 0.75 in^3

In a cube, L=W=H, hence its volume is equal to V = L x L x L = L^3 , and the cube root of this volume is L

1 cu. in. = 0.554111786 US fl. oz. volume =~ half a fluid ounce = 0.5 fl. oz
1 US fl oz = 1.80469 in^3 , taking the cube root of this we have a cube with a side length of: 1.217496 in =~ 1" + (3.5/16)"

1 cu. ft = 1 cubic foot = 1ft^3 = 1ft x 1ft x 1ft = 12 in x 12 in x 12 in = 12^3 in^3 = 1728 in^3
1 cu. ft = 1 ft^3 = 1 ft x 1ft x 1 ft = 30.48 cm x 30.48 cm x 30.48 cm = 30.48^3 cm^3 = 28316.85 cm^3
1 cu. ft. = 30.48^3 cm^3 = 0.3048^3 m^3 = 0.028316846 m^3 , from this we have:
1 cu. m = 1 m^3 = 35.31466672 ft^3 = roughly: (3ft x 3 ft x 3 ft) = 27 ft^3 = 1 cu. yd = 1 yd^3 + 8 ft^3 = 1yd^3 + (2ft)^3
1 cubic inch = 1 cu. ft / 1728 = 0.000578703 ft^3
1 cu. ft. = 7.481 gallons = 28.317 liters = 1728 cu. in. = 28316.8466 cm^3
1 cubic yard = 1cu-yd = 1cyd = 1yd^3 = 1yd x 1yd x 1yd = (3ft L)(3ft W)(3ft H) = 27 ft^3 = 27 cubic feet
1 cu. m. = 1 cubic meter = (1m)^3 = (1m)(1m)(1m) = (100cm)^3 = ((10)(10cm))^3 = (10^3)(1000 ccm) = 1000 Liters =
= 35.31455 ft^3 , and if this volume was a cube, it would have a side length of: ~ 3.280835 ft = 3ft + (9/32) in

Substance	**Weight / U.S. Gallon**	**Substance**	**Weight / cubic yard = 27 ft^3**	**Substance**	**Weight / cu. ft**
alcohol	6 lbs	dry sand	2600 lbs = 96 lbs / cubic foot	oils	55 lbs

oils	7.7 lbs	water	1686 lbs = 765.234kg	steel	490 lbs =~ 500 lbs
water	8.34 lbs = 18.37 kg equivalent mass value		, 1L of water "weighs" 1 kg	lead	708 lbs
liquid paint	11 lbs (typical)		on a weight to mass scale	gold	1206 lbs

For any same volume chosen and filled with a material, such as for example: a cubic foot of gold, and a cubic foot of steel, the ratio of the weight of gold to the weight of steel is: (1206lbs/cu.ft) / (490lbs/cu.ft) = 2.46 It could be said that gold is 2.46 times heavier than steel, or roughly 2.5 times heavier than steel. It will be also shown below that gold likewise has about 2.46 times the mass (the measure of real, physical substance) as that of steel, and that is why gold is also heavier. For reference: 1 gallon = 3785.312 cc = 3785.312 L of volume , 1 lb = 454.592g = 0.454492 L = 454.492 cc if water , and 1 cu. ft = 1 ft^3 = 28316.8466 cc = 28.3168466 L of volume

The density of gold is 19.28 g/cc, and the density of steel is 8g/cc. The ratio of the density of gold to that of the density of steel is:is about : (19.28g/cc / 8g/cc) = 2.41 . This is about the same ratio of their corresponding weights, hence **weight and density are directly related and proportional**. **Since weight is directly related and proportional to mass, mass is also directly related and proportional to density. Given the same volume of two elements or substances, the ratio of their weights, and the ratio of their masses are the same.** For the above example, the radio of the density of gold and steel is 2.41, and the ratio of their corresponding weights is:
(1206 lbs/cu.ft) / (490 lbs/cu.ft) =~ 2.461 , If 500 lbs/cu.ft was used for steel, the result is: 2.41

Gold has 19.28g/cc , Dividing both num. and den. by 19.28 so as to make an equivalent fraction, we find that
gold has 1g/0.05187cc or using the reciprocal of this we find: 0.05187cc / 1g = ~ 0.052cc / 1g

Steel has 8g/cc. , Dividing both num. and den. by 8 so as to make an equivalent fraction, we find that steel
has 1g / 0.125cc or by inverting (ie., reciprocal) this expression, we have: 0.125cc / 1g

Since steel has a lower density than gold, therefore, steel has less mass and weight per same volume than gold does, and it will take more volume of steel so as to have an equivalent mass and-or weight of gold such as 1 gram, or 1 ounce of weight, and therefore: **density and volume are inversely related. Note that 1 gram of steel has the same mass as that of 1 gram of gold, aluminum, or any other element. A gram is not related to the density, volume or size of a mass, but it is actually a specific amount of mass (ie., real substance, matter or material) for any and all elements. A gram of any element will also weigh the same, and for the common weight-to-mass or weight-to-grams calibrated scales, a gram of any element will be said as "weighing" 1 gram.**

Given a certain volume of a specific substance or element, if the volume of it changes by a factor of (n), both its mass and weight will also change by that same factor of (n), but its (natural, at standard air pressure) density will still remain the same value. It is of note that gasses can be easily compressed by using a force and-or pressure so as to increase the density of it, such as to make some liquid oxygen from a large volume of oxygen gas.

Alcohol, the natural form. from say wood, is **methanol or methyl-alcohol** is C1H3OH = CH3OH. C1H3 is methyl, and OH = O1H1 is an extra hydroxy or hydrogen-oxygen molecule. This type of alcohol is **poisonous,** and some is sometimes made during the fermentation process of making edible grain or food alcohol that is called **ethyl alcohol or ethanol** that is produced by yeast, and the methanol must be removed before it is consumed, and this is usually done by the manufacturer. The USA law permits a maximum of 7 grams per liter, and the EU permits a maximum of 10 grams of methanol per liter of pure, 100% ethyl-alcohol.

Methanol is sometimes called "wood alcohol". Its molecular weight or "molar mass" is about 32 grams per mol-atoms. A wood alcohol molecule has 32amu. Each carbon atom has 12amu, each oxygen atom has 16amu, and each hydrogen atom has 1 amu. The density (mass/volume) of methyl alcohol is 0.792g/cm^3 = 0.792g/mL = 792g / L = = 0.792kg / L = 792kg / m^3 . This being < 1g/ml, will float on liquid water since water has a greater density of 1g/mL. 792g =~ 27.937 wtoz = 1.746 lbs

Water has a molar-mass of 18.01528 g/mol since each water molecule = H20 contains 2 hydrogen atoms and 1 oxygen atom, and that each hydrogen atom contains 1amu, and each oxygen atom contains 16amu. The total sum of amu in a water molecule is: 2amu + 16amu = 18amu. Note that for the metric system, the (mass) density of water was defined as 1g/cm^3 = 1000 g / 1000 cm^3 = 1kg / L.. 1g = 1L/1000 = 0.001L = 1mL. 1 gram of mass in the influence of Earth's gravitational acceleration force will weigh (a measure of force) nearly a hundredth of a Newton: F = ma = (0.001kg) x (9.8067m/s^2) = 0.0098067N =~ 0.01N. 100g of mass will weigh about 1N. 1kg of mass will weigh about 10N.

Although alcohol weighs less per unit of volume (a gallon size in the example above), an alcohol molecule weighs nearly twice as much than that of a water molecule, and this is due mostly to the carbon in alcohol. A larger, heavier (more massive) molecule will occupy more space in a given volume, and this results in having less molecules in a given volume. Less molecules for a given volume is indicative of that substance weighing less per unit volume. Note that less molecules of any single element will always result in less weight.

Some extra mathematical considerations about area and volume:

Area of a square = square area = $As = s^2 = d^2 = (d)(d)$: $s = d$ = side distance of a square
$V = s^3 = d^3 = (d)(d)(d) = (d^2)d = A d$, Ex: (base Area)(height distance) : V = volume of a square
cube root of volume = $s = d$
$V / A = d^3 / d^2 = d$

If the dimensions of an area increased by a factor of (n), the area will increase by $(n)^2$:

$A2 = (n \text{ length})(n \text{ width}) = n^2 (\text{length})(\text{width}) = n^2 A1$

If only one dimension of an area increased by a factor of (n), the area will increase by that same factor of (n):

$A2 = (n \text{ length})(\text{width}) = (n) (\text{length})(\text{width}) = n A1$

If the **area** = A increases by a factor of (n), and becomes A1, the side distance (s=d) increased by the factor of the square root of (n):

$A2 = nA1 = n(d^2) = n(d d) = \sqrt{n} d \sqrt{n} d = (\sqrt{n} d)^2 = (\text{side})^2$: here, let: $A1 = d^2$

If d increases by a factor of (n), A increase by a factor of (n^2):

$A2 = (d2)^2 = (n d1)^2 = n^2 d1^2 = n^2 A1$, and $A2 / A1 = n^2$: here, let: $A2 = (d2)^2$ and $A1 = (d1^2)$

If the side (s=d) of a square area increases by 1, A will increase by (2d + 1), and this value is not a constant, but depends on the given, initial value of (d). :

$A1 = d^2 = (d)(d)$: here $d = d1$ in reference to A1 , $d2 = (d + 1)$: technically, d^2 is a quadratic equation, b=0, c=0
$A2 = (d2)^2 = (d+1)^2 = (d+1)(d+1) = d^2 + d + d + 1 = d^2 + 2d + 1$: a quadratic equation in variable (d)

The difference in these two areas is how much the area will increase:

$(A2 - A1) = d^2 + 2d + 1 - (d^2) = d^2 + 2d + 1 - d^2 =$
$(A2 - A1) = 2d + 1$: a linear equation , mathematically:

$A2 = A1 + \text{increase} = d^2 + \text{increase}$
$A2 = (d2)^2 = A1 + (2d + 1) = A1 + 2d + 1 =$
$A2 = (d2)^2 = (d+1)^2 = d^2 + 2d + 1$: A2 with respect to A1 when (d) increases by 1 , a quadratic equation

---

If the dimensions of a volume increased by a factor of (n), the volume will increase by $(n)^3$:

$V2 = (n \text{ length})(n \text{ width})(n \text{ height}) = n^3 (\text{length})(\text{width})(\text{height}) = n^3 V1$

If only one dimension of a volume increased by a factor of (n), the volume will increase by that same factor of (n):

$V2 = (n \text{ length})(\text{width})(\text{height}) = (n) (\text{length})(\text{width})(\text{height}) = n V1$

If the **volume** increases by a factor of (n), the side distance (d=s) of that volume increased or increases by the factor of the cube root of (n):

nV = n (d^3) = n (d d d) = 3√n 3√n 3√n (d d d) = (3√n)^3 d^3 = (3√n d)^3

If (d) increases by a factor of (n), V increase by a factor of (n^3):

V2 = (n V1) = (d2)^3 = (n d)^3 = n^3 d^3 = n^3 V1 : V2 / V1 = n^3

If the side (s=d) of a cube volume increases by 1, V will increase by (3d^2 + 3d + 1). First,

V1 = (d^3) = (d)(d)(d) : here d = d1 in reference to V1
V2 = (d2)^3 = (d+1)^3 = (d+1)(d+1)(d+1) = (d+1)^2 (d+1) = A2 (d+1) =
= (d^2 + 2d + 1) (d +1) = d^3 + d^2 + 2d^2 + 2d + d + 1 =
V2 = d^3 + 3d^2 + 3d + 1 : V2 with respect to V1 when d increases by 1 , a cubic equation

The difference in these two volumes is how much the volume will increase:
(V2 - V1) = d^3 + 3d^2 + 3d + 1 - (d^3) = d^3 + 3d^2 + 3d + 1 - d^3 =
(V2 - V1) = 3d^2 + 3d + 1 : a quadratic equation , mathematically:

V2 = V1 + increase
V2 = V1 + (3d^2 + 3d + 1) = V1 + 3d^2 + 3d + 1 =
V2 = (d2)^3 = (d+1)^3 = d^3 + 3d^2 + 3d + 1 : a cubic equation

Here is a somewhat or related note about the mass, gravity, and volume of an object. If the volume of a substance or material doubles, the mass of that substance or material doubles. If the length (such as a diameter or radius doubles) of an object doubles, its area (A = l x w) doubles: A = l x w. If l or w doubles, the total area is now: 2A = (2l x w) = 2(l x w), but if the object was a sphere or cube, its volume increases by the cube of this factor (here 2) value, and this is equal to a factor of: (factor)^3 = 2^3 = 8 applied to the initial volume.

Vcube = l x w x h = l x l x l = l^3 . : In a cube, l=w=h. If the side length of a cube is doubled:
(2l) x (2l) x (2l) = (2l)^3 = (2^3)(l^3) = 8(Vcube) : the volume is 8 times more, and volume is said to change or increase rapidly as the linear dimensions change

From this, if a volume is 8 times more, its dimensions are the cube root of 8, hence 2 times (twice) that of the reference mass volume. In general: linear dimension increase = cube root of volume increase factor.

If only one dimension of a volume doubled, then the volume will only double:

Ex: If v1 = (l)(w)(h) , and if h doubles: v2 = (l)(w)(2h) = 2 ((l)(w)(h))= 2(v1) = 2v1

As a simple thought example, if you had a cylinder filled with a liquid, and if the length of that cylinder doubled, the total volume is doubled. This is also the same total volume of two of the original cylinders. If the mass of an object increases by (n), its weight, volume and gravity will increase by (n).

Ex. A volume 1 liter of water = 1L has a mass of 1kg of water substance, and will weigh 9.81N.

If this volume is doubled:

A volume of 2L of water will have a total mass of 2kg, and will weight 19.62N.

In the **Extras And Late Entries** section of this book, and in the topic: Some of the commonly used units and conversions for volume measurements, there are some volume and conversions mentioned of which were mentioned previously and some possible new understandings for the readers.

TIME

Time is often called the fourth-dimension. Physical changes, motion and-or processes are not instantaneous and are said to need an amount time or duration to complete. An object can't be located at two positions simultaneously or at the same instant or time value, and if it were so, it would make two objects from one object. If timed stopped, there would be no further processes or changes possible, and it would be as things were essentially frozen or halted in position. An object in motion, fast, slow or temporarily stopped will have three standard location or position coordinates of: p(X, Y, and Z), and it will also have a fourth or time coordinate (T), hence the coordinates of a point or position could be expressed as:
p(X , Y, Z , T)

The time dimension or simply Time is a measure of and between past (already happened, "time ago"), present (now, currently), and-or future (to happen later) events (happenings, realities, other time points or reference times). Time elapsed is much like a total length duration and number of (accepted) time units of measurement. In general, time is often how long a certain event or process takes, hence it is also the difference between the ending time value and the starting time value. The basic units for time measurement are usually seconds (s), which is a fraction (1/60) of a minute, which is a fraction (1/60) of an hour, which is a fraction (1/24) of a day, which is a fraction (1/365) of 1 year of standard "(24 hour) clock time". The Earth rotates (spins) on its (imaginary) polar axis of rotation, once a day unit of time which is equal to 24 hour units of time. The Earth revolves around the Sun in one year (=365 days) unit of time. "Current time" is the present or "now" time and-or date. Time on Earth is in reference to these natural periodic (regularly repeating, and usually having the same time duration between and-or during these events, cyclic), events, and clocks and calendars are therefore also made so as to be periodic.

Things that happened in the past are things that happened (became true, real, reality, existed) at a previous, lesser or earlier time. Things that happen in the future are things that have not happened yet and will happen at a later or increased amount of time past the current time. The "present", or present time, is the "current" or "now" time, and of which things are happening now, existing at this "current" (or more correctly for time as: "currant") instant in time. The "cur" portion of similar words that mean "to flow or mean" is derived from the ancient word "ker" or "kers", and of which is the basic of "car", "chariot", "occur", and "chair".

In the simplest wording, a time value is a measure of past, present and future events using an accepted unit of time such as the second. If the present is now, this can be considered as the time of reference for all other times, and it will therefore have a value of 0. The past or a previous time will have a negative signed time value, and a future time will have a positive sign. Time is a gauge of when an event happened, or will happen, and-or the time duration of that event. The time on an accurate clock is the "now" or current time, and is in reference to an accepted reference time and that is usually the Greenwich Mean Time (GMT) as mentioned in this book.

Now,
A basic "timeline" of events: **Past <**.......................**Present**,....................> **Future**
. . . -5 , -4 , -3 , -2 , -1 , **0** , 1 , 2 , 3 , 4 , 5 **. . .** : time units
Already Happened Reference To Happen (s) , (min) , (hr) ,
of time measurements (day) , (yr)

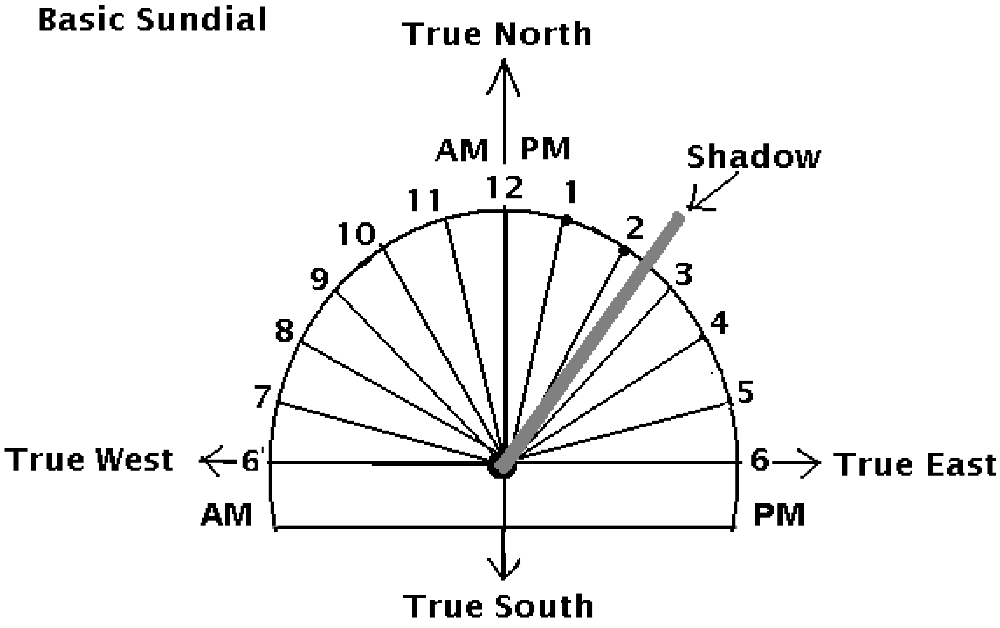
Ex. An event will happen 3 time units from now, and be 1 time unit long.

The event will start at (now + 3) = (0 + 3) = 3 , and end at:
(start time) + (duration time) = (start time) + (change in time) = (ending time) = (event time) + 1 = (3 + 1) = 4

If a previous (past, before) event started 7 units before the event at 3 units, the start time of that past event in reference to the current time of t=0 is:

(event time) + (change in time) = 3 + (-7) = 3 -7 = -4 = 4 time units ago from the current reference time of 0

The Earth revolves or orbits around the Sun at about 1 degree of arc of a circular orbit per day. Every day, it also appears that the Sun revolves or orbits the Earth, and this is due to that the Earth is rotating (from the westward to eastward direction at its surface) on its (true, geographic North to South) polar axis. As the apparent angle between the ground (horizontal) and the Sun changes throughout the day, it will create a shadow from an object such as a vertical rod or stick, and this shadow will likewise change throughout the day as the Sun appears to move from its current position. Since the Sun appears to change position by 15° per hour, the corresponding shadow of the rod will likewise appear to change by 15° per hour, and a basic sunclock, solar-clock or commonly called a **sundial** can be created from this concept. This vertical rod is perpendicular (ie., 90°) to the local, flat surface level or horizontal sundial scale where the numbered hour lines are placed. From where the center of the vertical rod or stick is, draw radius or "radial" (like the spokes of a wheel) lines extending from it that are 15° apart about it, and these lines will be used as hour lines of the sundial of which the current hour is indicated by the shadow of the rod. This has described a basic sundial and is very simple, practical and useful for a large geographical area, particularly several hundred miles radius of your geographical location, such as your latitude and longitude on Earth, and since the apparent Sun angle will be about the same value in this region or area. A basic sundial can also keep a standardized time for a group of people that are also using the same basic sundial design. The time at all geographical points along a (north to south) longitude line of the Earth is the same. For the initial calibration of this basic sundial, the hour lines or planar dial or scale of this sundial is placed on level or horizontal ground. Then, the 0 or 12pm hour line of this sundial must be aligned with the true north and not the (unstable in location) magnetic-north direction line of the Earth **unless agreed upon** to use, such as during the daylight when the stars cannot be seen. For a person in the Norther hemisphere, true North is usually considered in the horizontal direction to the North Star which is also known as Polaris. People living south of the solar plane are blocked from viewing the north star by Earth's local horizon surface and-or land being in the way of view. **The angle to the star Polaris is equal to the latitude of the observers location**, and this angle can be used in the construction of some types of sundials. The 6pm hour line will then be automatically aligned in the true south direction of the Earth. The sundial will only function during the local 12 daytime or daylight hours of the day; hence from 6AM to 6PM, with noon (12) between these two time values, and if the local sunlight is not blocked by clouds, hills or mountains. Again, for the sundial as shown below, **the rod at the center must be vertical with respect to the horizontal and-or local horizon**, and the numbers and lines are placed horizontally about this rod and on the ground or a stand. [FIG 221]



The shadow is indicating the time is about 2:30pm

On the spring (~ March 21) and fall (~ September 21) equinox day of the year, the Sun will appear to "rise" at the distant horizon in the Eastern direction, and the shadow of the vertical pole on the sundial will indicate 6AM in the morning. If you were at the equator, the Sun will appear to travel exactly westward to eastward, and will be directly overhead and the highest in the sky for the day at noon (12pm) on the two **equinox** ("equal day and night") days of the year. At local noon (12PM), the shadow created will have its smallest length depending on the sundials latitude. Low latitudes will have the shortest shadow seen. At solar or Sun noon, the Sun is directly in line with your local longitude, and the shadow of the pole will be the shortest length throughout the entire day, and it will point to the true north direction if you live in the northern hemisphere of Earth. At the equinox days of the year, the equator is in line with the solar (ie. Sun) plane of Earth's orbit around the Sun, and the day time will be 12 hours long, and the night time will be equivalent at 12 hours long. Considering up to an hour before sunrise, and-or up to an hour after sunset, there is often enough light to see.

Another type of sundial has its pole tilted at an angle equal to your local latitude. The top edge of this structure is in line to the star Polaris. This discussion in this book about sundials and the displayed time is for an ideal sundial, such as if placed on Earth where the solar plane is currently at, and informally always considered at the equator, and where the hour lines of the sundial are separated by 15°, but there are more precise equations for these hour line positions and which depend on your latitude from the equator. The more your latitude, the greater your tilt away from the solar plane and-or Sun, and the longer the resulting shadow created. There is much literature, books, clubs or "societies" devoted to sundials and clocks. For simplicity, a vertical stick in the ground, and 15° hour lines is acceptable so as to have a common time within the same region or area on Earth.

If the weather is cloudy, and-or at nighttime, a water-clock or sand-clock can be used. It is even very possible to tell the time by the position of the stars throughout the night as they (apparently) revolve about the north star (Polaris). After each hour of time, the start will appear to have revolved about Polaris by an angle of 15°.

The current or present numeric time of day is actually the duration from the reference or start of the day considered as 0 hours, 0 minutes, and 0 seconds which is at midnight (typically indicated as "12am" [but is actually 0am] on a typical time measurement device or clock) where the Sun is directly on the opposite side of the Earth. At you local noon (12pm or actually 0 pm), the Sun will appear to be at the highest angle (with respect to your horizontal or ground level at your location) in the sky for the current day of the year. Because of the apparent tilt of the Earth throughout the year, the apparent Sun angle angle in the sky will slowly change (~ +-23.5°) in a cyclic, periodic or repeating manner. The maximum height and-or apparent angle value of the Sun throughout the year depends on your latitude angle or position from the reference 0° Equator line.

The Earth spins (rotates) on or about it's (north to south, central polar) axis in 1 day (or 24 hours) of time. Each hour, the Earth rotates on it's axis about 15 degrees per hour. This gives us the illusion that the Sun, Moon and stars are going around the Earth at about 15 degrees per hour. (24 hours) x (15 degrees/hour) = 360 degrees, a full rotation.

The Earth will go around or orbit the sun after 365 days of time = 1 year. (A 360° circle or rotation is based on this value.) More precisely, the Earth orbits the Sun in about 365.256 days = ~ 365.25 = 365 and 1/4 of a day. 1/4 of a day is 24h/4 = 6h. After 4 years this unaccounted for 1/4 of a day becomes a full day, and a day (called "leap (year) day") is added into the year as February 29 to account for this unaccounted for 1/4 day each year. In short, it takes slightly longer than 365 days for Earth to go around the Sun, and "New Years" day is celebrated 6 hours earlier than when Earth actually completes the full orbit around the Sun, and an adjustment must be, and is eventually made as February 29, an extra day placed in the year. 365.256 is the true sidereal or ("about the sun") year time.

Each day of time is divided so as as having 24 hours of time. 1 hour = 1 day / 24 = (1/24) day = about 0.0417 day = about 4% of a day of time. Each hour has 60 minutes of time. hence 1 minute is (1/60) of 1 hour. The word "minute" means a small part or fraction. Each minute has 60 seconds of time, hence each 1 second is (1/60) of 1 minute. The word "second" essentially means a "second minute" part, which means a minute part of another minute part, and this is essentially a fraction of a fraction of an hour: A second is a fraction of a minute which is a fraction of an hour.

From 60s = 1m , mathematically:

1 second = (1 minute) / 60 = (1 hour / 60) / 60 = (1/3600) hour = 1s = $0.000277\underline{8}$ hr

From 60m = 1h , after dividing both sides by 60: 1m = (1/60)h = $0.01666\underline{7}$ h

1 Day = 24 hours = 1440 minutes = 86400 seconds. 1 Year = 365.25 Days = 31,557,600 seconds

24 hr / 1 day = 1 hr / (1 / 24) day = 1 hr / $0.041666\underline{7}$ day , that is 1 hr = $0.041666\underline{7}$ day =~ 4.2% of a day

1 day / 86400 s , dividing num. and den. by 86400: = 0.000011574 day / 1 s , that is 1s = 0.000011574 day

Years past present and of the future are often expressed in reference to the yearly calendar or date system based on the year of the birth of the famous spiritual teacher and social influencer named **Jesus** (the English transliteration of the Jewish (ie., ethnic race) name of **Yeshua** , and of which many have transliterated it as **Jesus,** and the Muslim faith calls him **Isa**). Jesus from Nazareth, Israel, and who is also called by many as the Messiah, God's Prophet, Son Of Man (Mankind), Christ and the Light to the world - much like a new beginning offered to mankind from the God of the universe. Jesus and many of the unique events surrounding him are believed to have been prophesied (ie., spoken and then written, predicted by other prophets) many years before his birth. That year is considered as the modern starting or reference year of 1 or "1 A.D." (in the Latin language: "A.D." = Anno Domini = "In the year of the Lord", invented in 525AD in eastern Europe). He lived in the city of Nazareth of Israel after being born in the city of Bethlehem in Israel about 2,025 years ago from the current year (about 2025A.D) of this book writing. Years before this are indicated as: year-value BC, and BC means "(in the year) Before Christ". Ex. 1 BC is in the first year or 1 year previous or before 1 AD, the "first year" of this date system. There is not a defined year of 0, and since 0 or "nothing" was apparently an odd concept at those times. 2 BC means in the second year or roughly 2 years before 1 AD. 10,000 BC is roughly 10,000 years before 1 AD. The "first century" is technically the first one-hundred years after 1AD, hence it consists of the years of and between 1AD and 99AD. Things which happened in the "second century" happened between the years 100AD and 199AD. 1900 or 1900AD is roughly 1900 years since or after 1AD. The year 2020AD is considered as a year in the 21st century which started at year 2000. Some may consider AD as meaning "after death, of Jesus", but this is technically incorrect, and many have estimated Jesus left the Earth between 30AD and 36AD. Related to the abbreviation and meaning of AD is CE which means "in the **C**ommon **E**ra" (ie., of the common or current times). BCE means "before the Common Era" = BC also. Who made the CE dating system? It was **Dionysius Exiguus,** a Romanium Monk, who introduced it in 525AD, but it took a few centuries for it to become commonly used. He calculated that 1 AD as being 753 years after Rome was founded, and that he was then in the CE year of 525AD, and that year then being 1278 years after Rome was founded. These values have since been accepted worldwide as being fair.

A Year or 365 days is typically divided into 12 month (named after the word Moon) units of time, with each month being (1/12) of a year which is about (365/12) =~ 30 days of time duration or length, and this amount roughly corresponding to the length of one Moon cycle or orbit around Earth. Each month has 4 units of time called a week = (1/4) of a month unit. 1 year = 52 weeks. Each week has a 7 day cycle with each new day called: Sunday (Day of the Sun, Sun-day), Monday (Moon-day), Tuesday (Mars-day), Wednesday (Woden's-day or Mercury-day), Thursday (Thor's-day or Thunder-day, Jupiter's-day), Friday (Frigga's day, Freya's day or Venus-day), Saturday (Saturn-day). These names are generally of ancient Roman and-or northern-European origin, often in reference to some god that was once considered.

MONTH OF THE YEAR	**DAYS IN THE MONTH**	**DESCRIPTON OF THE MONTH**
1. January	31	[named after Janus, a Roman god for times and changes, February is from "Februa" = purification]
2. February	28	[a "**leap-year**", ex. 2020, is a time correction every 4 years, and February will be 29 days long]
3. March	31	[1st month in Roman calendar, named after planet ("wandering star") Mars, and a Roman god of War]
4. April	30	[means "second"]
5. May	31	[named after Maia, a Roman fertility goddess, and possibly means major and older]
6. June	30	[named after Juno, a Roman queen god, and possibly means "junior" as meaning younger and youth]
7. July	31	[named after Julius Caesar, a famous Roman leader, born ~100BC, died 44BC, about 56 years old]
8. August	31	[named after Augustus Caesar, first Roman Emperor, born 63BC, died 14AD, son of Julius Caesar]
9. September	30	[name derived from "seven", since it is the seventh Roman month from the start of March]
10. October	31	[name derived from "eight"]
11. November	30	[name derived from "nine"]
12. December	31	[name derived from "ten" or "deca" , "decimal" means pertaining to 10]

The etymology or word origin of the words "Moon" and "month" are generally based upon each other. A lune is an ancient word for a crescent (ie., crest, having a peak) shape, such as that made by two circles that are not aligned. The Moon is sometimes called as Luna. Things pertaining to the Moon are sometimes noted using the word "lunar". The word "lute" for a string musical instrument, often having a half-round-like shape, seems to be based on the word "lune" and "flute".

Typical or common time indicating, notation or expressing formats:

Date (within the Year)
month / day / year :in U.S.A
day / month / year :in Europe, etc.

Time (within the day)
hours **:** minutes **:** seconds
[Standard or Civilian Time uses two 12 hour periods: 1 to 12 for hours.
Military Time uses numbers 0 to 23 for indicating the hour,]

"Time duration", "time length" or "time change or= the change in time" is the difference between two time points or measurements. If a process started at 10s, and ended at 30s, the time duration or length of that process is:

time duration = ending time - starting time and for this example:
20s = 30s - 10s

Typically, on many "count up" (duration) timers or manually, the starting time is considered as 0s.

If a new process is said to take twice (2) as "long" as another, its time length, duration, or simply time, will be twice as much or "twice as long":

The new process, length, or duration time can be expressed with multiplication as:

old duration x (time or duration factor) = new duration , or simply:
old duration x factor = new duration or:
(old time) x (factor) = new time which can be expressed as:
new time = (factor)(old time) : a linear equation , for ex:
new process time = 2 (old time of process) , for example:
10 minutes = 2 (5 minutes)

Ex. If a new process is said to take only half (1/2 = 0.5) as long as another, its time length, duration, or simply time, will be half as long, length or duration as of the reference time value given, and is said to be twice (2) as fast, hence it will be a less or shorter time duration. The new process, length, or duration time will essentially be expressed as a division of the old duration time. The time of the new faster or quicker process is now less than, and is only a fraction of the time duration or length as that of the old process:

new time = (factor that is a fraction or multiple of the old time duration) time or:
new time = (factor)(old time) and for the given example:

new time = (1/2) (old time) = 0.5 old time which can be expressed as:

$$\text{new time} = \left(\frac{1}{2}\right)\frac{\text{old time}}{1}$$ which can be expressed as:

$$\text{new time} = \frac{\text{old time}}{2}$$

Here, the new lesser time value of that is a factor of (1/2 = 0.5) of the old time can be considered effectively as a 200% quicker or faster in the speed of getting things done, hence "twice as fast" = "in half the time". Consider this analysis:

From the concepts of: distance = (speed) (time) = 1 complete distance

$$(\text{1 completed process}) = 1 = (\text{effective speed of process}) \times (\text{total time of process})$$

Since their product is 1, these factor values are reciprocals of each other:

$$(\text{effective speed of the process}) = \frac{1}{(\text{total time of process})}$$

$$(\text{total time of process}) = \frac{1}{(\text{effective speed of the process})}$$, for the example:

If the total time of the process is halved, or divided by 2, and which is the same as multiplying it by a factor of (1/2 = 0.5):

$$(\text{effective speed of the process}) = \frac{1}{(0.5)\,(\text{total time of process})} = \left(\frac{1}{0.5}\right)\left(\frac{1}{(\text{total time of process})}\right) = 2\left(\frac{1}{(\text{total time of process})}\right)$$

The effective speed or rate of the process so as to have a 1 completed process is shown to be doubled (ie., a factor or 2 more) when the time is halved. For both sides of the above equation to be in balance, the (effective speed of the process) must also be multiplied or increased by a factor 2.

Ex. If the time duration, or simply the time, of an event or process is said to be 1.5 times faster:

$$\text{new duration} = \frac{\text{old duration}}{1.5} = (0.667)\,(\text{old duration})$$

: hence only 66.7% of the old time duration which means it's now a less time (duration), hence a faster or quicker process in terms of time length or duration. Consider:

(time of process) (effective or relative speed of the process) = 1 process done
and:

$$(\text{old total time of the process}) = \frac{1}{(\text{effective or relative speed of the process})}$$, for the example:

$$(\text{new total time of the process}) = \frac{1}{1.5\,(\text{effective speed of the process})} = (0.667)\,\frac{1}{(\text{effective speed of the process})}$$

For both sides of the above equation to be in balance, the (effective speed of the process) must also be multiplied or increased by a factor (1/1.5) = 0.667 . This can be expressed as:

(new time of process) = 0.667 (old time of process)

In short, a process is said to be (x) times faster or quicker, the amount of time needed for that process is a fraction of (1/x) that amount of time. If a process is said to be (x) times longer, the amount of time needed for that process will a factor of (x) times more.

For a **mechanical clock** that uses physical force to move (ie., rotate) the gears so as to rotate the attached time indicators (ie. "hands", or pointers), the passage of time is indicated on a circular disk surface. For the hour hand, pointer or indicator, each quarter hour = 60minutes/4 = 15minutes, corresponds to a 90° of rotation. For the minutes hand or indicator (or "pointer"), and-or the seconds hand or indicator, each 15 minutes or 15 seconds, respectively, of time passage corresponds to 90° of rotation of the corresponding hand or indicator. This amount is one-quarter or 1/4 of a full circle and-or rotation (ie., turning). 15 is 1/4 of 60. 60/15 = 4. 15min/60min = 0.25 = 1/4 , 15sec/60sec = 0.25 = 1/4. and 360° / 4 = (360°)(1/4) = (360°)(0.25) = 90°. Each 1 second and-or minute corresponds to: 360°/60 = 6° Each hour of time corresponds to 30 degrees of pointer rotation: 12hours / 1 rotation = 12 hours / 360° = 1 hour / 30°. If the hour hand corresponded to 24 hours (a full day) instead of 12 hours (a half of a day), each hour would then correspond to 15 degrees of rotation per hour. Extra: The rotation of the Earth on or about its polar axis, and-or the apparent movement of the stars across the sky, is also 15° / 1 hour.

> A mechanical clock is much like a mechanical counter with a numeric base of 60. When the seconds hand rotates once after 60 seconds of time has elapsed, the minute hand is incremented or increased by 1. When the minutes hand rotates once after 60 minutes of time has elapsed, the hours hand is incremented by 1. When the hours hand rotates 24 times, a day of time has passed.   When 60 units of seconds and-or minutes have been expressed on the clock, the values "rollover", "back to" to 0, and to "start over", advancing and-or incrementing again.

In the summer months, the northern hemisphere is effectively tilted toward the Sun during the day, and it will receive more daylight time, and shorter night time. During this same time of year, the southern hemisphere is effectively tilted away or back from the Sun during the day, and it will receive less daylight time, and will be in its winter season.

ANGLES AND ROTATION:

Degrees and radians are units of angles and-or rotation. Degrees are man made practical units made before the concepts of radians was known, whereas radians are units derived from the natural and true concepts of circles and rotation. Degree units are still commonly used everywhere for practical, non-scientific uses.

1 degree is a fraction of a full rotation that is 360 degrees about a point. 1° / 360° = 0.002777...
1° = (1 part of a full rotation / total parts of a full rotation) = (1 part / 360 parts) = 0.002777... parts of a rotation
1 degree = 0.0174532925199433... radians

1 radian = 57.29577951308231... degrees : *

> From C = 2(pi)r =~ **6.2832** r , hence:
> The radius can go about the circumference about 6.2832 times: C / r = 2(pi) =~ 6.2832
> Total angle in degrees about a point or circle = 360° : man made
> Total angle in radians about a point or circle = 2(pi) =~ **6.2832**...
>
> $$\frac{360^\circ}{(6.2832 = 2(\text{pi}))\text{rads}} =\sim \frac{57.3^\circ}{1\text{ rad}} \quad : *$$

A **steradian** is a "solid radian angle" shape that is naturally based, and is a radian angle of 1 rad rotated about its center axis, like a (3-D) cone. Energy or "(energy) rays - straight, line like outward travel" transmitted from an ideal (spherica-like) infinitely small point source can be thought to have this type of cone shape as it travels away from that location and outward and into a larger circular area.

360 degrees = 2(pi) radians = 6.283185307... rads = 1 revolution or rotation = 1 rev

In some astronomy and navigation angle measurements: 1° Degree =or has 60' Minutes , and 1 Minute =or has 60" Seconds. DMS is the Degrees, Minutes, and Seconds, system. Here, a minute ('), or arcminute, is an (arc) angle that is a fraction (1/60) of a degree = $0.0166\underline{7}$° A second ("), or arcsecond, is an angle that is a fraction (1/60) of 1 minute = (1/3600) of a degree = $0.000277\underline{8}$° The value of 60 was chosen for use since it evenly divides 360° up into smaller angles. Arcsecond and arcminute are not associated with time values such as seconds of time, but rather specific angles values. 1 arcdegree, or "1 degree of arc", corresponds to 3600 arcseconds.

Ex: 5° 10' 26" = 5 degrees, 10 minutes, and 26 seconds in the DMS (Degrees, Minutes, Seconds) angular notation system.

The known visual or apparent angular diameter or "width" of the Moon is about 0.5° and this corresponds to 30 arc-minutes of angle. 0.5 degrees / (0.01667 degrees per arc-minute) = 30 arc-minutes. 1 degree of arc. = 60 minutes of arc. Since angle = arctan (tan ¢) = arctan (opp/adj) = arctan (2159miles wide/ 240000miles away) =
~= arctan (0.009) = $0.51\underline{5}$°

From: velocity = distance / time, we have: angular velocity = w = angle / time = ¢ / time = ¢ / s

We must use the "natural value" of radians for the angle in these types of equations, rather than the man made degrees units of which was decided that there should be arbitrarily and non-scientific 360° degrees, angles or parts per circle, and probably since it nicely approximates the (days / year) known in those ancient times.

For the amount of rotation (rather than distance) per second, we have rotational velocity or rotational speed:

From: linear velocity or speed = $\frac{\text{distance}}{\text{time}}$, we have rotational velocity or speed = $\frac{\text{amount of rotation}}{\text{time}}$

angular velocity = angle / time = w = radians / s = rads / s :it is very possible to measure it with revolutions or degrees per second:

1 revolution / s = 1 rev / s = 1 rotation / s = 1 rot / s = (2)(pi) rads / s =~ 6.28 rads / s = 360° / s

If there is a multiple of revolutions (1 rev = 360° = 2pi rads) or revs per second:
w = (radians / s) = ((revs)(2)(pi) radians) / second : angular velocity in radians per second

Rotational speeds:

revolutions per minute = rpm = rev per min = revolutions / minute = (rps)(60)
revolutions per second = rps = rev per sec = revolutions / second = (rpm / 60)

w = ((2)(pi) (rps)) radians / second = (2)(pi)(rpm/60) radians / s or= (pi)(rpm/30) radians / second : w = angular velocity

1 rps = 1 cycle per second = 1 cps =1 hertz = 1 hz = 360° / second = 1 rev / s = (2)(pi) radians / s =~ 6.28 radians / s

hz = cycles per second = c/s = cps = (2)(pi) radians / s : frequency = F is a-the rate of cycles = cps

1/ frequency = time of each cycle, wave, revolution or rotation in seconds , hence:

1 / Fhz = 1 / (cycles / second) = seconds / cycle = s / cycle = time / cycle = Period of cycle = T = P

F = cycles / s = (2)(pi) radians / s = the frequency expressed in terms of revolutions per second or cycles per second, and radians per second = the angular velocity = w

rps = revolutions per second = revs / s = rot / s
rpm = revolutions per minute = revs / min. = revs / 60s = rot / min

1 rps = 1 rev / 1s , and after multiplying num. and den. by 60:
1 rps = 60 rev / 60s = 60 rev / min = **60 rpm** , multiplying both sides by N:
N rps = N 60 rpm

rpm / 60 = rps , Ex. 120 rpm = (120 rpm / 60) = 2 rps , 600 rpm = 600 rpm / 60 = 10 rps

For the linear velocity of a point on a circle:

For a circle, circumference = C **= 2(pi) r =~ 6.28 r** : circumference (C) is a distance , (r) = radius of the circle

From : speed = distance / time = v = d / t , for the speed of an object rotating about the center point of a circle, the distance traveled for each rotation or orbit is equal to c:

$$v = \frac{d}{t} = \frac{C}{t}$$

: the velocity when the distance traveled = 1C = 1 revolution.
: here, v **=** equivalent rotational velocity at point (r) from the center, rather than angular velocity = w , and:

Total distance = (C)(revolutions) = (C)(revs) = 2(pi)(r) (revs) = (6.28 r)(revolutions)

angular velocity = w = $\frac{\text{(amount of rotation)}}{\text{time}} = \frac{\text{¢}}{t}$, for each revolution: ¢ = 6.28 radians , **w =** $\frac{6.28}{t}$ using substitution:

$$v = \frac{d}{t} = \frac{C}{t} = Cf = \frac{6.28\,r}{t} = w\,r$$

: linear velocity of a point on a circle or in a circular orbit, and in terms of the angular or rotational velocity. Also:

$$d = vt = C f t = C \text{ (revolutions / second) (seconds)}$$

Ex. A vehicle wheel has a circumference of C = 2m, and the vehicle is moving at 7m/s, what is the frequency of the rotating wheel? From v = C f , we have: **f = v / C** = (7 m/s) / (2m) = 3.5 (1/s) = 3.5 / s = 3.5 hz = 3.5 cycles / s =
= 3.5 revs / s = 3.5 hz

$$w = \frac{v}{r} = \frac{\text{radians}}{s}$$ **: rotational or angular velocity in terms of linear velocity and the radius of rotation. v = w r , r = v / w**

Converting between degree and radian angular velocities. This essentially resolves to converting between degrees and radians, and since the time value will be the same, such as 1 seconds.

$$w = \frac{n \text{ radians}}{s} = \frac{\frac{n\, 360^\circ}{(2)(\pi)}}{s} = \frac{n\ 57.29578^\circ}{s} = \frac{\text{deg}}{s}$$

$$w = \frac{n \text{ degrees}}{s} = \frac{\frac{n^\circ \text{ rads}}{57.29578^\circ}}{s} = \frac{\text{rads}}{s}$$

distance = d = (speed) (time) **= v t** = (w r)(t) = **wrt** : a point at distance (r) from the center of rotation will travel this (equivalent linear) distance in the given amount of time

Ex. An automobile (ie.,a "car") is traveling at a velocity or speed of 20 miles per hour = v = d / t = 20 mi / 1hr.
Since: 1 mile = 5280 feet and 1 hour = 3600 seconds , for the distance traveled in 1 second:

$$\frac{20 \text{ mi}}{1 \text{ hr}} = \frac{(20\text{mi})(5280/\text{ft/mi})}{(1\text{hr})(3600\text{s/hr})} = \frac{105600 \text{ ft}}{3600\text{s}} = \frac{29.33 \text{ ft}}{1\text{s}}$$, to find how many revolutions per second = rev/s = rps :

From: distance = (velocity)((time) , velocity = speed = distance / time = (d / t)

An angular velocity or rotational velocity of: w = (1 revolution / time) = (6.28 radians / time) = (6.28 / time) ,
and this corresponds to a linear velocity of: v = (circumference / time) = (6.28 r / time) : r = radius

If the wheels of that car have a radius of 1ft: C = 6.28(r) = (6.28)(1ft) = 6.28 ft
1 rev corresponds to a distance of 6.28 ft, and x rev corresponds to 29.33 ft? , using a proportion equation:

$$\frac{1 \text{ rev}}{C} = \frac{1 \text{ rev}}{6.28 \text{ ft}} = \frac{x \text{ rev}}{29.33 \text{ ft}}$$, x rev = (29.33 ft) (1 rev) / 6.28 ft = 4.67 rev , And this corresponds to 4.67 rev / s = 4.67 rps since the distance was expressed per second.

$$\frac{4.67 \text{ rev}}{s} = \frac{(60)\,(4.67 \text{ rev})}{(60)\quad(1\text{s})} = \frac{280.2 \text{ rev}}{60\text{s}} = \frac{280.2 \text{ rev}}{1\text{min}} =\sim 280 \text{ rpm} = 280 \text{ cycles / min}$$

From the above concepts, we can find that 1 mi/hr = $1.466\underline{7}$ ft/s =~ 1.5 ft/s , hence 10 mi/hr is about 14.6ft/s =~ 15 ft/s, and 100 mi/hr is about 147 ft/s =~ 150 ft/s. The average adult human walks at about 1 mi/30min = 2 mi/hr ~= 2.93 ft/s =~ 3 ft/s.

A special note about the actual units of frequency and time in terms of cycles or repetitions:

Frequency and time are mathematically inversely related, and are mathematical reciprocals of each other. In some other words, this could be stated that the number of cycles, repetitions or rotations are inversely related to the time. As the frequency or amount cycles increases, the duration of each cycle decreases:

$1 = \text{(frequency)(time)}$,

$1 = F\,t$, and mathematically:

$F = \frac{1}{t}$ and $t = \frac{1}{F}$: reciprocals, and showing that the units are also reciprocals:

$\text{frequency} = F = \frac{\text{cycles}}{1\text{s}} = c/s$: c/s = hertz

$\text{time} = t = P = T = \text{period of cycle} = \frac{\text{seconds}}{\text{cycle}} = s/c$

If (t) = T = P decreases by (n), the corresponding frequency will increases by that same factor of (n).
If (t) increases by (n), the corresponding frequency will decrease by that same factor of (n).

$$1 = F\,t = 1\,Ft = \frac{(n)}{(n)}\,Ft = (n\,F)\left(\frac{t}{(n)}\right) = \left(\frac{F}{(n)}\right)(nt)$$

Ex. If t = 1s , **F** = 1 / t = (cycles / t) = cycles / 1 s = **cps** : cps = "cycles per second" = hertz = **Hz**

Ex. If F = 1000 hz = 1000 cps , t = seconds / cycle(s) = s / F = 1s / 1000hz = 0.001s = "one milli-second"
F = cps = **c/s** , 1 / F = 1 cps = (1 / (c/s)) = **s / c = t**

Ex. If n = (1/10) = 0.01 = F = 1000hz / n = 1000hz / 10 = 100 hz = 100 cps , t = 1 / F = 1s / 100 hz = 0.01s
We see that if the frequency decreases by 10, the time or period of each cycle increases by 10 which indicates a longer wavelength, and which is actually 10 times longer. If the frequency increases by 10, the time of each cycle or period decreases by 10, and which indicates a shorter wavelength, and which is actually 10 times shorter for this example.

In short, the time or duration of each cycle or period is inversely related to frequency.
Wavelength is inversely related to frequency, hence it is also directly related to the cycle or period time.

Extra: What is "red-shift" in terms of a frequency(s)?

This topic is an advanced topic, and you may skip over it. If you were to walk along and rub a stick against evenly spaced wooden fence boards, and at a constant rate (ex., boards per foot of distance and-or boards per unit of speed and-or time), a certain frequency of striking those boards will be obtained and usually heard. If you were to increase your velocity to a higher value, and-or the fence and its boards were also moving towards you (ie., here for this example, parallel to you), the frequency of striking the boards will increase. This concept is basically called a "shift in frequency", and if the fence or say a distant galaxy was moving away from you as you struck the boards, then the frequency of that would then decrease because it would take a longer time to strike the boards of the fence. A "shift" (ie., change) in frequency is when the light from a galaxy moving away from the observer, and the expected frequency will become shifted into the longer wavelengths, as if the waveform was being stretched longer, and which have a lower frequency. In this instance, it would be called a "**red-shift**". A "blue-shift" or increase in the expected frequency is rare in astronomy, and the Andromeda galaxy is said as having a "blue-shift" since it is coming closer to our Milky-Way galaxy and-or vice-versa. Perhaps in a few million years these two galaxies will collide, however since the space between any two stars is a few **l**ight-**y**ears (here, about **4 ly**) of distance on average, and that all the known stars are relatively very small as compared to this distance, the galaxies will mostly "pass through" each other. The stars in each galaxy will be only be minimally affected by each others gravity and there will be relatively few collisions of stars and-or their planets.

[This space for book edits.]

SOME COMMON MATH FORMULAS

The following formulas and discussions are presented so as the reader may have at least a basic, acceptable or minimal awareness, knowledge and understanding of some of the typical scientific concepts they may possibly encounter at some point in various fields of study and-or in everyday life. For most people, this would be enough to have available and to consider, but these topics when fully explored could easily fill volumes of other books that are more needed for those who have focused on these specific topics or fields of study, experimentation, and work.

distance = (speed) x (time) :The most common equation of these three variables. We also see that to know distance, we need to first know what speed = velocity is. Mathematically:

speed = distance / time :after the division is performed, speed is essentially the rate of an amount of distance units traveled with respect to and during one unit of time . Speed is how fast or how steep, intense or rate" (ie. a rate called "speed"), and its value is defined as how much distance has, is will changed with respect to the change in time. After division and-or simplification of the fraction, this equation essentially reduces to how much distance changed or how much an object traveled in 1 unit of time. Speed (s) is formally called **velocity** (v) in science studies.

Ex. 100miles / 2 hours = 50 miles / hour
Ex. 200 miles / 4 hours = 50 miles / hour , hence the same distance and time rate as the last example. Mathematically:

time = distance / speed : here, time can be mathematically described and-or equal to as the ratio of the change in distance with respect to the amount of speed

Examples of the (mankind made) units of measurement for distance are units of length such as: feet (ft), miles (mi), kilometers (km), etc.

Examples of the units of measurement for time are: seconds (s), minutes (min.), hours (hr), months (mo), years (yr), etc.

Two times values can even be expressed as a ratio, and for example: "days per year" = days/year = = 365.25 days /1 year, and the reverse ratio of this is: 1 year / 365.25 days. Both of these fractions include 1 year unit. Dividing the numerator and denominator values of the first fraction by 365.25, we have these equivalent fractions which include 1 day unit and the equivalent amount of year units: 1 day / 0.00273785 yr = "1 day is to 0.00273785 years" and-or "0.00273785 years is [equivalent] to, or corresponds to 1 day".

Examples of the units of measurement for speed or velocity, and which is a combined unit of distance divided by a unit of time such as: (miles/hour) = "miles per hour" , (feet/second) = "feet per second".

When speed is not an average value, but for a specific point in time during the travel, it is often called the (current or instantaneous) velocity. Distance is a length value.
Units, such as for example: speed = meters/second, or miles per second, are sometimes called "derived units" that are composed of other basic units of measurement.
velocity is another scientific word for speed.

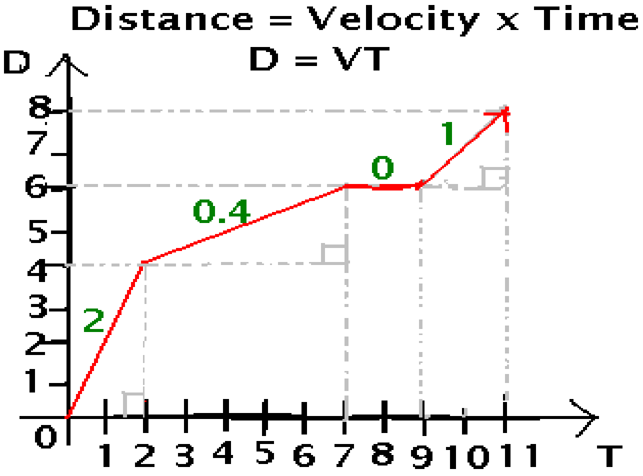
velocity = change in distance / change in time , and if both values started at 0m and 0s, then this formula reduces to the same formula as the speed formula:

velocity = distance / time , and this becomes the same formula for speed

velocity or speed is a ratio or rate of two other values. It is the rate of change in distance with respect to a change in time.

If speed or rate is constant, the distance equation: D = VTs is a linear or line equation of the form: y = mx , or more formally as: y = mx + b where (m) is the rate of change of (y) with respect to (x). (m) is also called the "slope" or steepness value of the line. (b) would be an initial start point or distance already covered when (t) is considered 0.

Below is an example graphing of the distance equation of Distance with respect or in reference to Time. The graph helps visualize the situation and the understanding of it. The velocity or speed is indicated in green next to the current total distance traveled. [FIG 225]



velocity = (change in distance) / (change in time) : the slope of the red line indicates (v)
Ex. From T=2 to T=7. velocity = (6-4) / (7-2) = 2 / 5 = 0.4

First, the equation of D = VT is a linear or line equation of the form y = mx. Clearly in the above graph, the line is not continuous from the start, and the line now becomes line segments that essentially "curves" or changes direction and-or steepness since the velocity of the object at and during those time values has changed.

Ex. This example also shows a deeper understanding of the distance equation, along with a forward example of **acceleration** which is discussed shortly thereafter.

If an object travels at distance of 1 meter after 1 second of time, it is said that the speed or velocity (v) is 1 meter per second of time. v = 1 m/s. The total distance traveled after 10 seconds is:

$$d = v\,t = \left(\frac{1m}{1s}\right)\left(\frac{10s}{1}\right) = 10m \qquad : v = d / t$$

It the total time of travel was 20s, t=20s , the total distance traveled is:

$$d = v\,t = \left(\frac{1m}{1s}\right)\left(\frac{20s}{1}\right) = 20m$$

If an objected is constantly increasing (ie., changing) its speed or velocity by 1 meter of distance per second after each second of time, it is said to have an **acceleration** of (a) = (change in velocity / time) equal to (1 meter per second) more, after each second of time, hence:

$$a = \frac{(\text{change in velocity})}{1s} = \frac{1m/s}{1s} \quad \text{and this is mathematically equal to:} \quad a = \frac{1m}{s^2} = \frac{1m}{(1s)^2} = \frac{1m}{(s)(s)} = (1m / s) / s$$

We also see that the (change in velocity) mathematically equals:

(change in velocity) = (acceleration) (time) = at , and if the initial velocity v1was 0m/s:

(v2 m/s - 0 m/s) = v2 = **v = a t**

If the initial velocity is 0m/s, after 10s, the (accelerating or increasing) velocity will have a value of:

$v = a\,t = \frac{1m}{1s^2}\,\frac{(10s)}{(1)} = \frac{10m}{s}$: here, at v1=0m/s, $a = \frac{v}{t}$

For simplicity of some of these expressions, let the delta symbol of: Δ represent the change in a value:

(change in a value) = (difference in the values) = (value2 - value1) = Δ value

$a = \frac{\text{(change in velocity)}}{\text{(change in time)}} = \frac{(v2 - v1)}{(t2 - t1)} = \frac{\Delta v}{\Delta t}$, If v1 = 0, and t1 = 0, then: $a = \frac{v2}{t2} = \frac{v}{t}$

Δ v = (v2 - v1) , therefore: v2 = v1 + Δv , Note, if there was no change in velocity: Δ v =0, there was no acceleration: a=0, and vice-versa

Δ d = (d2 - d1) , therefore: d2 = d1 + Δd , if d1 = 0 , d2 = Δ d

Δ t = (t2 - t1) , therefore: t2 = t1 + Δt , if t1=0 , t2 = Δ t

Since: d = v t

Δ d = Δ (v t) , to have a change in distance, a change in velocity and-or time is needed:

Δ d = Δ v Δ t = a Δ t Δ t = a (Δ t)^2 : to have a change in (v), a change in (a) is needed, and of which is caused by a change in applied force.

If a velocity, say v2, is 2m/s faster than its previous value of v1, the change in velocity is: Δ v1 = 2m/s: new velocity = old velocity + change in velocity = v2 = v1 + Δ v1 = v1 + 2m/s. If the time of traveling at this new velocity is 3 seconds, the increase in distance that corresponds to, or is due to this change in velocity is:

Δ d = Δ v Δ t

Δ d = (2m/s) (3s) = $\frac{6\text{ m s}}{1s}$ = 6m , also, and as an example and check:

Δ d = a (Δ t)^2 , First, a = Δ v / Δ t = (2m/s) / (3s) = 0.667 m/s^2

Δ d = a (Δ t)^2 = (0.667m/s^2) (3s)^2 = (0.667m/s) (9s^2) = 6m : checks

Some useful mathematical considerations:

d2 = d1 + Δ d1 , therefore: Δd1 = (d2 - d1) = (Δ v1 Δ t1)

d2 = (v1 t1) + (Δ v1 Δ t1) , since v2 = v1 + Δ v1 , Δ v1 = v2 - v1 :

d2 = (v1 t1) + (v2 - v1) (t2 - t1) , for the above example:

d2 = (v1 t1) + (2m/s) (3s)

d2 = (v1 t1) + 6m

dt = total distance = sum of each distance segment, portion or instance of the total distance traveled

dt = d1 + d2 + . . . dn

Each distance, length segment or portion of the total distance has a corresponding velocity and time of travel value associated with it, and needs to be considered in the calculation:

dt = (v1 t1) + (v2 t2) + . . . + (vn tn)

A change in velocity or speed per unit of time is the basic definition of **acceleration.** When velocity changes or increases, it is due to an acceleration that has happened. When velocity decreases, it is due to a deceleration that has happened.

Ex. If more fuel or energy is applied to the engine of a vehicle, more power and force can eventually be applied to the wheels of the vehicle, and it can then accelerate (ie., change, increase) its speed. The vehicle will "go faster". If the fuel is reduced and-or the brakes are applied to the vehicle, the vehicle will decelerate (ie., change, decrease) and its speed will decline. The vehicle will "go slower".

For speed or velocity changes to happen, some force must act upon the object so as to speed it up or slow it down, and-or change its direction. Where the line in the above graph changes direction and-or slope is where there is where a change in velocity happened, hence an acceleration or deceleration has happened. On this graph, the speed changes are abrupt (happen quickly in a short amount of time, such as due to a short pulse or application of force) rather than a more gentle increase and curve. Generally accelerations or decelerations to reach a new speed value happen over a reasonable amount of time.

Ex. If the change in velocity was from 30 feet per second to 40 feet per second, the change in velocity was (40fps - 30fps) = +10fps, and if the change in time for this to happen was 20 seconds, the acceleration could be describe as :

$$\textbf{acceleration} = \frac{\textbf{(change in speed)}}{\textbf{(change in time)}} = \frac{\Delta v}{\Delta t}$$

: acceleration is the rate of change of speed with respect to a change in time

acceleration = +10fps / 20s = +0.5 feet / 1s = +0.5 fps.

Whenever the change in speed is to a lower value, a deceleration has happened and the change in speed will have a negative sign, and therefore the acceleration value would have a negative sign which essentially indicates a negative acceleration = opposite of an acceleration = a deceleration.

Acceleration or deceleration is a measurement for how the speed or velocity of an object changes over or with respect to time (t) due to a force acting upon that object. It is the rate of the change in speed per unit of time. If an object is going very fast but maintains its speed, no forces acted upon that object to change its speed, and therefore, it did not accelerate to a higher or lower speed (velocity). It had 0, or no acceleration.

acceleration = (change in speed) / (change in time) , or after simplifying the fractions:
acceleration = (change in speed) / (1 time unit)

The formula for acceleration is actually be expressed as a rate of another rate that is also with respect to the same variable that is time (T), and because of the definition of acceleration, we can express acceleration in relation to just distance and time, and with this formula for acceleration, it will include a squared variable of time (T)..

Since **speed** or velocity = (D / T), and using substitution into the above formula for acceleration:

acceleration = (change in velocity) / (change in time) , and this reduces to:
= (change in speed) / (unit time) = (change in (D / T)) / T =
= (change in distance) / T^2 = D / T^2

Ex. 3m/s^2 = An acceleration of "3 meters per second squared" = "3 meters per second, per second" = (3m/s) / s . A change in velocity of (3 meters per second) for each second of time considered.

Ex.: If the acceleration was noted or calculated at: "five meters per second squared" = = 5 (m / s^2) , this could be thought of as the objects speed or velocity increased by 5 meters per second of time for (per) each second it was accelerating or increasing in speed. If an objects initial velocity was 100 meters per second of time, and the time of accelerating was 10 seconds, the objects new or total velocity would be:

First note that mathematically from equation for acceleration:

(change in velocity) = (acceleration) (change in time) = AT : a multiplication or product

total velocity = original velocity + change in velocity : all values with respect to time
And:

Vt = Vo + (acceleration)(time) , and:

Vt = 100 m/s + (5 m/1s^2)(10s)
Vt = 100 m/s + 50 m/s combining like terms:
Vt = 150 m/s

Also of note as shown above is:

(acceleration)(time) = (a speed value) when the change in time was from an initial time value considered as 0 seconds, and therefore, the change in time is equal to just the total time value that the acceleration was applied.

A helpful summary of velocity and acceleration:

velocity (v) is the rate of change in distance with respect to, or in reference to the change in time, or in other words it is the time rate of change in distance. v = d / t = Δ distance / Δ time . At a certain point, value or instant in time where the change is very small or "infinitesimally small", velocity is the derivative (ie., like a slope value) of distance with respect to time.

Acceleration (a) is the rate of change in velocity with respect to, or in reference to the change in time, or in other words it is the time rate of change in velocity. a = v / t = Δ velocity / Δ time = Δ d / Δ t / Δ t = Δ d / (Δ t)^2 . At a certain point, value or instant in time where the change is very small or "infinitesimally small", acceleration is the derivative (ie., like a slope value) of velocity with respect to time.

[This space for edits.]

Gravitational Acceleration , The acceleration of an object due to the constant force of gravity.

When the force of Earth's gravity (attraction) is constantly applied to a falling object, it will cause that object to not just change speed once to some new value, but will cause the object to keep increasing in speed since the force is always or constantly applied to it, and is therefore not just a temporary event or pulse of applying the force during a short or quick amount of time. **Force** can be defined as the application or transfer of energy from one thing to another, and the longer a force is applied to an object, the more energy it can gain or store. With the application of force to an object, the object can accelerate and gain speed. The speed an object is part of the total energy that the object is storing and which can be applied and given to some other object. A change in speed requires an acceleration and which requires a force.

Galileo make a public demonstration that two objects of different weight (and mass) rolled down a declining plank or dropped from a tall height, will both reach the end or ground at the same time for each method and-or from other heights. Before this, it was "naturally common and natural" to think that a heavier object would reach the ground first. Galileo demonstrated that there must be some force upon all and various weighted objects, and it must be a constant value. This type of motion due to gravity (ie., gravitational force, the force of gravity and-or mass) alone, is sometimes called "free-fall" or "free-fall motion" since there was no input energy or motor. Galileo found that the distance covered per unit time is mathematically related to the square of the time value. The objects were accelerating (increasing in velocity or speed) and at a constant rate which must be due to a constant force applied to them. **Isaac Newton** later called this force "gravity" since it is in the downward direction, and he later wrote the very useful equation for any applied force in about 1687. Later in this book, there is a article called "**A Note On Newton's Force And Gravity Equations**" which mentions how Newton most likely developed this formula for force:

(force) = (mass) (acceleration) or= **f = ma**. : with units of: $\frac{\text{(kilgrams)(meters)}}{(\ \text{s}^2\ )}$ = **(kg-m / s^2)** = **N**ewtons
(kg) (m per sec.) (per sec)**.**
"per sec" = "for each second"

If you drop an object from a low height onto the ground, it will make a small dent in the ground, but if you increase the height and drop it again, the dent will be deeper. This indicates there was a larger force applied to the ground. Since the object has more time to fall, it gains more and more speed due to the constantly applied force of gravity. A change in speed or velocity is called an acceleration. A constantly applied force will cause an acceleration. The larger the mass and-or weight of the object, the larger or deeper the dent will be. We find that the falling or moving object will apply a force to the ground, and that amount of force is directly related to the mass of the object and the speed it is traveling. When the object impacts (strikes, collides with) the ground, its speed will decrease, and this is called a deceleration. If the ground has a sponge, spring or soft dirt on it, the time to decrease the objects speed of 0 is now longer, and the deceleration (or "negative acceleration") = (- a = change in velocity / change in time) will not be a high such as for a direct impact, but will be a lower value, and this will cause the speed or velocity of the object to slow down just before impact and produce a smaller dent in the ground. It could be said that the object lost some of its energy (ie., ability, force ability) to make a dent. We find that force is now rather, or more "technically", directly related to mass and acceleration since the velocity is constantly changing. Acceleration (or deceleration) considers how much of the objects velocity was actually used (or lost) during the application of the force or transfer of energy such as an impact. Acceleration (a) is the rate of change in velocity: (a) = (v2 -v1) / time. If the change in velocity is small, the acceleration or deceleration will be small, and the applied or impact force and dent will be less. If the change in velocity is high, such as a what happens during a quick (a low value of time) impact, the acceleration or deceleration is very high and the impact force and dent will be larger. The transfer of energy (energy / time = Joules / s = power , watts) is at a higher rate for quicker impacts where the change in velocity is higher, hence the acceleration is higher. When an object slows down, it will loose some of its force or dent ability, and this is technically due to that it lost some of its (kinetic, moving) available energy. A box that is pushed across the floor will slowly loose its kinetic energy due to (surface) friction (ie., a force to overcome) with that floor surface, and its mass of the box will remain the same, but its remaining kinetic energy and remaining velocity value will decrease to 0 because of the (drag) force of friction and transfer of energy (mostly as heat, and some a sound) causing a deceleration of that object. In general, the heavier the box or weight to move across a surface the more the friction force. Smooth, hard and flat surfaces have the low friction.

A derivation in this book shows that: $F = ma = \frac{Energy}{distance}$ or $= \frac{J}{d}$: Energy = Work = Fd : units of Joules = J
Here, d = distance = meters

If a given amount of energy is depleted in a short distance (and time), such as for a strong impact, the value of force will be high. Also from this equation: $a = J / md$ which indicates acceleration is related to the amount of energy applied to a mass. A higher amount of energy can apply a higher amount of force. A higher amount of force can apply more energy. Also from this itself, we have: Energy = J = mad = Fd = Work .
Shown in this book in this book is that: Kinetic Energy = mv^2 / 2 Joules = Fd Joules = mad Joules

A force, such as gravity, that is constantly applied to an object will cause that object to have an acceleration or change in speed and-or direction. An acceleration due to gravity is called gravitational acceleration and has a constant value since the mass of Earth and its gravitational force is constant. Earth's gravitational acceleration is often given the symbol of (g). **(g) = 9.80665 m/s^2 =~ 9.8$\underline{1}$ m/s^2**. Expressing this in the general force equation: f = ma = mg.

The weight of an object is the mass of that object being influence by the force of gravity, causing it to accelerate and effectively creating a force equivalent to the weight of that object: **weight = f = ma = mg**
With this equation, the mass of the object can be found, and the gravitational acceleration:

m = f / a = f / g = weight / g and **a = g = f / m = weight / mass : the higher the acceleration, due to a higher force applied to the mass, the higher the weight and-or the (force per mass).**

Earth's gravity (attraction) force is due to Earth's large amount of mass (material), and it effectively extends outward from its center and causes an ("gravitational" [force]) induced acceleration of: g = 32.$\underline{2}$ft/s^2 = 9.81m/s^2 upon any sized mass or object in a vacuum (no air or other matter, and zero internal pressure), but is nearly the same value for objects in an air medium when the object is smooth and has low air resistance (ie., air collision, "drag" or "drag force" in the opposite direction, reducing its kinetic energy) due to it colliding with air and slowing it down by an effective application of a force in the opposite direction. Another way to consider this is that the object essentially looses some of its energy as it compresses the air beneath it and causing the air to have some pressure or force in the upward direction, and the object will have difficulty gaining any more kinetic energy due to gravity.

velocity = initial velocity + change in velocity
v = vo + v1
v = vo + (g)(t) : see (*) below for a derivation of velocity = (g)(t)
v = vo + (9.8m/s^2)(t) : time (t) will also have units of seconds (s).

(*) When the initial velocity of the object is 0m/s, as when simply released by a persons hand at a height above the ground, and the time is considered as 0s:

acceleration = (change in speed) / (change in time)
a = (final velocity - 0) / (final time - 0) = velocity / time = v / t , therefore, mathematically:
v = at , since we are dealing with Earth's gravitational acceleration (g), this equation can be expressed as:

Ex. If the initial velocity is 0m/s, and an object accelerates at: a = 1m/s , the velocity of the object after 10s is:

$$v = \text{initial velocity} + \text{change in velocity} = 0 + \text{change in velocity} = a\,t = \left(\frac{1m}{s^2}\right)(10s) = \frac{10\ m}{s}$$

v = at = gt : the units of t = time are usually seconds (s), unless otherwise noted.
v = (g)(t) = (9.8m/s^2)(t) = 9.8m / s :this has the form of: velocity = distance / time , from: distance = (speed)(time)

Here is an algebraic example of acceleration that uses the gravitational acceleration (g) constant. Shown is how to find the distance an object has traveled after it has been dropped from a height and after an amount of time has elapsed:

a = acceleration = change in speed / time = $(S1 - S0) / t$ mathematically:

$at = (S1 - S0)$: S0 is the starting speed of the object, hence its is equal to 0 at t=0. S1 is the speed of the object after at a certain time value. If S0=0, the equation can be reduced to:

$v = at = gt = S1$ = current or instantaneous velocity or speed of the object after a certain time has elapsed

distance = (velocity)(time) = $\dfrac{(g\,t)\,t}{(2)} = \dfrac{gt^2}{2}$: $g = 9.8\underline{1}\ \text{m}/1\text{s}^2$, t = time in seconds (s).
: this denominator of 2 is basically due to using the average velocity throughout the distance and where the starting velocity was 0m/s rather than a constant or an average value throughout that distance. In other words, the distance would of been effectively and incorrectly doubled, and therefore must be halved.

These equations for a (unaided, from rest) free falling body are for relatively short distances or heights since air resistance or "drag" (**d**e**g**r**a**din**g** and deceleration force, in the opposite direction) will keep increasing on the object as the more speed it has. The shape of the object, such as a hin flat plate of some material (such as cardboard) can cause significant drag to where this equation can't be used, but perhaps a unique equation that uses some average values measured for a certain object to get only an average result. Drag (force) can be reduced if the cross sectional area of the objected is reduced. A thin, pointed and (directional) stabilized vertical rod shape will have less drag than a wide, flat shape. As a surface moves through the air, it both collides with and compresses the air directly in front of it, and like a spring, it will then have a force in the opposite direction. This force will therefore reduce the speed and-or kinetic energy of the object. The maximum speed or velocity of a certain shaped object is called the objects "terminal velocity". At terminal velocity, motion still continues, but acceleration ceases since the gravitational force is essentially eliminated due to the drag force having the same value in the opposite direction. The object will still remain in constant motion due to its kinetic energy, and keep moving or falling in its (downward) direction due to the force of gravity still affecting the motion of the object.

It is of note that the force due to gravity is similar to that of a magnetic field and electric field where the strength of the field (g=a) and or gravity exponentially gets weaker as the distance from the source increases, and is in fact, related to the inverse square law. In a pseudo equation: (force2 at distance2) = force1 / (distance1^2 from force1)

Some other related equations to consider:

$f = ma = m\,\dfrac{(\text{change in } v)}{(\text{change in } t)}$, If v0 = 0, and t0=0: $\mathbf{f} = ma = \dfrac{mv}{t} = \dfrac{m\,(d/t)}{t} = \mathbf{\dfrac{md}{t^2}}$

$\mathbf{d = vt = \dfrac{f\,t^2}{m}}$: the distance an object will move after a constantly applied force will apply and transfer (kinetic) energy to it and accelerate it and increase its velocity. If the force is applied in outer space, the objects distance will continue to increase at the same velocity, and without any more force applied. Since d and m are mathematically inversely related, if m gets smaller, the distance the object can be moved given the same value of force. From the above equation, we also have many other equations to explore:

$\mathbf{\dfrac{d}{t^2} = \dfrac{f}{m} = a}$ **:** since $f = ma$, $a = f / m$

$\mathbf{d = v\,t = (a\,t)\,t = a\,t^2 = (f / m)\,t^2}$ as shown above : $t^2 = d / a$, therefore: $t = \text{sqrt}(d / a)$

$\mathbf{t^2 = \dfrac{dm}{f}}$ **, and:**

$$t = \sqrt{\frac{dm}{f}} = \sqrt{\frac{d}{a}} = \frac{d}{v} \quad \text{and} \quad t^2 = \frac{d^2}{v^2} = \frac{dm}{f} \text{ , hence } f = \frac{mv^2}{d} \text{ , hence } \frac{v^2}{d} = a = \frac{d}{t^2}$$

Mathematically: v^2 t^2 = d^2
Taking the square root of both sides: d = v t

For consideration: E = W = f d , f = E / d
a = f / m E / dm , E / f = dm / m = d = v t
E / f = KE / f = mv^2 / 2 f = d = v t

force = (mass) x (acceleration) Force is the application of energy to an object. Energy used up, transferred or applied is called and measured a work or "work done". For the units of measurement of force:

F = (mass)(acceleration) , having units of: (kilograms)(meters/s^2) = Newtons = N
1N of constantly applied force could be thought of as that needed to accelerate 1 kilogram at 1meter per second, for each second that force is applied. If you know an objects acceleration during a certain amount of time, you can find its velocity at a certain point or instant in that time using: v = at

work = a force applied for a distance, its units of measurement are equal to that of the units of energy which is Joules (J) since this is how much total energy was used up, applied and-or transferred.

work = (force)(distance) = (mass)(acceleration)(distance) =
= (ma)(Meters) Having units of: (kilograms)(meters/s^2)(meters) =
= (kilograms)(meters^2) / (s^2) = kg (m/s)^2 = kg (v^2) joules

The rate of using energy or doing work is called power (P), and its units are watts (W):

power = **Pw = work / time = energy / time**.
For the units of power: **W = watts = joules / second**

For example, consider that a battery may have a lot of available energy that was slowly accumulated over some time value, and stored within it, and if only a small amount of it is used during each unit of time, the power value and-or energy usage rate will be a low value. For example: 5 watts means 5 watts of power used per second = 5 joules of energy used or drawn from that energy supply (ie., an electric battery) per second = 5W = 5J/s.

Due to an applied force, an object will then change speed which is called **acceleration**. (accelerate = change from one speed to another) and-or direction. If the object is caused to go faster, it has gained (**kinetic=movement**) energy which is an ability to do work such as applying a force to something else. It is possible to define energy as stored force. For example if you compress a spring with your hand, it will store the force used to compress it, and you can feel an equal and opposite (directional) force or pressure applied to your hand as the spring tries to release it's new stored and-or **potential energy** (ie., potential or ability to do work). Another example is if you stretch something elastic such as an elastic cord or rubber-band, there will be both a stretching force outward, and an compression force inward of equal value.

As another example, a rechargeable battery can be charged by the force of falling water at a distant hydroelectric generating station. The battery with stored energy is also said to have "(electric, charge) potential (potent, future ability, available to be applied) energy". Since water has a much higher density than air, moving or flowing water at the same velocity as that of air will contain or have much more moving matter, and the total kinetic energy and-or or power per second (ie. watts) will be much greater. Water is about 816 times denser than air. The density of water is typically: 1g/cm^3, and the density of air at sea-level is typically 0.001225g/cm^3. Density of water / density of air = (1g/cm^3) / (0.001225g/cm^3) =~ 816. In general, a hydro-electric generator will produce more power or electricity than a wind-generator when the velocity of the water and wind are the same. A high dam can be used so as to increase the velocity, energy and resulting force of the water striking the turbine of the electricity generator and producing a torque (rotation force) so as to rotate it and the rotor of the generator connected to it.

Force can be thought of as like a **pressure**, influence, ability, cause or driver upon something else. An object in outer-space will keep it's speed and direction if there is no forces (like a collision and-or friction with another object(s), etc.) causing it to loose, or gain (kinetic) energy and cause it to accelerate and change it's speed and-or direction. A "push" (away), or a "pull" (toward) is applying a force and in a certain direction so as to give a motion or movement to an object so as it will go (move, or to move faster) in that direction. An object can also be compressed if forces are applied to it from opposite (ie., 180°) directions, much like a clamp. An example is a compressed spring which is now storing the applied forces in the springs newly bent, twisted or tensioned atomic and-or crystalline structures, and the spring now has (stored) potential energy that can be transferred and applied as a force to something when needed.

The basic formula for force as indicated previously above, is: f=ma , and this formula is credited to **Issac Newton** at around the year 1667AD.

The units of force are the units of mass times the units of acceleration, hence (kilograms)(m/s^2) and are usually called Newtons (N). f = (m a) Newtons

A force of: 1N = $0.2248\underline{1}$ lbs =~ 0.225lbs of weight : roughly, a quarter of a pound
A force of: 1lb = 4.4482 N =~ 4.45N of force : roughly, four and a half Newtons

Also, by the original equation: acceleration = force / mass
: = "the force applied per unit of mass" : per = "for each"
and:
mass = force / acceleration

Since: force = (mass)(acceleration) = f = ma

a = f / m , If a constant force of 1N is applied to a mass of 1kg for 1 second, it will accelerate or change its velocity or speed by 1m/s^2 = 1 meter per second, per second
a = f / m = (ma) / m = 1N / m = (1kg)(m/s^2) / 1 kg = 1m/s^2

Since: force = (mass)(acceleration) = f = ma, 1kg of mass will weigh (ie. have a force): weight = f = ma = (1kg)(9.8 m/s^2) = 9.8N, or roughly 10N, on Earth where g = 9.8m/s^2. (g) on the Moon is smaller since the Moon has less mass than the Earth, and therefore it will have a less gravitational force on objects or masses. The **mass of the Moon** is about (7.35)(10^22)kg and this is about (1/8) that of the Earth, but it is also condensed into a smaller sphere or radius than the Earth, and its gravity is not actually (1/8 = 0.125) of that of the Earth, but a little higher at (1/6 = $0.166\underline{7}$). (g or gm) on the surface of the Moon (m) is about (1/6) that of the Earth (e), therefore:

(g)moon =~ ge/6 = (9.81m/s^2)/6 = 1.635m/s^2. A 1kg mass on the surface of the Moon will weigh: f=ma = (1kg)(1.635m/s^2) = 1.635N. A 1kg mass on the surface of the Earth will weight six times more at 9.8N. (g)mars = 3.72 m/s^2 which is about 37.9% as that of Earth. Lower gravity also means a lower amount of rocket engine force needed and therefore, a lower amount of rocket fuel needed to overcome the local gravity.

The weight units may commonly (though incorrectly, since weight and mass are different concepts) be given the units of mass (here, kilograms) when the weight value is understood to be a force (Newtons) or weight value. A 1kg mass may be said as weighing 1.633kg on the Moon, and as weighing 9.8kg on the Earth due to the effects of gravitational acceleration (g), and that weight, a force = f = ma = mg. Still, a force of 1N is the same on both the Earth and the Moon. Basically, weight is like an effective or enhanced force due to gravity acting upon the object or mass. A mass and its value will not change, and is "universal", and will be the same value anyplace in the universe.

Extra: M earth / M moon =~ 6 (10^24) **/** 7.35 (10^22) =~ 0.81 (10^2) =~ **81** times more, but only about 6 times more gravity than the Moon. For a general comparison, consider 1 cube, and if its sides (L,W,H) doubled (2), the cube becomes 8 times as much mass and-or volume, hence an exponential and-or cubic (here, n^3) increase when the linear dimensions increase. Given the Earth is 4 times wider than the moon, 4^3 = 64 for starters, however, the Earth also has a much larger metal core with a high mass, and hence why its actually closer to 81 times as more. Using Vsphere =~ 4.1889...(r^3), the ratio of the volume of Earth to the volume of the Moon can be shown to be about **50** times more.

A force applied to an object (mass) will continue to give it acceleration until that force is released or removed to 0 applied force. The amount of force that was applied to the object can therefore be indirectly measured by the effects of it after its application to the mass and the change in velocity or acceleration that the mass had. The measure of the force applied is directly related to both the mass and acceleration of it. f=ma. That is, acceleration of the mass is rather directly related to the force applied and indirectly related to the mass: a = f / m. It is also more difficult to accelerate (or decelerate) a larger mass, and to give it more kinetic energy. As can be seen in the formula, mass is indirectly related to acceleration and vice-versa. Given a fixed and constant value of force applied to a mass, if the mass is larger, the acceleration is then smaller.

We found that the value of acceleration is inversely related to mass, and that the smaller the mass given a certain force, the greater the acceleration of that mass due to the applied force upon it. In other words, a force will have more effect on a smaller mass. Larger masses are said to have more **inertia** or "resistance" to change in acceleration and hence more of a (natural, property of the mass alone) resistance to a change in speed (ie. motion). It could also be said that larger masses resist change in their total energy, hence it will therefore take a longer time for them to gain or loose their stored energy, and that they have a greater ability to do work as compared to smaller mass. A simple illustrative analogy example would be a large or massive volume or pot of hot water, and a small cup of hot water. The large pot of hot water has a greater heat capacity or "heat-momentum" and will take a longer time to initially gain, such as heat up, and then release its acquired energy into the surroundings and cool off. Another illustrative example of inertia would be like trying to change (increase or decrease) the same depth of water in a container with a large surface area of water as compared to that of a small container with a small surface area of water. In short, more massive or larger things have a greater capacity to store energy, but also have a greater resistance or "slowness" to a change in some value or physical property such as gaining or loosing energy, such as temperature and-or speed (ie. kinetic energy). A larger battery is said to have more "energy capacity" or power ability than a smaller battery of similar construction.

For a "thought example", consider an object traveling in a direction in space at some value of speed, and a faster moving object comes straight behind it and headed in the same direction. The faster moving object will now effectively have some resistance to its free motion in space when it collides with the slower moving object. The faster moving object will essentially cause the slower moving object to increase its speed due to the force of the collision. The faster moving object essentially transfers some if its (kinetic) energy to the slower moving object. The faster moving object will be reduced in speed and (kinetic) energy, and the slower moving object will increase in speed and (kinetic) energy. The total (kinetic) energy, before and after, of this system of two objects is still the same since energy cannot be created or destroyed, and this is a part of the "conservation of energy" concept.

Pressure is a measure of force applied to a unit of area. : It is essentially a measure of the distribution and-or concentration of force, or the force concentration in a given area.

pressure = force / area = $P = F / A$: therfore, force = F = (pressure)(area)

For force, the units for the measurement of mass are kilograms in the metric system. It is still common to hear of "pounds per square inch" (psi) in the older English system.

Ex. If a weight (F) of 100 lbs is applied to an area that is 10 square inches, the pressure applied can also be expressed as: 100lbs / 10 in^2 = 10lbs / 1 in^2 = 10 psi

An object that is sharpened to a point, such as a nail, pin, knife or needle, will have a high pressure or force per unit area available at the small tip area for the given applied (input) force value, and is then able to apply that concentrated (output) force to penetrate surfaces more easily. Essentially, all the applied input force will be concentrated at the point or tip which has a very small area.

Since Pressure = force / area, if the area decreases, the pressure or "pressure force" increases. This is a good example of an inverse physical and mathematical relationship.

Daniel Bernoulli's (1700-1782), from Switzerland, created **Bernoulli's Principle** which he formulated in 1738, and it mathematically states the pressure and speed relationships of fluids and gases, such as moving through a pipe of different diameters and-or cross-sectional area. The basics of his understanding and equation shows that there is an inverse relationship to the speed of a flowing or moving liquid and its pressure, such as within pipes of different diameter. What is happening is that as the speed increases, the effective pressure or force upon the inside surface of the pipe and within the substance itself decreases. Essentially the force or pressure is now being applied at less of an angle, or less directly (ie., perpendicularly) to the wall of the pipe and is now more directed towards the forward motion of the substance in front of it. This helps to push it and give it kinetic energy. As speed increases, more of the input energy is converted to to kinetic energy of the substance rather than static pressure (ie., substance compression or stored potential energy). For a substance to even move in a pipe, there must be a net or combined pressure difference place upon it, and it will naturally move by force to or into a region of lower pressure and at an increased velocity due to the net pressure difference upon it. If you had a tall container of water and put a small hole or tube in the bottom region of it, the pressure (when >14.7psi) in and of the water will cause a stream of water to move out of that hole and into the lower pressure region (here normal atmospheric pressure of 14.7psi). The net or effective pressure upon the water is the difference in the pressure in the water where the hole is, and the pressure of the atmosphere outside that container. Ex. pressure difference = change in pressure = = (20psi at the bottom - 14.7psi external pressure) = 5.3psi. and this amount of effective, difference and-or resulting pressure will determine the velocity of that stream of water.

As for Bernoulli's principle, this is actually the principle happening when faster moving, lower pressure air is over the top surface of an **airplane wing** (see FIG 246), and it effectively reduces the normal downward pressure or force of air on that wing surface (area). Therefore, there is effectively a higher air pressure or force on the opposite side or beneath that wing. The difference in pressure or force leaves an net upward force giving the airplane a upward or vertical "**lift**" force so that it can go higher and-or remain at some height and resist falling due to the constant force of gravity upon the airplane. If the upward "lift" force is greater than the weight (downward force due to gravity) of the plane, the plane can go higher. When the two forces are in balance, the plane will be flying in a "level" or horizontal direction. An airplane can only fly so high due to the thinning atmosphere at higher altitudes, and that there will then be only a tiny pressure difference upon both sides of the wing and only a small to no lift force possible to overcome the weight of the plane and the force of gravity. By increasing the speed of the airplane, the pressure difference on each side of the wing will increase, and even the force of the air striking the bottom wing surface can also help increase the pressure difference upon both sides of the wing so as to lift the airplane further upwards. Even if the pressure difference (Pd) between the upper and lower surface of a larger wing is the same, the effective lift force (here as F) will then be larger since from: $P = Pd = F / A$, we have: $F = Pd\ A$.

If a material can be compressed due to an applied force or pressure, its density will increase. Water, that is effectively a condensed gas due to its atomic structure of hydrogen and oxygen, is said to be nearly incompressible. Air can be compressed to a high compression ratio (pressure / volume), such as often done in a combustion engine for automobiles and other machinery. It is possible to compress air that it will become dense enough to be liquefied. An engine converts one form of energy (ex. gasoline, oil) into mechanical power such as for a car or machine, and is often called a "**motor**" which is that which provides **motional** energy, power and-or motion (ie., movement).

Momentum = **Mass x Velocity = mv** , also then: velocity = momentum / mass

Momentum is a measure of an objects ability to keep moving at the same velocity and direction, hence it is technically a vector quantity having both a magnitude and direction. It is also much **like** a measure of the total (moving or kinetic) potential energy or force available due both the object's mass and its speed. **Momentum can be thought of as a measure of an objects motion** at a given moment in time, and rather than its kinetic energy in Joules. A small particle having a low mass going at high speed can have the same value of momentum as a very large mass going at a slow speed. Also, consider that there is a law of motion stating that an object in motion will continue or keep that speed and direction until some outside force acts upon it, and this could be described as part of the concept of momentum. Momentum is rather a measure of its ability to keep its motion, and the more mass and-or velocity an object has, the more energy needed to alter its direction and-or speed, hence it has more momentum or ability to keep its motion, including if it was initially at rest where it has the same mass, but 0 velocity or speed.

If a first object with more momentum strikes a second object, it applies a force to that second object, and vice versa, since that second object is also then applying some force to that first object, and this is an example of the concept of equal and opposite forces. Some of the energy or momentum of that first object will be transferred to and gained in that second object with less momentum. Basically, what is happening is that the object with more momentum (and has more "potential influence" upon another object) is using up, loosing, transferring, or applying some of its KE energy and momentum to a second object which gains that amount of transferred energy or momentum. In particular, since when the masses remain the same, an energy or momentum increase is indicated by a velocity increase in that second object. The first objects mass will still be the same, but it will have a reduced velocity. The total sum of the KE energy or momentum of both masses will remain the same after a collision of two masses or objects.

The more the mass or "massive" an object, the more inertia (resistance to changes in velocity which is a resistance to acceleration) it will have, and therefore, the more difficult (ie., more energy needed) to change its speed (ie., motion).

One easy to understand example of momentum is when water is flowing in a pipe, and a water valve is shut quickly. Before it is shut, that flowing (moving) mass of water had speed. The water is said to have momentum (ie., a certain movement and ability to keep moving). When the valve (such as connected to a control knob to control the water flow into a sink and-or tub) is shut off quickly, the kinetic energy available or stored in the water then needs a place to go and be applied elsewhere, and the water pressure in the pipe and upon the side walls of the pipe will quickly rise, and it will cause the pipe to rattle and-or "knock" like someone hit it with a hammer and to make it move and produce quick pulse of sound. This effect is commonly known as the "water hammer".

It is said that for every force there is an equal and opposite force. The downward force of an object near the Earths surface is actually equal to the weight of the object. As the object sits on the ground or table, the object will be stationary and not moving, and this is because of the surface tension of the Earth prevents that mass from going further downward, even though the force of gravity is constantly applied to it.

A lower mass object has less inertia or resistance to an applied force, and its speed is therefore more affected by the (same) value of the force of attraction of two masses. It is simply easier to move a lesser amount mass; less force and-or energy is required. It could be said that a certain value of force applied per unit of mass is greater when the mass is less. Acceleration is mathematically equal to force per unit of mass and is therefore essentially a measure of the concentration and effectiveness of the applied force, much like how pressure is the force applied per unit area. A concentrated or more local (ie., in a close and-or small .area) force will be more effective at doing local work. The Earth with its much higher mass value will have a much greater inertia (ie., resistance to external forces, and therefore less changes in motion) value than the smaller object. The Earth will still move (ie., be attracted) toward the lower mass object, but the acceleration, change in velocity and distance will be very small and unnoticeable:

force = (mass)(acceleration) , solving for acceleration:

acceleration = force / mass : the lower the (constant) mass affected by the (constant) force, the greater its (constant) acceleration value. Higher acceleration values mean a greater achieved velocity and distance traveled during an amount of time. Mathematically, when the force is a constant value, (mass) and (acceleration) are reciprocal in value.

A momentary pulse or application of force upon an object will give it either pressure and-or a movement having a direction and velocity. If that force is constantly applied to the object it will accelerate and gain more motion or speed. When an objects speed is increased, its distance covered per unit of time will increase: An objects current speed is directly related to current and all other past accelerations due to applied forces, and distance = (speed of travel or motion) (time of travel or motion) = st = vt.

The equation for force = ma , is very similar to that of momentum = mv . A mass with a higher velocity has the capability of applying a higher force. Now consider two masses traveling in the same direction at the same high velocity, and it will still take a change in velocity (ie., an acceleration) for one of the masses to apply even a small force to the other mass and their same velocity (slow or fast) is irrelevant to the amount of force applied due to their "relative motion", therefore force is rather related to acceleration (or deceleration), rather than velocity. Something that accelerates quickly to a speed is initially due to a high force causing a high acceleration. If the speed of an object decreases quickly, such as when it hits the ground, it has a high value of deceleration, and this is due to an equal and opposite force of the Earth upon it. Earth, an object having a high mass and therefore momentum and then being more difficult or resistance to change. If the Earth was able to move due to the impact, some of the kinetic energy of the object would be transferred to Earths kinetic energy or movement or velocity and the dent of the impact would not be as much, indicating that the force of the impact was less and the deceleration was less.

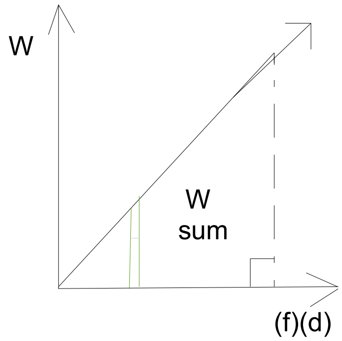
Kinetic Energy = (KE) = $\frac{mv^2}{2}$: Kinetic energy is the (potential) energy an object (mass) has due to its amount of mass and its motion. If the speed (velocity) is doubled, KE increases by a factor of 4. This also means that the input energy must also increase by 4 so as to double the speed.

m = mass of the object, with units of kilograms, v = velocity of the object, with units of $(M/s)^2$ = (meters per second) squared. The units for energy, such as kinetic energy, is joules (J):

1J = 1Nm = newton-meters = (force)(distance) = (ma)(distance) = work = energy

Friction and-or collisions with other objects will cause an object to waste, transfer or loose some of its kinetic energy. It will slow down unless more force is applied to it. Since it will take energy to apply a force, force can be described as the application of energy.

Here is a verification to the kinetic energy formula shown above: [FIG 226]



Work = (force)(distance). A small bit of work is done when there is a small bit of distance the force was applied. The (infinite) sum of all these small bits, slices or rectangles = (force)(very small change in distance) of work equals the total work done, and that can be visualized by the area beneath the curve above, and clearly it is equal to the area of a right triangle having sides of (f) and (d). One theoretical slice or rectangle is shown between the green colored lines. Though this rectangle is slightly longer on one side, when the rectangles gets very small due to the change in distance being very small, this difference also gets very small and negligible or insignificant to the (much larger) total sum.

$$\text{Area} = W = \mathbf{KE} = \frac{(f)(d)}{2} = \frac{(ma)(vt)}{2} = \frac{\left(m\frac{v}{t}\right)(v\,t)}{(2/1)} = \mathbf{\frac{mv^2}{2}}\ \textbf{Joules}$$

If the velocity of an object increases by a factor of (n), its KE increases by a factor of n^2:

$$\frac{m(nv)^2}{2} = \frac{mn^2v^2}{2} = n^2\,\frac{mv^2}{2} = n^2\,(KE)$$

This also indicates that for example, to increase velocity by (n) will require (n^2) times more input energy. For example, to double (2) the speed of an object will require 4 times the input energy. In space, with no friction losses, once a desired speed or velocity has been reached, the energy applied to create a thrust force upon the object is no longer needed, and the object will continue to travel at that faster speed. The object will also have 4 times the kinetic energy as it did previously. To slow the speed of an object will require a force in the opposite direction to its forward travel. A force in the opposite direction will reduce its velocity and available kinetic energy. The object will decelerate (a negative acceleration) as long as the force is applied. The energy and-or force required to stop a slower moving object having less kinetic energy will become lower.

current = **voltage / resistance** Therefore: resistance = voltage / current and voltage = (current) x (resistance) This is commonly known as **Ohm's Law** for electricity since he recognized and then formulated these physical and mathematical relationships into this simple, but very useful formula used in the study and measurement of electricity.

In honor of George Ohm, an **ohm** is the basic unit of resistance. **Resistance** is any device (such as a resistor) or material that will resist (impede, interfere) and therefore reduce the total flow and-or amount of current. Current is a description of "flowing" or moving electrons (microscopic, particles of an atom) of which have momentum, and therefore energy to do work. Electrons have a very tiny mass and their motion and-or direction will be influence by an (attractive or repulsive, polarity) electric field (ie., an electric or "electromotive" force (emf) field, or field of force) which induces (causes, applies) a force upon them, and they will gain momentum. This is very similar to how a magnet with its magnetic field can influence, force and move iron particles that are within that magnetic field (of influence).

A resistor that reduces current flow from within it (which also affects the current flow of the entire circuit or wires to and from that resistor)can basically be thought of as blocking some of that current from passing through it by reducing or removing the momentum and energy of some of the electrons. This can be simply considered as removing some of the energy and-or power of the current. An analogy to this would be like a valve (flow restrictor or adjuster) or some blockage being in a pipe (directs and allows the transfer or conducts the flow of the water fluid) which then reduces the flow and amount of that water to and from that location.

When a resistor removes some of the energy from the flowing electrons, there will be an associated power loss, wasted and-or unavailable energy and-or power to the rest of the circuit. Usually, the energy removed from the current is transformed or converted to thermal or heat energy. Resistors can get quite hot an they need to be designed large enough to withstand that amount of (thermal) energy or power they gained and without being damaged (ie., melted, fire). Resistors are also often designed so as to radiate their heat (thermal energy) into the surrounding air so as that resistor will reduce and-or maintain its temperature to a safe level.

In general, elements that have a lower resistance, due to having more "free", movable, less bound electrons, have both higher electrical (electron) conductivity and higher thermal (heat) transfer or conduction ability. Solid metals such as silver, gold and copper have high electrical and thermal (heat) conductivity as compared or in reference to most other metals. **Graphite** which is a specific form of carbon, and having 1 unbound, relatively free and-or easy move (via an electrical force and-or energy) electron in its crystal structure, and therefore it has good electrical and thermal conduction ability. Diamonds are another form of (crystallized, dense) carbon, are poor conductors of electricity since the crystal structure does not have any free electrons, but are one of the best thermal (heat, energy) conductors.

Aluminum is a good conductor of both electric and heat energy, and is much more economical as compared to the better ability of silver. Although several time more expensive than aluminum, copper with its lower resistance value per foot and-or cross-sectional area, is perhaps the most commonly used metals for conducting electricity (ie., transferring power using electricity (ie. electrons transferring electric power)) and for creating magnetic fields in the wire coils of electric motors, and which the magnetic force is then used to give a (kinetic energy) movement or motion to the rotor (rotating) part of that motor and something such as an electric fan or wheels that are connected to it.

The units of current (the flow of electric charges or particles, such as electrons of atoms which have gained some kinetic energy, such as from a battery, to move and do work) are Coulombs of charge per second or= **Amperes** (A or sometimes (a)). A **Coulomb (C)** of charge (ex. electrons) is a specific amount **(6.28 x 10^18) of charged particles** such as electrons. An amount of 1 Coulomb of charge flowing (like a current) or passing by a point in 1 second is called an (1) ampere in honor of **Andre Ampere** ("amp" = A) who made significant advances in the study of electricity, specifically electro-magnetism, and charge movement or flow. Ampere also invented the (electric to magnetic, or "electromagnetic" movement which is essentially a type of [non-360 degree rotating] electric motor or movement) ammeter (or "amp meter") to measure the amount of current flowing through a wire. This device with its internal coil of wire has similar properties to the later developed (current-to-magnetic [electro-magnetic] movement) device called a loudspeaker which transforms or converts electrical signals or pulses into mechanical audio signals or pulses.

Electro-magnetism , (1820)

Hans Oersted (1777-1851), from Denmark, is credited to initially discovering electromagnetism in 1820 when he noticed a wire with electricity going through it would cause a (magnetic, directional) compass to change its direction away from the magnetic north direction of the Earth. This indicated that electricity in the wire was causing some magnetism in the wire. By using a compass about the wire, it can be deduced by observation that the magnetic field is circular about the wire.

In simple terms, magnetism and-or a magnetic field of a magnet is much like a gravitational field, but a magnetic field is much stronger locally within a relatively short distance, and that a magnetic field has two poles like an electric field, and can be thought of as a starting pole and a ending pole for the (imaginary) lines of force. Studies of the atoms of a magnet have shown that a directional alignment of atoms and their electrons spinning about the nucleus will create a net magnetic field in that direction. Due to the unpaired and-or unbounded valence electrons with the neighboring atoms in the crystal structure of **iron**, iron is well suited for both being a magnet and-or influenced by magnet.

A **permanent magnet** requires no electricity to create a magnetic field. When a piece of iron was made to be hot and in an external magnetic field, and then cooled, the alignment of atoms and their electrons remained fixed or permanent. Passing current through a wire will cause the electrons to be aligned and flowing in the same direction, and this will cause a net magnetic field, and here which is at a right angle to the electric field created by the flowing electrons. A magnet has a **north magnetic pole** and a **south magnetic pole**, and the magnetic forces at those poles will attract the magnetic poles of opposite polarity, and repel the same polarity. A magnet will also attract ferrous (having iron metal) materials in it by inducing that material to become magnetized and then having magnetic poles.

The electro-magnet , (1830)

In 1830, **Johann Schweigger** (1779-1857), from Germany, found that if the wire was placed into a coil shape, that the magnetic field created when a voltage (and resulting current) was applied would be concentrated, and therefore stronger. A device he made is an (electric) galvanometer, but unlike just sensing static electric charges and-or fields, his device could measure the flow of charges or electric current. An electro-magnet is sometimes called a **solenoid**, especially when it is used to cause a movement of a nearby piece of metal.

Magnetic induction or the creation of electricity by using a magnet and wire , (1830) , the creation or generation of electricity without a voltaic battery.

In 1830**, Michael Faraday** discovered magneto-electricity, whereas a magnet **(**either a non-electric permanent-magnet or an electro-magnet made from a coil of wire with a electric current [flow of electric charge going through it]) can induce a voltage and current in a nearby wire and especially a coil of wire where the effect is essentially larger (ie., more produced, generated or induced voltage and-or current) and more noticeable and practical. This effect only occurred when there was a relative motion between the magnet and-or coil of wire. More technically, it is rather a changing magnetic field strength, and which can be due to the relative motion and-or position (ie., distance to or from) between the wire and the magnet. If the relative motion stops, the magnetic field strength is a constant value at the wire, this field is not then changing position so as to not apply a force to the electrons and give them some kinetic energy to move or flow, and the induce current will likewise stop.

In 1821, Faraday invented a primitive device that created a consistent and circular motion due to the applied electricity, hence he created a **primitive type of electric motor**, and it inspired others to experiment with electricity and-or to create motors.

Ampere soon took great interest in Oersted's discovery of electric current creating a magnetic field in a wire, and basically he noticed that the larger the battery voltage, the greater the magnetic field produced, and this indicates that the amount (ie., current value) of electricity in the wire was now larger. Surely more electricity (ie., modernly called current or current flow) in a wire would also make the wire a higher temperature and we know this today as due to the resistance in the wire and causing a power loss in it, and we know this modernly that the kinetic energy of the electrons is converted to heat energy in a resistance (analogous to "electric friction") to the flow of current or electrons.

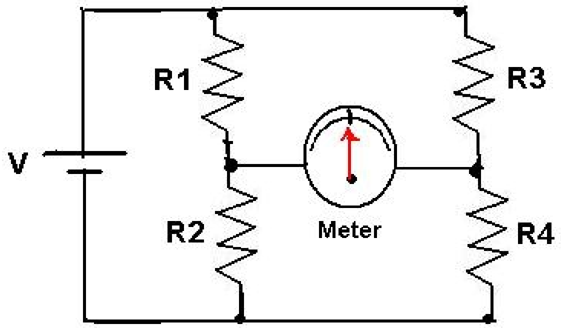
Oersted's Law is that electricity will cause a magnetic field around a wire, and this is electro-magnetism. **Faradays' Law** of electro-magnetic (or more correctly "magneto-electricity") induction is essentially the inverse of Oersted's Law.

In, 1827, **George Ohm** (1789-1854), from Germany, expressed the mathematical relationships of the electrical and-or physical relationships between voltage (V), current (A or I), and resistance (R), and created his famous equation for electricity called **Ohm's Law**, and which is presented in this book. This law relates how those variables and values affect each other, and it can be used to solve for an unknown value when given the two other values.

In 1834 **Heinrich Lenz** (1804 - 1865), from Russia , noticed that the current induced in a wire by a (changing in strength) magnetic field will flow in a direction so as to create a magnetic field of opposite polarity and-or direction, and this will then affect, oppose and-or or repel that which caused it, therefore also including motion. This is called **Lenz's Law**.

Charles Wheatstone is given most of the credit to an electric circuit for a device that can measure resistances, however an ammeter can also be used to determine a resistance when considering Ohm's Law and using: R = V / I . The circuit is called a **Wheatstone Bridge circuit** in 1843**.** See the figure below. This circuit was first initially invented by **Samuel Christie** in 1833, and it is essentially two voltage dividors (R1 and R2, R3 and R4) circuits in parallel with (R1/R2) = (R3/R4) equal in value when (voltage) "balanced" (ie., no voltage difference and-or remaining voltage potential), and with one resistor replaced with a sensor or to be inparallel to one. Any resistance "unbalance" will cause a voltage unbalance or difference and a current to then flow through the central bridge between these two voltage dividors. This current can be measured or put through a resistor and sensed as a voltage. It was also useful for telegraph communication such as for using uncoded (non-Morse coded with "dot" and "dash" signals) letter signals to be indicated on a (letter) pointer (or indicator needle) and readout display (visual) system. The basic circuit bridge circuit to measure a resistance did it by balancing the galvanometer readout pointer by using a resistance with an equivalent and known value also placed into the circuit. The equivalent and known resistance may also be a variable resistor (or "rheostat" [adjustable and-or stationary]) or resistance that is generally given credit to **Moritz Jacobi** (1801-1874) from Russo-Germany (Prussia) and who also invented **one of the first useful (electro-magnetic) electric motors** in 1834. If a third terminal is used between the end terminals of a variable resistor, it is called a **potentiometer** (ie. adjustable the voltage potential, or voltage adjustment device) or (variable) voltage divider that divides a voltage into two (same or different) values, and of which either or both can be used for some purpose. [FIG 226B]

A basic, Wheatstone Bridge Circuit.



A diode bridge circuit is similar in construction, however its function is very different than a difference meter. Both circuits mentioned are often drawn as a diamond shaped construction where the two upper circuit elements, here R1 and R3, are shown as connected to a common point, and R2 and R4 are shown as connected to a common point. The meter's pointer or indicator in the figure is showing it is centered or "balanced", hence there is no current flowing through it in either direction, and-or no voltage difference.

The units for voltage (ie., emf = electromotive force) are called volts (v). Electromotive force (such as for repulsion or attraction of charges [charge particles, usually electrons]) or "electric pressure" is what will cause charges to move from their position and "flow" as an electric flow or current. When two objects are charged (have an unbalance of charges on and-or in them, that is, having an excess of either a positive or negative charge) to opposite electric or charge polarity (a concept much like the two opposite polarities of magnets, and which attract or repel other magnets) they will attract or repel each other due to the static (stationary, unmoving, accumulated electromotive) charges and their corresponding forces. Electrons are considered as having a negative charge and surrounding electric field around them. Protons are considered as having a positive charge and surrounding electric field around them. These fields are naturally greater in strength at closer or shorter distances to those particles. Electrons and protons will attract each other. Objects with a net negative charge and objects with a net positive charge will attract each other. Objects having the same electric or charge polarity will repel each other.

The strength of an electric (force, or force inducing) field is called its electric field strength, and it varies in value depending on how much charge (Q) there is and how far (r) from the source it is measured. The basic formula for this is: **E = Q / r^2**. Electric field strength (E) at a certain point or location in it can be measured as, or by the (attractive or repulsive) force upon an electrically charged particle at that point or location in that field. Here are some related equations, and the reader may skip over them, and review them when ready and-or needed:

$$E = \text{Electric field strength} = \frac{\text{force}}{\text{charge}} = \frac{F}{Q}\text{ , with units of: }\frac{\text{Newtons}}{\text{Coulomb}} = \frac{N}{C}$$

Mathematically: F = EQ : note, the amount of charge of a single electron is:

(1.602564)(10^-19)C , since 1electron =
1 particles and charge out of
(6.24)(10^18) particles and charges = 1C

1 charge / 1C = 1 / (6.24)(10^18 charges =

1 charge = 1 electron / (6.24)(10^18) charges =
1 charge = charge on 1 electron = 1.602564 (10^-19) C

Or in brief: 1C of charged particles or electrons = (6.24)(10^18) charges or electrons, and if each side is divided by the factor of (6.24)(10^18), we find the charge of 1 single single electron to be: 1.602564 (10^-19) C

Since force is the application of energy upon something else, work is essentially a measure of using or applying energy for a physical distance or length, Therefore, work can also be measured with the same units used for energy, and those are in Joules. Note that since energy from a source is needed to do something, after that energy is used up with its application or doing work, that amount of energy has been removed from the source and-or system and transferred elsewhere during the work.

W = Work = (force)(distance) = Fn Dm , with units of Newtons-Meters = Joules

Mathematically: F = EQ and W = (EQ) Dm = FnDm and E

For negative charged particle such as an electron, the **electric field lines** are said to go **inward** to it from an external positive charge particle and-or quantity of where its field extends **outward** from it, and no matter how distance and weak its field is, it will have some influence upon another charged particle. Consider that very distant objects such as planets still have a weak influence of gravity upon each other, and this can be observed over a long duration of time and observations and noticing a slight change in a planets expected orbit.

Voltage (V) is technically defined as equal to the amount of work or energy required to move or force charge across or between two points. Since work is essentially equal to an amount of energy, voltage is also an amount of energy and is often called as "voltage-potential energy" or simply a voltage potential (ie., ability to move current so as to transfer energy (via electrons) and apply power or work). A higher voltage has a greater ability or potential to induce and move electric current. Consider this form of Ohm's Law where: (current) = (voltage / resistance) = (I) = V / R. Current is directly related to the voltage inducing, forcing or generating it. If the voltage increases by a factor of (n), current will increase by the same factor of (n).

Work is a measure of using or applying a constant force (= mass x acceleration) through a distance, and it could be said as being how much total energy was required and used, and the units of work therefore contain the same units for energy, which are Joules.

Voltage = Work / Charge or = Joules / Coulomb : "energy per coulomb of charge"
V = J / C

From the above equations, we can mathematically express an electric field strength using voltage and the distance between two points in an electric field (E):

V = J / C = W / Q = FD / Q = (EQ) D / Q = ED mathematically:

E = Electric field strength = Fn / Qc = Vv / Dm = , "volts per meter" , and:
E = FnD^2 / Q , and:

W = work = Fn Dm = Vv Qc = energy needed to do that work, and or transferred

Considering Ohm's Law: I = V / R, a voltage of 1 volt will cause (force and move) a current of 1 Amp (=1 Coulomb of charge per second) through a 1ohm resistance or resistor. If this resistance is halved to a lower value of 0.5 ohms, the same voltage can then force a greater current of: I = V / R = 1.0v / 0.5ohms = 2 amps through it. If a resistance was doubled, it will take twice the amount of voltage to force the same amount of current (here, 1 Amp) through it. 2v / 2 ohms = 1A.

Vvolts = Iamps x Rohms = V = I x R : typical expression for Ohm's (Electrical) Law

Ex. A resistor of 100 ohms has a voltage of 10 volts applied across it, calculate the amt. of current flowing through that resistor: I = V / R = 10v / 100ohms = 0.010A = 10mA

Today, there are some digital multi-meters (DMM) available that are inexpensive, and are very useful measuring and test tools for electricity and electronics. In particular, they can measure voltages (V volts), current (A amps), and resistance (R ohms). Values that can't be directly measured can be calculated from the other two known values using Ohm's Law: I = V / R or V = IR or R = V / I

CAUTION: Electric power can cause fires, damage and-or injuries to people. Consider necessary safety precautions. For example, when working with electric devices, first unplug them from their power supply, household outlet and-or remove the battery or other power sources for that device. Be cautious around capacitors that may still contain a static charge and its potential energy, and therefore, electric power which can shock you, and-or cause a fire if the charages in the capacitor drain rapidly due to a low resistance across its leads or wires.

Power = a measure of the amount of energy being generated, delivered and-or used over a time period, hence it is the rate of using energy (Joules) during a time period, and is essentially calculated like an average value:,

Power = energy / time : with units called watts : energy or= work has units of joules
Ex: Joules per second = Joules / second = watts, : **watts** is a derived unit composed of two other units since it is a rate. Also Joules = (Watts)(Time) = Ws

In terms of electricity: **Pwatts = Pw = V x I** : the derivation of this equation will be shown ahead in the book
Pw = (V) (I) = (J/C) (C/s) = (Joules/Coulomb)(Coulombs/seconds) = J / s

Even though a power value may be relatively a low value or rate, energy can also be accumulated over time, and a common example is charging a battery to store electric charges. Once a battery is charged it can deliver a high level of power for relatively brief periods of time as compared to the time needed to charge that battery, and then battery must be recharged before further use of it. This is typically what happens with many solar-power energy systems, and then the collected, accumulated and stored energy can be used to power some high power tools and other devices if needed. Any excess energy generated by the solar panels of a solar-power energy system would also be lost is not used and-or saved, such as in a battery.

1 horsepower = 1hp is defined as nearly 746 watts = ((550 (ft)(lbs) of force) / second, 1Kw = 1000w = 1.34hp
Ex. If an engine is said as having a 1hp output and can turn a generator that is 90% efficient at producing electricity, then it is capable of generating (1hp)(0.90) = (746w)(0.90) = 671.4w

James Watt (1736-1819), from the United Kingdom (UK, England, Great Britain) calculated the amount of work, and the equivalent energy needed and done by the average working horse. The (hp) was commonly used as a unit of power that is used for comparison of the power ability of various machines that eventually replaced horse and water-wheel power. The most common unit of power as of the year 2020 is called the **watt**. James Watt also invented an improved version of the steam (hot, pressurized water gas) engine in 1876 which helped the industrial (ie.,manufacturing) revolution which reduced time and costs, and improved the availability of many things till this day although most steam engines have now been replaced by high power electric motors. Watt's steam engine considered the previous steam and (first practical) piston (a cylinder with a disk in it which pressure can move that disk and then the connected rods attached to it) engine developed in 1712 by **Thomas Newcomen** (1664-1729), from England. Newcomen based his design on the first practical steam pump (engine) which was made by **Thomas Savery** (1650-1715), from England, in 1698 which was made to pump water upward from flooding mines. Newcomen's use of a piston powered by steam is based on the study and ideas of **Denis Papin** (1647-1713), from France, in 1690. Papin invented the first type of pressure cooker called a "Steam Digester" in 1679 and which was a heated container that had a high pressure release valve to prevent a very internal high pressure from damaging the container. This valve had a piston and (tub)e cylinder design. Due to the internal pressure increasing due to the steam having a high kinetic energy, the boiling point of the liquid, such as water, increases, and this super-heated liquid and steam holds a much greater thermal and kinetic energy, and which softens and-or breaks down the substances put in the container. Papin knew **Christiaan Huygen**s and **Robert Boyle** and some other scientists, and after contemplating about his vibrating piston, he came up with the possibility of a steam powered engine which utilized a piston held in position by a force (here a weight) which could be set as needed. He also invented the first leg powered paddle-wheel boat, and this has a type of mechanical propeller (transfers input force and-or power to the water, and which then due to an equal and opposite force, the water pushes and-or propels [e. moves, causes motion] the boat in the opposite direction - here forward.. The input power, the propulsion system for this boat to travel was human leg power, although the concept of the paddle wheel was known and used since antiquity. A paddle is basically a flat wooden or metal board attached to a larger wheel consisting of several paddles about it, and which the wheel will rotate due to the input power, A paddle can be thought of as the flat end of an oar. Papin's ideas were significant steps for further advances in many fields of study including steam powered machinery, the paddle-wheel steamboat and eventually the internal combustion engine.

The density of water at just below boiling temperature; 100°C = 212°F, is about 0.96 g/cm^3. The density of steam at just above boiling temperature is much less dense at about 0.0006 g/cm3, and it is a highly kinetic or energized gas. If 1 gram of water (which has the dimensions of 1cm^3) was converted to steam, it would theoretically occupy a space or volume that is about (0.96 g/cm) / (0.0006 g/cm) = 1600 times greater than 1 cm^3.
1600 cm^3 = a volume of 1.6 Liters

The most commonly known seam engine are those used for steam powered trains ("locomotives"), and some electric power generators. The basics of operation is that liquid water is heated to its gaseous steam phase, and which is then placed into a cylinder (tube shape) so as to force a piston away from it, and of which is attached to a rod and other mechanical parts ("linkages") so as to transfer power to the train wheels or generator. This steam, still at a reasonably high kinetic energy and pressure, will then be put into a large tank to cool off and reduce in pressure, and of which creates a vacuum which restores the piston to its original position. The water is recycled for use. Several one-way (ie., one direction flow) valves are also used to facilitate this process which is not unlike a modern combustion engine.

1 foot-pound = 1 ft.lb = the energy needed to move a weight or apply a force of 1 pound through a distance of 1 foot. **1ft.lb = about 1.35582 joules of energy and-or work**. 1ft.lb / 1s or = 1lb ft / 1s = about 1.35582 watts This concept and unit is of a general form of:
Energy = Work = (force) (distance) = (distance) (force) here, but see the torque units here:

For torque, 1 pound-foot = 1lb.ft = about 1.3558 Nm , Nm = Newton meters , hence the units of a force value . This is a pound of force applied at a (perpendicular) distance of 1 foot from the pivot, axis, center or turning point, and is essentially the length of the radius and-or lever-arm where the force was applied at.

Ex. For tightening or un-tightening bolts to a certain recommended and safe value.

As mentioned above, Pw = (V)(I), and here are some other mathematical equivalences based on Ohm's law: :

Pw = V x Ia = (I x R) x I = I^2 R = V x (V/R) = V^2 / R

Ex. 0.5 amps of current is flowing through a 100 ohm resistor: Pw = (0.5^2)(100) = 25w

Ex. If a 100 ohm resistor has a maximum power rating of 1W, what is the maximum continuous (ie. dc = direct current) current that can be allowed to flow through it when the resistor is being electrically (electronically) operated at it's maximum power handling rating?

From: Pw = I^2 R , Ia = sqrt (Pw/ Ro) = sqrt (1 / 100) = sqrt (0.01) = 0.1A
And:

If this amt. of current was flowing through that resistor, the voltage applied across it would be: Vr = Ir Rr = 0.1a x 100ohms = 10 volts, but this is not necessarily the maximum voltage that can be across it, for higher voltages can be across that resistor if less current passes through it so as the actual power applied to that resistor can still be equal to or less than the maximum power rating of that resistor.
And:

$$\mathbf{Pw} = \frac{\text{energy}}{\text{time}} = \frac{J}{s} = \left(\frac{J}{s}\right)\left(\frac{Qc}{Qc}\right) = \left(\frac{J}{Qc}\right)\left(\frac{Qc}{s}\right) = \mathbf{V\ I\ \ watts}\quad , \quad \mathbf{Energy = Work = Joules = (Pw)\ (time)}$$

$$Pw = \frac{\text{energy}}{\text{time}} = \frac{J}{s} = \frac{\text{work}}{s} = \frac{\text{(force)(distance)}}{s} = \frac{\text{(mass)(acceleration)(distance)}}{s} = \frac{Nm}{s}\ \text{, therefore:}$$

J = Nm = (Newtons)(meters) or= Newton-meters

Since P = (voltage)(current) , if given a certain amount of power, and if the current is reduced to a very small value, the total (kinetic, motion) energy and power delivered by those charges would correspondingly be a very small value. If the voltage (ie., emf = electromotive force) applied to that smaller charge is increased, such as by the same factor that the current was decreased, then the same amount of power could then be delivered. Consider this numeric verification example :
Pw = 120w = J/s = (voltage)(current) = (120v)(1A) = (120v)(n) (1A / n) = (120,000V)(0.001A) :n=1000

Ex. A certain battery having a voltage of 3v is powering a 3v white light LED which is drawing a current load of 25mA. How many joules of energy is it using each second, and-or draining from the battery each second? How many watts of power is it using each second?

From: V = Je / Qc , we have: J = V Qc , From A = Qc / s , we have: Qc = A s , and therefore:

J = V A s , = (3v)(0.025A)(1s) = **0.075 J** : this is the energy used or drained for each second of time.

P = J / s = 0.075 J / 1s = **0.075W** = V A = (3v)(0.025A) , and the amount of energy used for (1 hour = 3600s) is therefore 3600 times more:

J = V A s = (Pw)(s) = (3v)(0.025A)(3600s) = 270 J = 270 W-s (ie., watt-seconds)

Extra: Since 1 hour = 3600s , 1s = 1h / 3600 = 0.000277$\underline{8}$ h
270 W-s = 270 (0.002778 h) = 0.075 wH (ie., watt-hours)

Summarizing the above equations in the above example and-or to consider so as to solve for a variable:

V = Je / Qc : voltage

E = J = VQ = V A s = P s = P t : energy

A = Qc / s , Q = As : current

Pw = V I = E / s = J / s : power

s = Qc / A = (total charge) / (time rate of using or draining that charge) : time
s = J / P = Ej / Pw = (energy) / (time rate of using or draining that energy) : time

1J = 1W-s , 1 Wh = (1W-s)(1h) = (1W-s)(3600) = 3600W-s = 3600 J : total sum of energy used during a period of time.

A Reminder: A common rotating electricity generator converts mechanical input energy and-or power to electrical output energy and-or power, and a motor is the opposite of this. A solar cell converts light energy into electrical energy. An LED converts electrical energy into light energy.

MASS AND WEIGHT HAVE DIFFERENT MEANINGS, BUT ARE DIRECTLY RELATED

Mass is the physical amount of matter (the real, solid material, and not having any extra or empty space other than that between atomic particles), such as the quantity of atoms and other particles of a given substance such as a certain elemental metal (gold, iron, etc) or object, and weight (of a mass) is the force that a mass under the influence of gravity (a constant force, and which will cause a constant acceleration) will exert upon or apply to an object beneath it or holding it up, including a scale. **Mass and weight are directly related and-or mathematically, directly related and proportional in value, and so if one changes by a factor of (n), the other will change by that same factor of (n).**

This weight (force) of a mass will depend upon the specific force of gravity (ie., an attracting force) or other forces acting upon that mass. The force of gravity varies among planets, moons, etc., due to that they have different total amounts of mass which determines their effective (average) or apparent gravity to attract other masses. The more mass an object has, the more gravity it creates around itself. On Earth, the constantly applied force of gravity upon or influencing any basic mass or object that is at low altitudes near the surface of the Earth, will cause it to accelerate at about 9.81m/s^2 =~ 32.17ft/s^2 = (g) towards the center of the Earth. (g) was previously mentioned in this book, and it is a value of acceleration induced by the force of gravity, and is therefore commonly known as the gravitational acceleration (constant for Earth). Force = weight = mass x acceleration.

A weight measuring scale constantly showing the objects weight is a verification that weight (a measure of the total effective force) and acceleration, due to that constantly applied force, does not cease even when the object is at rest, such as it resting (not apparently moving) on the scale measuring its weight, and that gravity (a force which causes acceleration when constantly applied) is still being applied to objects even at rest on the surface of the Earth.

Objects at rest on the surface of the Earth do not move and have any further downward motion toward the center of the Earth because of the equivalent supporting upward force and surface tension (a force) of the Earth's surface, or a supporting table (of which is also an object at rest on the Earth's surface). The result is that the (mathematically positive and negative signed) directional forces balance or cancel each other out, resulting in 0 total or net force applied to the object and it remains motionless, but still, that does not actually stop the constant force of gravity from constantly being applied to the object and having a weight.

Even as you lay, sit or stand still, you can still feel or react to the (downward) force of gravity being applied to you. From force = (mass)(acceleration), a 1kg of mass (matter, material, substance only) will weigh (1kg)(9.8m/s^2) = 9.8 Newtons as a measure of force. From the force formula, mass and weight (a force) are numerically proportional, so for example, if mass doubles, the weight of it will also double, and in general it will increase or decrease by the same factor, and this is necessary to create equivalent valued fractions or portions (ie., ratios) having the same value. The constant of proportionality or ratio of weight and mass is (g):

$$\text{Weight} = F = (\text{mass})(\text{acceleration}) = ma = mg \quad , \quad \text{therefore:} \quad \frac{\text{Weight}}{\text{mass}} = g = a$$

Note that the air pressure (typically 14.7psi at Earth's surface), much like a low density fluid, is not considered since it is applied to all sides of the scale and-or object, and hence does not have a net downward weight.

IMPORTANT: Most scales are actually (and perhaps unknowingly) calibrated to measure mass rather than the weight of that mass. The scale essentially divides the weight in Newtons (N) by the gravitational acceleration constant and displays the result value which is the mass of the object and not its weight. People will usually call this the weight value, but it is technically incorrect. It is better to display mass since it is a universal or constant value associated with the constant amount of matter, whereas weight depends on local force of gravity, such as the gravity value of a planet such as Earth. This constantly applied force of gravity will cause an object to accelerate, therefore giving it energy which can be used to apply a force such as its weight. Weight = F = ma.

weight = force = (mass)(acceleration) : the units of force are Newtons (N) and Units of mass is Kg, and units of acceleration is m/s^2

Many formulas use the mass value of an object rather than its weight value. If given an objects weight value, to convert it to its corresponding mass value, then divide it by the force of gravity (g) = 9.81m/s^2 = 32.2ft/s^2 since from F = weight = ma = mg , mass = weight / g :

mass = weight / acceleration = N / g : the common units of mass is the kilogram (kg)
N is Newtons, the units for forces.
g is Earths gravitational acceleration constant of ~= 9.8 m/s^2

Since 1 gram = 0.001Kg = 1(10^-3)Kg , the weight of 1 gram of matter is:

weight = force = (mass)(acceleration) = (0.001Kg)(9.81m/s^2) = **0.00981N** : **weight of a gram of mass**

Most common scales will not display 0.00981N for when a mass of 1g is placed upon it, but the scale is calibrated to display the corresponding mass value of that weight sensed or influencing the scale. The scale will display 1g. This weight scale therefore is a mass scale. Since a kilogram is 1000 times more mass than 1 gram, its weight will correspondingly be 1000 times more than the weight of 1 gram:

weight of a Kg of mass = (weight of 1 gram)(1000) = (0.00981N)(1000) = **9.81N** : **weight of a Kg**

Density = Mass / Volume : Density is a measure of the amount of mass or substance (material such as the atoms, or atomic particles) per, or in a, three dimensional area of space or volume. Density can also be thought of a s the concentration or amount of matter within a given volume or space. A denser substance can be said as being more concentrated.

The units of mass are grams. If the units of volume are cubic centimeters, as commonly used in density tables. The units of density are derived units composed of the units for mass and volume, and for here, they are: (g/cm^3) = "grams per cubic centimeter".

If the mass of an object is unknown, it can be found from the objects weight since:
weight = force = (mass)(acceleration) = ma = mg ,
and m = mass = weight / g = (weight kg) / (9.8 m/s^2)
Most common "weight scales" display the equivalent mass of that weight, such as grams (g).

The amount of material or substance of water in 1cc volume is defined as the reference and unit mass of 1 gram.

1 gram of mass of water per 1 cubic centimeter (cc = cm^3) volume (space) is defined as has a density of 1g/cc = 1g/1mL at 4°C. This is also the max. density of water. This is the common reference (of measurement) and or unit of mass (ie.,the mass unit) when it comes to comparing densities of other elements and materials.

1 gram of water is also indicated as 1 gram of weight on most scales of which are calibrated so as actually express or display its corresponding mass values. This value is then more correctly called a "gram-weight" or "mass-weight" value. The weight or force of 1 gram of mass is called 1 gram-weight or 1 gram-weight unit, and commonly (and incorrectly) as 1 gram of weight. The readier is reminded that the units of mass are grams, and the units of weight or force are Newtons, therefore, the mass and weight of something are two different concepts and quantities.

An element that is twice as dense as another will have twice the mass or atomic substance per 1cc of volume of it, and therefore it will weigh twice as much.

A less dense liquid or liquefied material will float upon a more dense liquid or melt such as a hot molten (liquefied) metal that sinks lower due to its increased density, weight and therefore pressure upon any material below it.

An object made of a denser element, but still having the same weight as an object made of an element not as dense, will have (or "occupy", "take up", "fill") a volume that is less. For example, one ounce of gold will have a smaller volume than an ounce of aluminum, and this is because gold has a higher density or amount of material (atoms) per unit of volume than that of aluminum.

From: density = p = mass / volume = m / V , mathematically: **m = pV**

Force = F = ma = pVa , if the acceleration is Earth's gravity acceleration = (g) =9.81m/s^2 :

F = ma = Weight = pVg = (density of the substance) (Volume of the substance) (g) = **PA**

Weight = F = ma = (mass)(acceleration) Newtons , mathematically:

mass = F / a = Weight / a

ex: mass = 10N / g = 10N / (9.81 m/s^2) = (10 kg-m/s^2) / (9.81 m/s^2) =
= 10 (1000g) / (9.81) = 10000g / (9.81) = 1019.3$\underline{7}$g = 1.01937 kg

$$\mathbf{p = \frac{mass}{V} = \frac{Weight}{g\,V}}$$

: if something weighs more per unit, or the same volume, it has more mass and has a higher density (p). , (g) is a constant. Volume, if unknown, can be measured, and one way is to immerse the object into water and measure the amount or volume of water that it displaces. To see the largest change in the level of water, you can use a container that has a smaller cross sectional area. To calculate volume if the object has one material or element and is a solid structure : **V = Weight / pg**

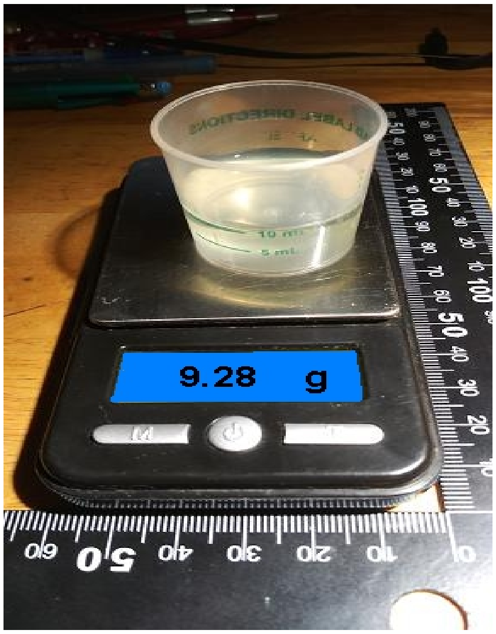
Ex. For the weight of 1000cc of volume of water. Note, 1000cc = 1000g of water.
F = Weight = pVg = (1g / 1cc)(1000cc)(9.8m/s^2) = (1000g)(9.8m/s^2) = (1kg)(9.8m/s^2) =
9.8 kg-m / s^2 = 9.8 (1(kg-m/s^2)) = 9.8N

Ex. In a small measuring cup, 10cc of volume of a food oil was "weighed", and its equivalent mass was displayed as 9.28g after the mass (2.71g) of the measuring container was subtracted or "tared". Note, 10cc = 10mL of volume = 10 (1/1000)L = 10 (0.001)L = 0.01L

The density of this food oil is = p = mass / V = $\frac{9.28g}{10cc}$, after dividing both the num. and den. by 10, creating an equivalent fraction:

p = 0.928g / 1cc : and this corresponds to the known density of most food oils. Water has a density of 1g / 1cc, hence the density of this oil is less than that of water, and this oil will float on water. Because oil has less density than water, it has less mass and weight per same volume as water. Dividing both num. and den. by 0.928 , and inverting the fraction, we find the volume of 1 gram of this oil substance: volume per gram = 1.0776 cc / 1 gram

Because the oil is less dense than water per volume, it has less mass in the same volume or space, and it will take more volume of oil so as to have an equivalent amount of mass as 1 gram of water. Here is an image of the density test: [FIG 227]



The length ruler is shown as a size reference, and each graduation or step is a millimeter.

If the substance in the measuring cup was 10mL = 10cc of water, it would have a mass of 10g since each 1cc of water has a mass of 1g. This is actually a good way to first calibrate a measuring cup and-or determine if its volume is gauged or marked correctly before measuring the volume of substances which have the same volume but different mass and its corresponding weight. To calibrate a weighing scale, you can purchase or use an object with a known calibrated mass and-or weight. The (average) mass of some objects such as coins is given in this book. A 1983 or later U.S. copper coated, zinc penny coin has a mass of 2.5g. Four of these coins weighs about 4 (2.5g) = 10g.

A List Of Some Common Elements, Substances, And Their Density

As mentioned previously, the density of a substance is formally defined as the amount of substance or mass per unit volume, hence it is the amount of mass per unit volume. **Density = mass / volume.** Usually, for this measurement and-or calculation, density is expressed as grams per 1 cubic centimeter.. 1 cubic centimeter of volume = 1cm x 1cm x 1cm = 1^3 cm^3 = 1 cm^3 = 1 cc = 1mL = 1 (1L / 1000) = 1(0.001)L = 0.001L = 1(10^-3)L : L = liters, a unit of volume

1 cc of water is defined as being the mass unit of 1 gram, and the 1 "gram of weight" or "mass-weight" concept where on a weight scale, 1 gram of water is commonly said to also weigh 1 gram, and without mathematically considering the gravitational force (g) acting on that mass and giving it force or weight. In short, the weight of that 1 gram of mass of water when in the effect of gravitation, does affect a weight (or force) scale but it is usually calibrated so as to express the weight (a force) of 1 gram of water as 1 weight-gram which is often commonly called as its weight or grams of weight, but is actually its (or any other substance being "weighed" on that scale) expressed mass value. Most scales in common use are therefore a "mass-weight" or simply a mass scale where a mass is first determined by its corresponding weight (a force) which is then converted to its corresponding mass value and displayed. This may all seem a bit odd at first, but it also allows the mass of a substance to be found by using an inexpensive weight scale, and without the need for a mathematical calculation by the user such as:

From: force = weight = mass x acceleration = ma, mass = F / a = F / g

Under the force of gravity a mass of 1kg will weigh (a force) about: f=ma = (0.001kg)(9.8m/s^2) = 980655 Newtons, however, a common scale is calibrated to indicate or express this the weight as being its corresponding amount of mass of 1kg which is commonly or simply said being "1kg of weight" which actually means "1kg of mass-weight" or "the corresponding mass of the weight".

1 cc of volume is equivalent to (1/1000) Liter = 1mL = 0.001L of volume.

1cc volume of water is defined as weighing "1 gram-weight" or "1 weight-gram", or more commonly (and incorrectly) as just "1 gram", but then this value by itself is actually 1 gram of mass since a gram unit is a unit of mass (substance) and not a unit of weight (a force) which has units of Newtons. 1 gram = 0.001kg of mass will actually weigh 0.0098N when being induced (being forced, pulled) by the force of Earths gravity which has a value of (g) = 9.81m/s^2 due to the mass and gravity of the Earth.

A "relative density" is how many times that the mass and-or weight of a substance is greater than that of 1cc = = 1mL = 1g of liquid water at 4°C, which is defined as the 1 gram of weight standard even though a gram is a unit of mass and not of the force (with units of Newtons) induced by gravity. This density is actually defined at the temperature where water is most dense but not hard yet like ice (crystallized or frozen water) which is actually slightly less dense per unit volume than of liquid water since the frozen water ("ice") actually expands slightly in size as it is freezing into its (atomically, atoms) arranged crystal structure. As water freezes into ice, the resulting force of this growing and expanding solid crystal structure can cause various types of natural erosion and damage such as cracks to man-made structures.

If ice is placed in water which is slightly more dense, that ice will rise upward from pressure beneath and around it, and the cooler and denser water will move (ie., sink) below it, effectively pushing the ice upward. The ice will remain floating on the denser liquid water, but it will not rise upward any further since air is less dense than ice. Denser objects have a larger weight and force per unit volume and-or area, hence they will exert a larger pressure (force per unit area) on any material placed below it and this effectively causes it to move into (ie., displace, sink - go downward) that material in the downward direction of the gravitational force attracting it. Just the same, cooler water will sink below warmer water, and warmer, less dense water will rise upward and away from the denser cooler water, and this is similar to a hot air balloon rising upward to a less dense region in the air.

Note also that there is no consistent linear relationship to an elements density and its melting point (temperature, "heat of fusion" where the atomic bonds are greatly weakened and-or become solid after cooling). For example, lead is considered highly dense and is therefore heavy, but unlike gold, lead has a fairly low melting point or temperature where it turns from a solid state, phase, structure or form, to a liquid form where the atomic bonds necessary for crystallization are much weaker. The atomic bonds are weaker due to the heat energy absorbed and this increase in kinetic energy (ie., atomic movement) prevents crystallization, solidifying or bonding of the metals atoms. For comparison, gases have very weak or no atomic bonding.

To convert grams per cubic centimeter to grams to cubic inch (ci = in.^3):

From: 1 cubic inch = 1 cu. in^3 = 16.3871 cubic centimeters = 16.3871cc , we can multiply a given number of grams in the grams-per-cubic centimeter value by 16.3871 so as to find the number of grams per cubic inch (ci = in^3).

Water, being 1g/cc will be (1g)(16.3871) = 16.3871g/ci .

Steel, being 8g/cc will be: (8g)(16.3871) = about 131.1g/ci , and since mass per unit volume is 8g and is (8g/1g) = 8 times more than that of water, that amount of mass will be both 8 times more and also weigh 8 times more than that of an equivalent volume (here, 1gram) of water.

To convert grams to pounds: Since 453.592g = 1 lb = 16 oz, divide the number of grams by 453.592 to convert to pounds. From this we can mathematically find that:

To convert grams to ounces: Since 28.35g = 1 oz, divide the number of grams by 28.35 to convert to ounces.

For when 30g = 1 "food ounce", then simply divide the number of grams by 30 to convert to "food ounces".

If a density is noted as 8 grams per cc of volume: $\frac{8g}{1\ cc}$

The reciprocal of this is: $\frac{1cc}{8g}$

Dividing both the numerator and denominator by 8, we can find the unit ratio of the amount of volume per 1 gram unit:

$$\frac{\frac{1cc}{8}}{\frac{8g}{8}} = \frac{0.125cc}{1g} \qquad \text{or:} \quad 1g / 0.125cc = \text{"one gram per 1/8 cc"}$$

Here is a list of some common elements and their density at room temperature and standard atmospheric or "air" pressure, which is 14.7lbs per square inch = 14lb / 1in^2 at sea level. This "1 standard atmospheric pressure = (1 atm)" value is reduced when the elevation, height or altitude is higher than at sea level. The air pressure per unit area is reduced since the amount or the mass of air ("air column", volume) in the atmosphere above that location is less and therefore weighs (a force) less and exerts less of pressure (force/unit area) upon things below it. As the altitude increases, the amount of air gets more "thinner", or more "sparse" per unit volume (ie., density) and is not as dense per unit volume and exerts less pressure on objects located there. The air at lower elevations has a greater pressure because of the weight (ie., force) and pressure of the "column" or amount of air pushing downward upon it. Because of this, the air at lower elevations is denser and-or compressed more.

In the following (partial) list or table of the more common elements, g/cc is "grams per cubic centimeter", and although (g) is a unit of mass (material, substance) and not weight (a force on that mass), here (g) is used as rather a "weight-gram" or "grams of weight" per cubic centimeter. The main reason for this method is that corresponding mass of a substance can be found from the weight of that object.

For a specific substance or element, mass and weight are proportional. For example, 2 pounds of iron will have twice as much mass as the 1 pound of iron. If the weight of a substance doubles, the mass of that substance will also double and vice-versa. For both measurements, the ratio of the mass per weight, or weight per mass, is the same value. An element that is more dense will have more weight per unit of volume.

Given g/cc or density of an element at standard temperature and pressure, we can find g/L by multiplying num. and den. by 1000 since 1000cc = 1000mL = 1L . Ex. if an elements density is 0.25g/cc 0.25g/mL, its density in grams per liter is: 0.25g/1mL (1000/1000) = 250 g/L. Also 0.25g/1cc = 1g/4cc after dividing num. and den. by 0.25

Since the volume of 1 cubic-meter = 1m^3 = 1000L = (100cm)^3 = 1000000cm^3 , for the mass of a liquid or gas at standard temperature and pressure (STP) per cubic meter, and which is equal to a density = mass / volume , such as for water which is 1g/1cc is: (1g/1cc) (1000 cc/L) = 1000g / L , After multiplying both num. and den. by 1000 we have: 1000g/1L (1000/1000) = 1000000g/1000L = 1Mg / 1000L = 1Mg/1m^3 = 1000kg / 1m^3

1 cubic foot of volume = 1 ft^3 = 1728 in^3 = 28.317 L
1 cubic inch of volume = 1 in^3 =~ 16.387$\underline{1}$ cc = 0.0163871 L
1 cubic centimeter of volume = 1cm^3 = 1 cc = 1L / 1000 = 0.001L = "a thousandth of a liter" =~ 0.06102374 in^3
1L of volume = 1000cc = 1000 cm^3 = 61.0234 in^3 = 0.035314$\underline{5}$ ft^3 = 0.264 gal.-US
1 gallon of volume = 1 gal =~ 3.78541178 L =~ 3785.4 cc

A list of many common elements, some substances (compounds of two or more elements) and their densities is given below. They are also in order from lower density to higher density.

ELEMENT AND ITS DENSITY (In grams of mass per 1 cubic centimeter of volume = g/cm^3)
(g/cm^3 = g/cc = g/mL = a volumetric density or amt. of mass or matter, measurement value)

This list also includes a few substances that are compounds of two or more elements.

hydrogen = 0.0000838 g/cc , liquid hydrogen is 0.07g/cc = 70g/L at 1atm (14.7psi) , temp is -423°F = - 253°C
helium = 0.0001785 g/cc , liquid helium is 0.125 g/cc at 1 atm (= 14.7psi) , temp is -452°F = -269°C
methane = 0.00072 g/cc , a compound of carbon and hydrogen, CH4, methane is flammable (can burn, a low level or slow combustion) Liquid methane is 0.423 g/cc = 423g/L = Liquid or Liquefied Natural Gas (LNG). A mixture of liquid methane and liquid oxygen can make a rocket fuel. A methane filled balloon will rise upward in the air.
water steam [hot, water vapor or gas] =~ 0.0006 g/cc , at just above the boiling temperature of water
nitrogen = 0.0012506 g/cc , liquid nitrogen is 0.804 g/cc at 1 atm (14.7psi) , temp. is -320°F = -196°C
oxygen = 0.001429 g/cc , liquid oxygen is 1.141 g/cc at 1 atm (14.7psi) , temp. is -297°F = -183°C
Liquid oxygen being (1.141/ 0.001429) - nearly 800 times denser than gaseous oxygen, will fill a volume nearly 800 times larger when it turns back into a less dense gas. An **oxide** is a molecule composed of an element and oxygen. For ex.: zinc oxide (ZnO), and iron oxide (Fe2O3).
chlorine = 0.002898 g/cc = 0.002898 g/mL or ~ 2.9g/L when both the 1g weight and the 1 cc volume are multiplied by 1000 so as to find the equivalent weight of the substance in 1L of volume.
air ~0.00124 g/cc = ~1.24g/L : the density of the mix of gasses in the air at sea level. See the note below.
: 1m^3 = 1000L, and the volume of air per cubic meter is: 1.225 kg / m^3

The standard air mixture of gasses that we breath is about: 78% nitrogen, 21% oxygen, 1% argon, and a small amount is carbon dioxide (CO2) but this value for (CO2) could dangerously increase to many times more without proper air ventilation in a room as the oxygen level gets depleted (reduced, used up, converted to carbon dioxide) from breathing. Plants use carbon dioxide to produce sugars with the aid (energy) from sunlight in a process called photosynthesis. Carbon dioxide is denser, and therefore heavier than common air. Air also contains traces of some other elements. Liquefied **air** is normally 0.870 g/cc at 1 atm (14.7psi) and has a temperature of about -200°C = -392°F =~ -400°F. This can be done by what is called the **Linde process** which condenses (increases its density up to about 700 times. 0.870 / 0.00124 ~ 702) the gas, but also heats it, and this will then be passed through a heat exchanger or radiator system to cool and liquefy it to its high density. It must be kept at pressure or it will boil (ie., evaporate into the air at standard pressure and temperature), such as seen as a vapor, cloud or mist in the air. Note that its density increased by 700 times, but its volume decreases by that same value of 700.

lithium 0.53 [a lightweight, soft metal at room temperature, a small amount is used in rechargeable batteries]
acetone 0.785 [a simple keytone - carbon and oxygen molecule , very volatile (evaporates easily) and flammable, typically used as a solvent for making plastics , is **miscible** (mixes well, completely) in water]
alcohol [pure, non-poison ethanol 0.789 , isopropyl 0.786 "rubbing" alcohol, poisonous typically used for antiseptics]
[Methanol is ethanol that is "denatured" with poisonous methanol, typically used for fuels and solvents]
[Alcohol boils at about 173°F = 78.33 °C , Methanol boils at about 148 °F = 64.4 °C]
potassium 0.862 [a soft, and very low radioactive (radiates or emits energy and-or particles) metal, many people are low in potassium and it is found in some foods and-or some salt-substitutes].
food oils 0.91 to 0.93 is typical [ex. olive oil 0.917, corn oil 0.93, will **float** on water since oil is less dense or heavy. Denser (m/V) objects also weigh more per unit of volume; (W/V), hence have more force of gravity upon them.]
sodium 0.971 [a soft metal, melting point of only 208°F, it is highly reactive with water, Table-salt contains sodium]
water (solid, ice) 0.9167 [ice is cold, crystallized water, and is less dense than liquid water because the crystal solid expanded into a larger volume, hence some of that material, here ice, is outside that reference volume, here 1cc = 1 cubic centimeter = 1 cm^3]. Water freezes at 0°C
water (liquid) 1.0 [comparative reference density, defined at 4°C, slightly above freezing, and max. water density. Water, H2O1 = H2O, as a liquid, is essentially many condensed (ie., now denser, more of a solid) molecules of hydrogen and oxygen gas. Sea-Water is about 1.03g/1 cc . Liquid water can be

thought of as condensed or concentrated water vapor (humidity and steam), and ice can be thought of as condensed or concentrated liquid water. When water vapor looses its thermal energy, it can condense and form into snow (fine ice crystals, at high altitude, where its very cold) and-or rain drops when the temperature is not water freezing (at or below 32°F = 0°C)] **Though water feels and is much softer than hard ice, water is actually more dense than ice in terms of the amount of mass per volume = mass density = mass/volume.**

amber 1.1 typical or average [hard or petrified ancient tree sap, usually a variety of pine tree, and usually having an amber (orange-brown) color, it does not have an atomic crystal structure, but is amorphous. Though slightly denser than pure water, it will float in brine (ie., high salt concentration) water]

milk 1.3 [typical, for whole milk containing some fats (oils)]

PVC 1.38 typical [Polyvinyl Chloride, a plastic, often used for electrical and water pipes. Made from petroleum (ie., crude oil). PVC pipes and material can be softened (at about 200°F) with hot air such as in an oven or hot-fan blower, and then bent into shape before cooling. **HDPE** is High Density Polyethylene, a relatively soft plastic made from petroleum, and can be recycled and-or melted (about 350°F) in an oven and made into products, including bulk plastic material available for other smaller projects. Being softer, the density of HDPT is lower than that of PVC, and is only about 0.95 g/cm^3 and will float on water which has a density of 1g/cm^3 = 1g/mL]

honey 1.42 typical

chalk 1.5 typical [calcium carbonate , ex., a construction material , **Do not breath in dust of any substance.**]

calcium 1.54 [a soft metal, used in some alloys (mixes) of metals, melting point of 1548°F , a bio-nutrient]

table sugar 1.59 [a food sugar, can be produced to have a crystalline, solid form]

magnesium 1.74 [a lightweight brittle metal, used to strengthen some alloys, highly reactive (burns) in water, can also be found in Epsom Salt (magnesium sulfate=MgSO4 which contains about 450mg of Mg per 5g, and plants so as to do photosynthesis. many people are magnesium deficient which can cause some health problems; various nuts and seeds like pumpkin and sunflower seeds are high in magnesium, and seeds can be ground and added into other foods, such as soups, as flavorings].

phosphorus 1.82 white, 2.34 red, 2.69 for black [white, highly reactive, a **non-metal**, soft, waxy, used in fertilizers] Phosphates are a certain molecular form of phosphorous that our body uses for a variety of functions and structures such as bones of which also have calcium. It is said that too much phosphorus can reduce calcium, bone mass and strength and cause dangerous higher levels in the blood and body via accumulations or deposits. Calcium can also reduce phosphorus absorption. Phosphorus is part of the **ATP** molecule for energy in our body. The RDA of phosphorous for the body is about 700 mg = 0.7g for an averaged size adult male. White and yellow phosphorous is toxic and can ignite in the air. People with kidney problems and-or disease may have to severely reduce their phosphorus foods intake (consumption, eating) due to the kidneys have problems excreting it from your body,and then it can build up in the body and cause a myriad or range of problems such as calcium deposits in the body. Animal products tend to have a high level of bio-available phosphorus. Many soda drinks have phosphorus acid added into their ingredients mix, and is actually a (subconsciously addictive?) source of phosphorus. Please try to be wary (ie., aware) or knowing of nutrition needs and in foods.

beryllium 1.85 [a rare brittle metal, a nickel or copper-beryllium alloy is used to improve heat and electric transfer]

carbon dioxide 1.96 ["dry ice" is cooled (frozen) and solid (condensed) carbon dioxide, with a density of 1.5 typical]

opal 2.1 typical [a mineral-like silicate (ie., silicon-dioxide) and water mixture, 8% water typ., colorful for gems]

sulfur 2.07 [a **non-metal** element, it is also a necessary nutrient for life, such as for making amino acids and-or proteins]

table or food salt 2.165 [a compound, NaCl, composed of 40% sodium ions with a net positive charge, and 60% chloride atoms (chlorine ions with a net negative charge, gained an electron from the sodium) by weight. These ions electrically attract and bond together to form each molecule. This is a ratio of (40% / 60%) = (0.4 / 0.6) = (0.2 /0.3) = (2 parts sodium to 3 parts chloride). That's also a total of 5 parts, and (2/5) = 0.4 = 40%, and (3/5) = 0.6 = 60%. Sea water which has a typical density of about 1.03g/cc, and is about 3.5% salt, hence it is slightly more dense and heavier than pure water. 1cc of table salt weighs 2.165g. 5g = 1 teaspoon of table salt has:
(5g)(40% sodium) 5000mg (0.40) sodium = 2000mg = 2g of sodium. 5g -2g sodium = 3g chloride

Note that granulated table salt crystals have much air space between the dense, hard crystals, and it is then less dense being at about 1200mg / 1cc = 1.2g / cc. 1.2g / 2.165g = about 0.55, hence the density is now only about 55%, nearly half the density, as it is in solid, granulated form. 5g of granulated table salt will require about:5g / (1.2g / 1cc) = 4.2 cc.

Salt is one of the many essential mineral nutrients for the human body, and requires more than a trace amount. The FDA (The United States, Food and Drug Administration) recommends that an adult male diet have less than 2300 mg = 2.3g of sodium per day. To get, consume or intake 2g = 2000mg amount of sodium from food salt = sodium chloride, will require about 5g = 5000mg of table salt which has the volume of about (1/2) of a level 5cc volume teaspoon. People having a lower body weight and-or a sedentary lifestyle will usually require a lesser amount than this. The RDA of essential chloride is 3000mg = 3g.
A persons body salt level is usually measured via a blood sample. Having too low of salt in the body can cause **hypomatremia**, and will cause dizziness and cramping, and in severe cases, shock (very low oxygen and-or blood flow) and death. A minimal amount of total salt per day has a recommendation of 500mg =0.5g . An estimated amount of salt lost (excreted by urine and-or sweat) per minute by working hard, jogging, or running is about 15mg per minute on average, hence these people need to consider replacing this lost salt and water by eating some more. When the body has or will get a low level of sodium in it, the body will try to maintain it, and not excrete it in the urine. When the body has an excess of sodium, it will try to excrete it through the urine, and will cause the person to feel thirsty so as to drink more fluids so as to excrete it in the urine and lower the level of sodium **concentration** [**(**amount of substance / reference value**)** = **(**sometimes called the particle or substance or particle density / reference value**)**] in the body. A concentration value in a substance or mixture might be stated as a percentage, for example: 35g per 1kg = 35g / 1000g = 0.035 = a 3.5% (of) sodium concentration (per unit volume and-or any amount of the substance . A concentration might be expressed as parts per thousand = ppt , or parts per million = parts of substance per million parts of the solution, "potion" or mixture = ppm

Salt is vital for the body and is used in many internal and-or chemical processes. Salt of any amount will cause a corresponding rise in blood pressure due to the fact that the body will retain more water, and this will cause a higher pressure upon your blood vessels since the heart will need to use more force to move a larger volume of blood fluid through the body. Normal and-or average blood pressure is usually noted as: 120 / 80 ("120 over 80"). Drinking water can help reduce a high amount of salt in the body. To much salt in the blood is medically called **hypernatremia**. The normal amount of sodium in human blood is about 140 **m**illi-**m**ol **Eq**uivalents per liter, or units of: (mmol Eq / L) or= (mEq / L) = about **3.22mg/ml = 3.22g/L**, and note that 1ml = 1cm^3 = 1cc, Adult human blood has a density of about 1.057 g/cc, and the amount of blood in a human is about 7.5% of the total mass, hence also about 7.5% of their corresponding weight. Infants will have a higher blood mass of about 9.5% An average adult person has about 1.36 gal = 5.11L =~ 10.5 pints of blood in their body, and can donate up to about 1 pint = 0.473L (nearly half a liter = 0.5L) of blood, but may then feel dizzy and need to drink water, and it helps if it contains some electrolytes such as a small amount of table salt. A derivation of 140 mmEq is shown in the **Extras And Late Entries** section of this book.

To much sodium can cause high blood pressure, a stroke, a heart attack, kidney disease, etc.

,

Studies have now shown that **potassium** levels in the blood also controls blood pressure. Many people are lacking in the amount of potassium and other nutrients (elements [minerals] and vitamins [ie., vital minerals in the form of other created molecules and-or compounds such as vitamin A, B, C, D, E, etc.]) in their blood. Potassium helps regulate fluid volume in the body, it is an important electrolyte like salt is, and is used for body processes. The recommended intake of potassium for an adult male is currently 3400mg / 1 day = 3.4g/day. Please check that your table salt is supplemented with iodine. If you are on a salt restricted diet then you might not then receive the (typically minimal) RDA of **iodine**.

limestone 2.2 average value
graphite 2.25 typical , a specific physical form or instance of a carbon element
carbon 2.267 [a **non-metal** element that is a vital part of living in all hydrocarbon (or hydro-carbon) based life forms, it is rooted in the word for charcoal (burnt, charred wood). Carbon-12 = C12 is a nuclide of carbon and is used for the reference atomic mass unit. A **carbide** is a hard crystal compound made from carbon and a metal such as iron, and is often used as a coating for some high wear items such as cutting and abrasive tools. Graphite and graphene are forms of carbon that can **conduct electricity** (ie., electric current, and-or energy) due to their atomic crystal structure where three carbon atoms are joined leaving a free electron per carbon atom which can carry its charge and kinetic energy.]
silicon 2.33 [a brittle semi-conductor metal, often used in diodes, transistors and solar-electric generating panels. Silicon can be extracted from quartz and-or sand which is basically silicon-dioxide. Silicon has a melting point of about 2500°F, and silicon carbide, 3.21g/cm^3, has a melting point of almost 5000°F]
boron 2.34 [a very hard, liteweight, brittle, generally a non-metal, low electrical conductance, and which is often used for "doping" (adding trace [tiny] amounts) to semi-conductors to improve conduction]
window glass 2.5 typical [heat tempered glass is stronger, but brittle, "safety glass" usually has a plastic layer]
marble 2.65 typical [a hard crystalline stone, usually from metamorphic limestone from calcium carbonate deposits]
aluminum 2.698 [will eventually react with air to produce a hard aluminum oxide, oxygen "rusting", surface coating. The melting point of aluminum is about 1220°F]. Aluminum is named after the mineral ore called alum. Aluminum was first discovered by Hans Christian Oersted, of Denmark in 1825.]
marble 2.5 average [a dense form of limestone, more corrosion resistant than limestone]
granite 2.7 typical [a hard stone, mostly quartz 2.65 which is silicon dioxide [like glass], but also has feldspar=6.0]
diorite 2.9 typical [a hard volcanic rock, often with black and white spotted colors]

antimony 3.0 [a mettaloid, brittle, used mostly for alloys with other metals]
barium 3.5 [a soft, reactive and toxic metal, used for some vacuum tube parts and semi-conductors]
diamond 3.51 typical [its density is not very high, but it is a very hard crystal, brittle (non-malleable or non-bendable), and is a slightly denser form of carbon (graphite)]

titanium 4.54 [a low density, lightweight, but high strength metal, relatively brittle and can crack rather than bend]
iodine 4.93 [a **non-metal**, poisonous, but a necessary nutrient in small ("trace") amounts to make vital or essential thyroid hormone which helps regulate body metabolism. Iodine is scarce and not generally needed by land plants, but ocean fish and plants, such as seaweed and kelp, do absorb dissolved iodine and concentrate it. Because of not eating seafood, inland people often need to be supplemented (such as in table salt) with iodine. Seawater has about 50 parts per billion (ppb) that is iodine. This is equal to 50 ug per liter of seawater. Evaporating the water out of **sea water** is one way to extract the minerals in seawater. 1L of seawater will contain "sea salt" (sodium-chloride, a compound of elements) weighing at 10 grams of sodium and 20 grams of chloride, plus other lesser quantity of dissolved minerals (elements) such as magnesium chloride, sulfate, calcium chloride, calcium, potassium, sulfate, bromine, iodine, etc. **In the United States, the (min.) RDA of iodine is 150 ug/day. Many people are unhealthily deficient in iodine and some other minerals. A well known and trusted form of iodine is called Lugol's Iodine (a potassium iodide mix) that is intended as a nutritional supplement.**

Note that evaporating seawater (especially when warm) may actually "gas-off" the (volatile, fragile) iodine into the air. Some sea plants, such as seaweed and kelp absorb iodine and have a much higher, less volatile, concentration of it. A pre-made mixture of alcohol and iodine is used to fight germs on some surface (non deep) skin wounds such as scratches, otherwise seek formal medical attention and treatment.

germanium 5.3 [a semi-metal or metalloid, brittle, similar to silicon and used for semi-conductor electronics]

basalt 5.5 typ. [a dark to black lava (= melted, volcanic) rock]
radium 5.5 [a highly radioactive and dangerous element, many more times naturally radioactive than uranium]
gallium 5.9 [a soft metal, brittle when cold, liquid at about 85°F, used for some semi-conductors and mirrors]

vanadium 6.11 [a rare, soft and ductile metal, its oxide resists corrosion, and is used in high strength alloys]
zirconium 6.52 [a hard metal, malleable, high strength, non-reactive]

neodymium 7.0 [a "rare-Earth" metal, soft, reactive, used in some high magnetic field strength magnets and lasers]
zinc 7.134 [a metal with a melting point of 787°F, often used in alloys, and for an additive in other products]
chromium 7.15 ["chrome", hard, non-reactive, used for a stainless, protective and shiny plating for other metals]
tin 7.29 [a metal with a low melting point of 750°F that can be reduced further if mixed with bismuth and-or zinc]
manganese 7.3 [a hard and brittle metal , used in some alloys for magnets , glass making, a chemical reaction catalyst ; a catalyst is a substance that helps to improve a chemical reaction, hence it speeds the chemical reaction process and reduces the total time and-or energy needed for a complete chemical reaction. An analogy would be that a catalyst is the spark which causes a combustion. Ex. To help remove potentially dangerous fumes or gas particles from the byproducts or exhaust of combustion engines, a metal such as platinum, palladium and-or rhodium is used to effectively filter it via a chemical reaction of this catalyst metal, and where the hot gas molecules of the exhaust are split apart into less dangerous gasses and water vapor. This device is often called a "catalytic converter".]
iron (steel is iron with some carbon) [7.87 for low carbon mild hardness steel, 8.0 for grade "316 stainless steel"] [Sometimes called ferrum (Fe), ferrous or ferrite, iron melting point is 2700°F, steel melting point is 2500°F, its name may mean "metal from the hot fire or furnace", "fire metal" or "furnace metal". Iron oxide is surface rust due to air-oxygen contact, Iron is an abundant element on Earth. **Harry Brearley** from the United Kingdom is credited to making the first practical stainless steel in 1913, and of which does not rust if made correctly. Most places that prepare and-or serve food to the public are required to have a stainless steel sink and food preparation table among some other things such as a license, being clean, possible refrigeration, etc.

The body uses a small amount of iron, as atoms, to carry oxygen through the body. Iron supplements may help some people lacking iron in the blood, but a blood test is generally needed to know if a person is indeed lacking in iron. **Do not take extra and-or unneeded iron supplements thinking it will enhance your general health since a high level is toxic, and the same could also be said for most other supplements.** Most of the iron atoms in a person is mostly found as part of the hemoglobin protein in red blood cells. Low iron levels is also a serious health issue and cause a variety of symptoms, and the main one is breathlessness. Eating nutritious foods is good to prevent and-or treat many health issues within the body, and of which includes the physical mind processes.

Iron-pyrite ($FeS2$ = 1 iron atom to every 2 sulfur atoms) or iron-sulfide is iron with traces of sulfur in it, and it occurs naturally, atom by atom in the presence of flowing water containing the supply of atoms, sometimes as a beautiful crystal form. It has a yellow color as that of shiny brass and is somewhat rustproof. The density of iron-pyrite is less than that of plain iron or steel, and is about 5gm/cm^3. Pyrite is a semiconductor with an electrical (for conduction) "bandgap" of about 0.95eV and could be used as a part in a "crystal" (ie., sold-state, radio).] Forged steel is compressed or "hammered" steel when it is red hot, and is stronger due to the increased size of the metal crystal structures. Many tools and machine parts are made from forged steel. Some iron artifacts have been dated to about 2000 BC, but before about 1200BC, smelted iron was generally not available to most people, and hammered iron from meteorites was sometimes used in a very limited basis. Bronze (an alloy of copper and tin was in much use by the time iron products became available. The first iron production and use is usually thought to be in south-eastern Europe, and India. Every piece of iron and-or steel was surely valuable at those times and until to the "industrial revolution" beginning at about 1800AD where many products began to be "mass (ie. massively, many) produced" and became much cheaper and available due to advances in science, technology and transportation. The ore form of iron is very abundant in the Earth.

brass 8.6 typical [an alloy of varying proportions of mostly copper, and with zinc, and is golden-yellow in color]
cadmium 8.65 [a soft and malleable metal, toxic, used in some rechargeable batteries]
bronze 8.5 to 8.9 typical [a hard alloy of mostly copper, and with tin, typically has a reddish-brown color]
[brass is much less of conductor of electricity than copper, and bronze is even worse than brass]
[bronze is harder than copper, and it melts at a lower temperature due to the tin additive]

cobalt 8.9 [used in some blue pigments, alloys, magnets, the B12 vitamin molecule contains 1 cobalt atom]
nickel 8.91 [a hard, malleable, an nonreactive or non-corrosive metal, **a potential toxic health risk from its dust**. **Avoid any dust from any metal or substance.** The melting point of nickel is about 2650°F]
copper 8.96 [an orange-red colored metal, has very good thermal and electrical conduction. The melting point of copper is 1984°F]
bismuth 9.81 [a dense, heavy metal with a low melting point of 520°F, an alternative to using toxic lead metal, when melted, it will contract, and like ice, it will expand when cooled to a solid, bismuth is not toxic]

molybdenum 10.3 [used in some stainless steels and other alloys]
silver 10.5 [a metal with excellent heat and electrical conductivity, but higher in cost than copper. silver reflects the most light for any metal, and is ideal for mirrors such as for reflecting telescopes. The melting point of silver is about 1760°F]

lead 11.342 [a dense metal, but relatively soft and malleable (ex. by hammer) metal because of weak crystalline atomic (atom) bonding. It is **toxic or poisonous**, and has a low melting point of 621°F]

mercury 13.53 [a dense liquid at room temperature, but highly soft being a liquid, **highly toxic or poisonous**]
tantalum 16.7 [a non-reactive or "inert" metal, used in some alloys, has a high melting point]
uranium 18.95 [a slightly radioactive metal element when stable, toxic, with a long half-life of decay, it is also malleable where its shape can be changed by hammering an pressing without it cracking]

tungsten 19.25 [a hard and brittle metal, has the highest meting point of 6192°F, and highest tensile strength - which is basically a stretching or tension strength before breaking failure, such as from the max. suspended load weight (as a pulling or stretching force) applied to the end(s) of the length of a certain standardized reference cross sectional area of the material that is held in a fixed in position. Tungsten has almost the same density as gold. The high melting point of tungsten is due to having a strong crystal structure - similar to carbon, having 6 shared and-or many bonded electrons.]
gold 19.28 [very dense and heavy, but relatively soft and malleable due to a weak crystalline structure bonds, gold has a shiny, yellow color which does not oxidize (ie., loose an electron(s) and become "gold-oxide") and rust or tarnish (discolor) in the air, etc. Gold has a melting point of about 1950°F]
plutonium 19.82 [a radioactive metal with a long half-life of decay, particles of it are toxic, such as if inhaled]

platinum 21.46 [a dense or heavy, malleable metal, high melting point of 3220°F, very non-reactive or "unreactive" to other chemicals, and is therefore superior to stainless steel which also does not corrode or rust easily]
iridium 22.6 [rare, very dense - heavy and hard, but brittle and will break or fracture by relatively low amounts of force, high melting point and corrosion resistant metal. The heaviest of metals are believed to be mostly at the core of Earth, and with only a trace amount in its crust (ie., surface), but higher concentrations can be found in some meteorite impact sites, and this indicates that the meteorite was probably from the core of a large asteroid or planet.. About twice as dense as lead.]

Most metals have a gray to silvery type of color except copper and gold which have a unique color due to its atomic (atom) and crystallized structure. Metals conduct electric current fairly well, and each metal element will have a unique resistance to the flow of electricity. Gold has a very low resistance to the flow of current as compared to that of steel, however gold and silver are very expensive and are then impractical to use because of that, and copper then becomes the preferred electricity conductor for most applications.

PHASES OR PHYSICAL STATES OF MATTER

The 3 common "states" or "phases" of matter are: solids, liquids, and gases. Given a substance such as an element or molecules, it can change to a different state, usually depending upon its temperature and-or state of energy. A "4th" state of matter is called **plasma**. "Plasma" is an old word that means something that is soft, and the word "plastic" is also a based on the word "plasma". Plasma is created when electrons are removed from many atoms of the substance. The plasma will then contain many positively charged ions and negatively charged electrons. Plasma's often give off some light, especially when a current is passing through or within it and giving it energy to do so. When an energized (kinetic energy) electron falls into orbit, it will release its gained energy as a photon of light. A plasma is like a very hot gas(s), and due to the high kinetic energy and-or velocity of the particles. Stars, such as the Sun, are composed of hot plasma consisting of gases of different elements - mostly hydrogen and helium. **Helium** is created by fused (fusion, joined together) hydrogen atoms in the very hot (high kinetic energy) and high gas pressures (ie., force / area) deep inside the Sun. A helium atom has 2 protons, 2 neutrons, and 2 electrons. Helium was discovered by **Pierre Janssen**, of France, in 1868 while observing helium's spectrum line in the light from the Sun, and this gas was later named after the Sun (Helios in Greek). Helium gas can be found on Earth, but it is often in relatively small quantities mixed with natural gas (**methane**, CH_4, classified as the simplest hydrocarbon, here,a molecule with 1 carbon atom in the center and then surrounded by 4 hydrogen atoms). Hydrogen has 1 proton and 1 neutron, and when two hydrogen atoms are joined together, they create helium which has 2 protons and 2 neutrons. The excess kinetic energy of the two hydrogen atoms will be released as heat (infrared or infra-red light) and light energy of that Star.

The three phases of water are commonly called: ice = frozen or crystallized water, liquid water, steam (water vapor or gas). With each phase of water, the molecules have a different arrangement.

The **phase or state of matter** mostly depends upon the temperature applied to that matter (ie., element), but may also depend upon the pressure applied to it such as to change the state of the matter. The states or phases of matter are usually then closely related to the density of that matter. Water has a rare property that in its solid form or ice, its density is less than that of liquid water form, and this is due to that water will slightly expand in size or volume at the molecular level when it crystallizes to ice.

Consider water, if it is heated to be hot (high) in temperature, it will boil (disassociate, "boil off", "come off", "loosen", "vaporize", "break away from", "release") and turn into to steam (a gas) particles. If steam is cooled, it looses energy and condenses together into tiny drops of which is a liquid state. If a drop of water is cooled, it will condense even further and freeze into a solid (ie., ice). Water is also a special case of where when it is frozen, it is actually not less in size, but slightly larger in volume. The atoms in the ice or solid water have a low kinetic energy and they have a greater ability to join, bond and remain near each other and form the (atomic, molecular))crystal structure of ice. The atoms in a gas have a higher kinetic energy. Gases have a low density, while solids have a high density. The **air** that we breath is a gas at standard temperature and pressure, and is mostly a mixture of **nitrogen (78%) and oxygen (21%)**. Ammonia (NH_3) is a gas that is a nitrogen and hydrogen compound, and it is used in fertilizers and cleaning products. Some ammonia is produced when protein is processed in the body. Ammonia has a "sharp", strong pungent smell and is found in urea and "smelling salts" that are sometimes used to awaken people after fainting and-or make them more alert.

Plasma is a state of matter that is a very hot gas and is high in kinetic energy, and its atoms have broken apart into protons (positively charged) and electrons (negatively charged). An example is a gas light such as a neon ("new gas", a natural trace element found in air) or fluorescent light which is basically a glass tube filled with a gas that gets **ionized** and turned into a plasma by applying electricity through it. Fluorescent lamps are coated on the inside by a material that will fluoresce, which means when struck by invisible high energy light radiation, it will radiate visible light radiation.

One definition of a gas is that a small unpressurized amount of it will fill or expand outward into any (empty) container of which it is placed into. When a gas spreads out into a larger volume, the density of that gas will decrease since there is now less matter (here, gas) per unit volume. A gas spreads out because the atoms or molecules are not joined together as like that of a liquid or solid, and may repel each other electrically, and-or have thermal, kinetic energy.

One definition of a liquid is that is will fill any volume it is placed into, but due to its density and the gravity (force) of Earth, it will only fill the lower (ie. in height) volume of that container. Unlike for the gas, the volume and density of the liquid will generally remain the same when pressurized. A liquefied element or molecules is more dense than the gas(s) that compose it. A liquid can be defied as the state of a substance when it is between its solid and gas form. A liquid is usually less dense than a solid.

Matter that is less dense is more compressible. Gases are more compressible than liquids. Liquids, though only slightly compressible, are more compressible than solids. In brief, gases can be converted to a denser or liquid state by using the Linde-cycle or process invented by **Carl Linde** (1842-1934) from Germany in 1895. In this process the gas is compressed and this increases the pressure of it and effectively increase its density. A side-effect is that the temperature of the gas will also rise when it is compressed. The hot, compressed gas is then let to cool off (release much thermal and-or kinetic energy and then it reduces in temperature (getting colder, more dense) and pressure) by thermal conduction (ie., transfer) through the wall of the smaller volume holding it, and-or through a heat exchanger, and then allowed to then expand and reduce in pressure, and the cycle is repeated until the gas is liquefied. This is also basically how a modern food refrigerator works. Liquid oxygen, nitrogen, liquefied natural gas (LNG, methane), and liquefied propane gas (LPG) are common examples of liquefied gases. Once liquefied and cold, if warmer air then comes into contact with liquid oxygen or nitrogen, some of that cooler liquid at the surface and boundary of the warmer air will then increase in temperature boil off into the warmer, higher energy air and make a visual steam or "fog" appearance of the less dense gas.

We see that the phases or states of matter (or atoms) are mostly due to the influence of external physical conditions such as temperature and pressure applied to that matter and its initial state.

A solid metal, usually with a hard crystalline atomic or molecular structure, can become soft when heated to a hot temperature, and before it is melted to a liquid state or status. The high heat will weaken its hard crystalline structure. When a metal is soft, it is more pliable (bendable, malleable), and more "plastic-like", and can be more easily **forged** or pressed or cut into a shape using a high amount of force and-pressure, such as with a hammer. This is usually how coins are made more easily, and also to have some design or inscription placed on them by another carved piece of harder metal. A person called a "black smith" can make many types of metal (usually of iron or steel) items by hammering and-or cutting the hot metal piece against a much larger piece of metal called an anvil. The metal is then allowed to cool naturally and-or is dipped ("quenched", heat extinguished) into water or an oil so as to harden it more quickly and to give the metal some specific property such as increased hardness. To anneal a piece of metal is heat it hot and then slowly cool it so as to help remove internal stress (ie.,hard areas) and to make it slightly softer to work upon.

The **melting point** of a metal or solid is the temperature at which it changes physical state from a solid to a liquid. When a metal is liquefied, it will increase in volume (ie., thermal expansion) and become slightly less dense , but when it cools to be a solid form again, it will decrease in volume (ie., thermal contraction). A metal can also boil and evaporate up into the air when its pressure becomes greater than that of the air or gas pressure. Adding in some other metals and-or impurities can affect the melting point of that alloy of metals since it alters the crystal structure of the resulting metal, and generally weakens the electrostatic bonds of the atoms and it will melt at a lower temperature. For example, Rose Metal is an alloy of bismuth, lead and tin which has a low melting point of about 205 °F A metal mixture or alloy is said to be **eutectic** ("melts easily and-or evenly into a homogeneous [ie., as one] mixture") when its melting point for the entire mass is lower than the lowest melting point (m.p. or mp) of any one metal in the mixture. Various types of (electronic, and plumbing) welding solder are eutectic alloys (mixes) of metals, and some do not even contain lead metal, hence making it safer, but at a higher monetary cost such as if it contains relatively high cost silver metal. Some other eutectic alloys are: Wood's metal (~ , 50% bismuth, 25% lead, 15% tin, 10% cadmium) with a melting point of 158 °F, Field's metal (~ , 50% indium, 33% bismuth, 17% tin) with a melting point of 144 °F, and Galinstan (~ , 68% gallium, 22% indium, 10% tin, with a m.p. of -2°F) of which can melt in your hand much easier than pure gallium metal (m.p. of 86°F) can. Galinstan can replace toxic mercury in many applications such as in thermometers. Note that most metals and-or elements can be toxic, depending on the element, amount, and use of it. Inhaled dust particles is a danger of any substance, so wear a breathing mask (ie., a breathing, debris filter), gloves and eye protection. A blood test can determine if someones blood contains high values of a metal(s) and-or other substances.

The amount of energy needed to change a specific element from a solid state to a liquid or melted state depends on the amount of mass of it and the type of element since each element has a various atomic bond strengths. This amount of energy to change between a liquid (near the solid state) and solid (near the liquid state) is called the **energy or heat of fusion (Hf rating or ratio)** and has units of: joules / kilogram or joules / gram. Fusion Energy = (mass)(Hf). For example, given a big mass or block of ice that is at the minimal freezing temperature, it will require a particular amount of energy to melt just one gram of it so as to change to and be in the phase or state of liquid water, and theoretically still be at the same temperature, and this specific amount of energy is called the heat of fusion of water. The heat of fusion or "latent heat" amount of energy for water is about 79.7 cal / gram = practically about 80cal / gram = 334 J / gram at standard atmospheric pressure. In a reverse manner, if liquid water is frozen, about 80 cal of heat / gram of water needs to be released as the kinetic energy of water is changed to another state, and here, the energy is released as heat (thermal energy). The amount of energy, the heat or energy of vaporization, Hv, to change from a liquid state to a gas state is not generally the same value as the heat of fusion. Hv of water is more than other elements and is about 2245 J / gram to change from liquid to water to ("steam, vapor") gas. This relatively high amount of energy is due the large number of hydrogen bonds in all the water molecules in a gram of water. Steam, and particularly when concentrated and-or having pressure (ie., force) due to its kinetic energy, is said to contain high thermal and-or kinetic energy and is therefore useful for (mechanical, input force operated [ie., as the supply force, "fuel" or energy] and-or output) machinery such as a steam engine for moving trains.

An example of the many different alloys of two or more metals:

Nichrome (NiCr) is a mixture ("alloy", joining, combination) of nickel and chromium, and might have a small amount of manganese and-or iron. Nichrome has a relatively high resistance per unit of length due to it having a relatively low number of free electrons. This wire is often used for various types of high temperature (up to about 2000 °F) heating elements such as for coffee makers, toasters and soldering irons that get hot and-or create warm air for heating rooms. This ability make nichrome wire valuable in terms of common usage. Nichrome dust and-or fumes from being machined do have some toxicity. Nichrome wire is also called "resistance wire" or "heating wire". The resistance of nichrome wire, and like other metals, depends on the alloy ratio used, length and cross sectional area, and as a basic reference, 22 gauge nichrome-60 (contains 60% nickel ,and 40% chromium) wire has about 1 ohm of resistance per foot of length. and 32 gauge has about 10 ohms of resistance per foot of length. Unlike other metals, the resistance of nichrome wire does not change much per degree change in temperature, hence it is said as having a low thermal coefficient. This is good if your making a calibrated, high power (and heat ability to then dissipate)) resistor from the wire and are expecting various amounts of current (and power loss) through it . The retail (ie., for the consumer) cost of 22 gauge nichrome-60 wire is averages about 15 USD per 100 feet of length. Generally, when making a nichrome resistor components for electronic devices other than for heating purposes, it is wrapped around and-or encased in a hard ceramic type of non-flammable and non-melting material to electrically insulate it. The higher the amount of power applied to the wire of a given length, the hotter it will get. If the wire is made shorter, it will bet hotter for a given amount of power, and when the wire is made longer, it will get cooler for a given amount of power. For general electronic device where the current and-or power drops are relatively low, the maximum power rating of nichrome wire, say at its melting temperature, is generally not exceeded. For an air heater it is better to have a longer length of "heating element" wire, such as nichrome wire, so that the total surface area of the wire is larger, and so that there is then more contact with the cooler air and the thermal heat transfer and-or or exchange to the air is more efficient and-or faster.

CAUTION: For high power, household devices, and of which often have a low resistance such as for an air heater, it is recommended to **not use an extension cord** (ie., essentially, a two wire cable to transfer AC power) with it. This rule is due to the voltage divide concept with two low resistance values, here the device resistance and the cord resistance, and that the cord will therefore have a significant amount of power loss in it which will raise its temperature, and it could melt its insulation and-or cause injury and-or fire.

When a metal is put in a more pliable state.

When a metal is made pliable (ie., somewhat like plastic, bendable), its state could be described as being between the state of a solid and the state of it being liquid. It is generally obvious that a thin metal is more pliable than a thicker piece of that same metal. A common example of deliberately placing a metal in this pliable state is with blacksmithing, and this is briefly discussed next.

A **blacksmith** can take a piece of pre-made steel from a steel factory or scrap (unused product remainder, "left over", unused, used and-or to be recycled) metal, and cut and hammer (ie., "forge") it to produce a product. It is of note that thin metals are often bent and-or shaped without first heating them when using the powerful bending and-or shaping machines which have a high amount of force, accuracy and quality. Heating them will make them more pliable for these machines to work with, and particularly for bending and-or shaping thicker pieces.

Before blacksmiths and machinist works with the metal such as steel, they will soften or "**anneal**" the steel by heating it hot and then allowed to slowly cool so that it is slightly softer and less brittle to work with, and this allows it to be more easily shaped and is less prone to breaking in the process. Once the steel has been worked into the desired shape, it is usually "**heat-treated**" so as to have a better, more uniform and stronger (atomic, atom) crystal structure that is more resistance to wear since it is harder. This process is usually done by heating the steel to a high temperature and then quickly quenching or dipping it in water or oil. Making the steel harder will also make it more brittle, therefore, this process may also be followed by what is called "**tempering**" the steel so as to help reduce its brittleness slightly and yet still maintain a fairly hard steel, and this process is to heat it up to a lower temperature, and then let the steel cool slowly.

LIST OF THE KNOWN ELEMENTS

1 Element , 2 Symbol , 3 Atomic Number , 4 Standard Atomic Weight (g / mol) , 5 Density = p = (g/cc)

3: (# of proton mass units per atom)
(2)(Atomic Number)=Atomic Mass
= Atomic Mass Units = AMU
for the element atom

4: ("molar mass")
(Total sum of mass of
1 mol of atoms)
(typical, average)

5: (Mass of 1 cc of volume)
(g/cc = g/cm^3 = g/mL)
Weight is proportional
to mass, volume, density
and gravity. Mass is
constant: m = p V = F / a

1	2	3	4	5	
Actinium	Ac	89	227	10.07	: radioactive , a bright colored, soft metal, has a faint blue glow
Aluminum	Al	13	26.98	2.698	: a lite-weight metal, often used for soda cans, etc.
Americium	Am	95	243	12	: man-made, radioactive, often used in smoke detector alarms-
Antimony	Sb	51	121.76	6.68	-having less than 0.5ug of Am-241, half-life of 450 yrs
Argon	Ar	18	39.95	0.001784	:a gas, at STP (Standard [reference] Temp. and Pressure)-
Arsenic	As	33	74.92	5.72	-STP = 0°C = 32°F and 1 **Atm**osphere = 14.7psi
Astatine	At	85	210	6.35	: a non-metal
Barium	Ba	56	137.33	3.59	: a soft metal, used in the medical and electronics fields
Berkelium	Bk	97	247	14.78	
Beryllium	Be	4	9.012	1.85	:a lite-weight, hard brittle metal, for alloys, crystals called emeralds
Bismuth	Bi	83	209	9.81	: melts at 520 °F , slightly toxic - avoid inhalation of its dust
Bohrium	Bh	107	270	26.5	: man-made, synthetic, has a short half-life
Boron	B	5	10.81	2.34	: has a high melt point at 3770 °F; has a strong crystal structure
Bromine	Br	35	79.9	3.12	: a non-metal
Cadmium	Cd	48	112.41	8.65	: a soft metal, a carcinogen to lung and body, **toxic** build up
Californium	Cf	98	251	15.1	: a synthetic element, highly radioactive, decays to curium
Cesium	Cs	55	132.9	1.88	: some isotopes are radioactive, melting point is ~ 83 °F
Carbon	C	6	12.011	2.267	: a non-metal,but the graphite forms can conduct electricity
Calcium	Ca	20	40.08	1.54	:a soft metal, reactive with water, a nutrient, used in alloys
Cerium	Ce	58	140.12	6.7	: a moderately soft metal, named after the proto-planet Ceres
Chlorine	Cl	17	35.45	0.0029	: a gas at STP
Chromium	Cr	24	52	7.15	: stainless steel has about 10% or more chromium
Cobalt	Co	27	58.93	8.9	
Copernicium	Cn	112	285	23.7	
Copper	Cu	29	63.55	8.96	: greatly used for electricity wires, coils, electromagnets, pipes-
Curium	Cm	96	247	13.52	: synthetic, highly radioactive - copper melts at 1948 °F
Darmstadtium	Ds	110	281	34	
Dubnium	Db	105	268	29	
Dysprosium	Dy	66	162.5	8.54	: can be used to increase max. temperature of NdFeB magnets
Einsteinium	Es	99	252	8.84	
Erbium	Er	68	167.26	9.07	
Europium	Eu	63	152	5.24	
Fermium	Fm	100	257	9	: man-made = synthetic, highly radioactive , decays to californium
Flerovium	Fl	114	289	14	
Fluorine	F	9	19	1.7	:a gas at STP, very high reactivity, used to help melt metals, toxic
Francium	Fr	87	223	1.87	
Gadolinium	Gd	64	157.25	7.9	a rare metal, used to improve MRI scans, may cause kidney issues
Gallium	Ga	31	69.72	5.9	: a metallic liquid at just 85.58 °F = 29.76°C , for alloys and -
Germanium	Ge	32	72.64	5.3	: used in semiconductors - semiconductors
Gold	Au	79	197	19.28	: a precious metal, malleable , non-reactive, melts at 1943 °F
Hafnium	Hf	72	178.5	13.1	:a rare metal , for special alloys , melting point =~ 4050°F

Hassium	Hs	108	269	41	
Helium	He	2	4.0026	0.0001785	a gas at STP
Holmium	Ho	67	164.93	8.8	a rare earth metal, reactive , used in lasers, MRI machines
Hydrogen	H	1	1.00784	0.00008988	a hydrogen atom has 1amu, 1mol of hydrogen is ~1 gram- -hydrogen is a gas at STP
Indium	In	49	114.82	7.31	
Iodine	I	53	126.91	4.93	a non-metal , a vital nutrient in trace amounts, often put in salt
Iron	Fe	26	55.85	7.87	melts at 2800 °F
Iridium	Ir	47	192.22	22.6	rare, high corrosion resistance, melts at about 4430°F
Krypton	Kr	36	83.9	0.00373	a gas at STP
Lanthanum	La	57	138.91	6.15	a soft metal, reactive in air and water, various uses
Lawrencium	Lr	103	266	16	
Lead	Pb	82	207.2	11.342	melts at 328°F , **toxic** , moderately soft, very malleable
Lithium	Li	3	6.94	0.534	the least dense metal, soft , reactive with water , floats in H2O
Livermorium	Lv	116	293	12.9	
Lutetium	Lu	71	175	9.84	rare, a hard metal
Magnesium	Mg	12	24.31	1.74	an esential nutrient to humans and for photosynthesis in plants
Manganese	Mn	25	54.94	7.3	hard, but brittle, used in alloys, an essential nutrient
Meitnerium	Mt	109	278	28	man-made, synthetic , has a short half-life
Mendelevium	Md	101	258	10.3	
Mercury	Hg	80	200.6	13.53	a liquid at about -38°F = - 38.8°C , toxic - need a license
Molybdenum	Mo	42	96	10.3	a hard metal, an essential nutrient, used in alloys
Moscovium	Mc	115	289	13.5	
Neodymium	Nd	60	144.24	7.0	used in a mix of metals (NdFeB) so as to make strong magnets
Neon	Ne	10	20.18	0.0009	a gas at STP
Neptunium	Np	93	237	20.4	
Nickel	Ni	28	58.7	8.91	used in some magnets, coins and stainless steel
Nihonium	Nh	113	286	17	
Niobium	Nb	41	92.9	8.57	used for some alloys, and special magnets for MRI scanners
Nitrogen	N	7	14.007	0.0012506	a gas at STP
Nobelium	No	102	259	9.9	synthetic, highly radioactive, short half-life , decays to fermium
Oganesson	Og	118	294	5	
Osmium	Os	76	190.23	22.5	rare, the most dense metal known, 22.5 times denser than water
Oxygen	O	8	16.0	0.001429	a gas at STP
Palladium	Pd	46	106.42	12.02	a reare, prescious metal
Phosphorous	P	15	30.974	1.82	a non-metal , white phosphorous is toxic and can ignite , glows
Platinum	Pt	78	195.08	19.46	a rare, prescious metal, used to reduce smog from vehicles
Polonium	Po	84	209	9.35	extremely radioactive, danger
Potassium	K	19	39.1	0.862	a soft metal, reactive to water, a nutrient in small amounts
Plutonium	Pu	94	244	19.82	extremely radioactive , danger
Praseodymium	Pr	59	140.91	6.7	
Promethium	Pm	61	145	7.26	
Protactinium	Pa	91	231.04	15.39	
Radium	Ra	88	226	5.5	"ray" , highly radioactive, from decayed uranium , danger
Radon	Rn	86	222	0.0097	a gas at STP , from decayed radium , radioactive , danger
Rhenium	Re	75	186.21	21	rare, very dense, high melting point of 5767 °F
Rhodium	Rh	45	102.91	12.4	rare, very expensive, high heat tolerable, corrosion resistant
Roentgenium	Rg	111	282	28.7	very dense
Rubidium	Rb	37	85.47	1.53	
Ruthenium	Ru	44	101.07	12.4	a very rare metal, hard, corrosion resistant , used in electronics
Rutherfordium	Rf	104	267	17	man-made, synthetic , has a short half-life , decays to nobelium
Samarium	Sm	62	150.36	7.53	a rare metal, used in high temp. samarium-cobalt magnets
Scandium	Sc	21	44.96	3	a rare-earth element
Seaborgium	Sg	106	269	35	

Selenium , Se , 34 , 78.97 , 4.8 : a non-metal, is one of the trace, essential nutritional minerals
Silver , Ag , 47 , 107.87 , 10.5 : a precious metal , melts at 1762 °F
Silicon , Si , 14 , 28.085 , 2.33 : used in semiconductors and solar-cells , melts at 2577 °F
Sodium , Na , 11 , 23 , 0.971 : a soft metal, reactive to water, part of the food Salt NaCl molecule
Strontium , Sr , 38 , 87.62 , 2.64 : radioactive
Sulfur , S , 16 , 32.065 , 2.067 :a non-metal (ie., does not conduct normal electricity, not reflective)
Tantalum , Ta , 73 , 181 , 16.7 : dense, used in high capacitance capacitors and alloys, mp=5468F
Technetium , Tc , 43 , 97 , 11.5
Tellurium , Te , 52 , 127.6 , 6.28 : a rare metal, brittle, increases conduction with temp. and light
Tennessine , Ts , 117 , 294 , 7.2
Terbium , Tb , 65 , 158.93 , 8.25 : relatively soft, used to hehlp make green phosphors, electronics
Thallium , Tl , 81 , 204.38 , 11.85
Thorium , Th , 90 , 232.04 , 11.71 : has potential for safer nuclear fueled , electric power plants
Thulium , Tm , 69 , 168.93 , 9.32
Tin , Sn , 50 , 118.7 , 7.29 : commonly used in alloys of metals, melts at 500 °F
Titanium , Ti , 22 , 47.87 , 4.54 : has a low density, but strong
Tungsten , W , 74 , 183.84 , 19.25 : very dense , has a very high melting point of 6192 °F
Uranium , U , 92 , 238.03 , 18.98 : a nuclear fuel for the generation of electricity via fission and heat
Vanadium , V , 23 , 50.94 , 6.11 : a hard metal, used in alloys
Xenon , Xe , 54 , 131.3 , 0.0055 **:** a gas at **STP** (**S**tandard [reference]**T**emperature and **P**ressure)
Ytterbium , Yb , 70 , 173.05 , 6.95
Yttrium , Y , 39 , 88.9 , 4.47
Zinc , Zn , 30 , 65.38 , 7.134 : melts at 787 °F , used in some batteries
Zirconium , Zr , 40 , 91.224 , 6.52 : cubic zirconia is a crystal of zirconium dioxide (ie., has oxygen), and it may look like carbon diamond gem crystal, but with more rainbow colors or prism effect output of the incoming light.

The above values for atomic mass considers the typical amounts of natural isotopes in typical samples of the element, and are then essentially an average atomic mass, and where a small fraction of that mass is due to the mass of the low percentage of isotopes (ie., slightly changed atom structure) in the sample of the element.

Carbon has the highest melting point (mp) temperature of any element. The melting point of carbon is 6420 °F, and this is even higher than that of tungsten. This is due to its atomic structure and bonds. Graphite (a crystalline form of carbon) electrodes can be used in high current electricity and heating applications. Regular Carbon electrodes have a shorter time of use than graphite, but are also less expensive.

As of the year 2024, the 23 elements (or 20% of all the known elements) with atomic numbers from 95 through 118 are man-made and-or synthetic, and since they have not yet been found naturally. These elements are radioactive to some degree, and the higher the atomic number, the shorter the half-life time, hence they decay (release radiation) and-or change to another and more stable element more rapidly, hence radiate more radiation. A few other elements having atomic numbers 84 to 94, except 90 and 92 and including 43 and 61, are very rare and as only trace elements naturally, and they are rather also produced synthetically in particle accelerators ("atom colliders" or "atom smashers") and nuclear reactors by using an element with a lower atomic number and adding some protons or neutrons to its nucleus. It does this by giving a high kinetic energy to an atomic particle(s) which will be aimed at and strike the target material or element. Americium is a synthetic element that is used in many smoke detectors so as to help save lives and property, but there is other ways to detect some smoke such as by using a light sensor. Americium is made from a certain isotope of plutonium and has a much lower half-life. Americium decays to neptunium.

Hydrogen is considered the first and fundamental element, and that all other elements came from it later by applying huge forces to hydrogen atoms and further atoms of other elements created. The "Big-Bang" central explosion (still difficult to prove as of 2024, and some say a higher intelligent power could create it) which probably started the expanding universe. It is now thought that neutrons are another state or construction of a proton which has 2 up quarks and 1 down quark particles. Helium contains 2 protons, 2 neutrons,and 2 electrons. A neutron has 1 up-quark and 2 down-quark particles.

Sometimes when a radioactive or unstable element with extra neutrons emits radiation and decays, a proton and electron is created from a neutron. From observations, it is understood now that the mass of a neutron is slightly more than the mass of a proton, and therefore the atomic number of an atom of a element may have a small fractional value added to it. It could be thought that the mass of a neutron is equal to the mass of a proton and electron, and-or that a neutron is composed of the both mass of the proton and electron, and that the proton and electron charges either do not exist in the neutron and will arrive only when a neutron breaks apart and-or decays, and-or that the electric charges balance and cancel each other when in the neutral charge neutron.

Of the 118 known elements as of the year 2025, about 80% of them are **metals**. Of the remaining 20% of elements, they are classified as **metalloids** (about 5% of the elements, typically elements of which semiconductors are made from after mixing traces of other elements in them), and **nonmetals** (about 15% of the elements).

The 7 common **metalloids** are: antimony, arsenic, astatine, boron, germanium, silicon and tellurium

The 11 typical **nonmetal** elements that are gases are at STP (Standard temperature and pressure conditions): hydrogen, helium, oxygen, fluorine, neon, nitrogen, chlorine, argon, zenon, radon, krypton

The 6 typical **nonmetal** elements that are solids at STP are: carbon, phosphorus, sulfur, selenium, bromine (liquid at room temperature), iodine

The 6 **noble gases** at STP are: argon, helium, krypton, neon, radon (dangerous for long exposure), and xenon Nobel gases are also called inert gases, and of which are nonreactive (ie., stable) and non-bonding with other elements so as to make molecules. Their outer electron shell is full, hence it does not contain a loosely bound electron(s), or an electron gap or hole for other atoms and their electrons to bond with. These gasses are usually nonflammable, colorless, odorless, and have a relatively low boiling point temperature.

It is interesting to note that at standard temperature and presssure, the first two elements: hydrogen and helium are gasses, and already **the third element: lithium is already a solid and not a gas**. This is so even though llithium is a low density solid and metal, but it is still much higher than that of a gas. If the atoms of an element can join together into a crystal structure, they will create a solid.

How a star such as the Sun releases heat and-or light energy.

A star contains condensed hydrogen gas where each hydrogen atom has 1 proton and 1 electron. This hydrogen is from large hydrogen gas cloud in space, and of which will naturally condencse together naturally via the gravity of its atoms. This condensed hydrogen gas can then ignite due being subjected to intense pressure at the center of the Sun, and this then becomes a self-sustaining chain reaction of the **fusion** or joining of hydrogen atoms together, and into helium atoms. During this process, excess mass and energy is converted to energy (usually light, photon energy) and is radiated during that process where essentially two or more atoms becomes one atom. This fusion process in a star will convert hydrogen atoms into helium atoms. In particular, 4 hydrogen atoms consisting of a total of 4 protons and 4 electrons, will eventually be fused together, one at at time, so as to form 1 helium atom having 2 protons, 2 neutrons, and 2 electrons. Here are the common proton-proton chain of fusion steps and results within a star:

1 Hydrogen atom fused with 1 hydrogen atom becomes 1 deuterium atom having 2 protons.
Deuteriuim is an (heavier, more mass) isotope of hydrogen, and is sometimes called as hydrogen-2.

2. 1 deuterium atom fused with 1 hydrogen atom becomes 1 heliium-3 atom having 2 protons and 1 neutron.

3. 1 helium-3 atom fused with 1 helium-3 atom becomes 1 helium-4 atom having 2 protons and 2 neutrons,
The 2 extra protons will become free protons after this process. Helium-4 has slilghtly less mass than the hydrogen atoms used to make it. Helium-4 is a isotope of helium, and it is stable.

Common Particles Within Atoms (Atomic Particles)

Fundamentally, each element has a unique and the same number of protons, neutrons and electrons in each of its (similar) atoms. These basic parts of an atoms are what give the atom its mass (a measure of the amount of physical matter). Protons and neutrons are called atomic mass units, and are generally thought of as the main particles of mass in an atom. Note that the number of **amu** (or u, **atomic mass units**) per mole of an element in basic atomic theory is:

amu per mole of atoms of an element = (number of amu per atom of the element)(number of particles in a mol unit)
amu per mole of atoms of an element = (2)(atomic number)(Avogadro's number)

The number of amu per gram of atoms of an element in basic atomic theory is:

amu per gram of an element = (amu per mole of atoms of the element)(number of mol of atoms per gram)

The number of atoms per gram of an element in basic atomic theory is:

atoms per gram of an element = (amu per gram of the atoms of an element) **/** (amu per atom of the element)
or (amu per gram of the atoms of an element / 2) **/** (number of protons in each atom)

: For hydrogen, atoms per gram = (amu per gram of hydrogen), and not divided by 2 since hydrogen does not have a complementary neutron for each proton. Also hydrogen has 1 amu per atom, and which is 1 proton.

The number of atoms of an element, per mol of amu is: (Avogadro's number) / (amu per atom of the element)

Note also that 1 mol of amu is defined as having a mass of 1g, hence the value above is also equal to:
number of atoms of an element per gram = (Avogadro's number) / (amu per atom of the element).

It is believed, and expressed here in simplicity, that the "Big-Bang" (ie., like a highly energetic "supernova" or explosion of a star) origin of the universe contained all the initial particles (electrons, protons and neutrons) of the atoms and mater, and that the first atom created shortly afterwords was the hydrogen atom. It would later take the gravitational forces of a large hot energized star to create (ie. due to a "fusion" of particles) most of the other "heavier (in weight)", more massive elements from the hydrogen gas and some other low density atoms or elements such as helium. To create all the other elements that are more dense than iron, a star will need to undergo a supernova (ie., explode, creating tremendous pressures in regions of and near it) and-or collide with a relatively small (about the mass of the Sun), very dense neutron star that is the remnant of some "collapsed star" such as from a previous supernova, and has an abundance of neutron atomic particles that do not have an electric charge. In general, and statistically, the greater the density of an atom or element, the less abundance of it and the less stable it is, and can "decay" into, change or convert to a lighter (less dense, less weight), less massive element (same atoms) and having greater stability. After the (probable) big-bang, by the force of gravity (ie., force of attraction of matter), matter condensed into stars, orbiting planets, moons, asteroids, comets, and galaxies of stars held by their own gravity. The majority of the mass of the Earth and its life are sometimes said as being made of "**stardust**". In general, given a hot molten planet, the more heavier, denser elements will sink to the core region.

The metals called **alkali metals** are generally found in nature only as an oxide (molecule contains an oxygen atom) form since the react with other substances such as water and easily loose a valence electron and become positive charged ions, here with a net charge of (+1), and are sometimes called cations (cathode or cathodic ions). Sodium, potassium, lithium, rubidium and caesium (aka: cesium) are alkali metals, often called the "lithium members, family or group" of metals in the periodic table of elements. These metals are soft and very reactive, and will oxidize in the air and react highly with water and-or moisture. Sodium, potassium, and a trace amount lithium are essential or vital nutrients for the human body. Alkali metals area also aid to be base (on the pH scale, > 7.0) metals and will form hydroxide ions (OH-) when dissolved in water. Calcium metal is a soft metal, and is also an essential or vital nutrient, but is not in the same group of metals as those just mentioned, and is in the "alkaline earth metal" group along with metals such as magnesium and barium, and these are also often found in nature in its oxide (molecule contains an oxygen atom) and compound forms such as limestone, and having lost two valence electrons, and hence having a net positive charge of (+2). About

4% of the Earth's crust in weight is calcium metal, hence it is farily common. **Hardening of the arteries** is a serious health issue and is caused by **calcium** buildup on the walls of blood vessels; seek doctor and-or nutritional guidance.

Notice that most elements except the gases and a few other elements are metals. Carbon, sulfur, phosphorous and iodine are the most common non-metalic elements. Some elements such as the ones known as semi-conductors are sometimes called **metalloids**. The most common metalloids or semi-metals are silicon, germanium, boron and antimony,, tellurium, arsenic Metalloids have properties of both metals and non-metals, hence they are often semiconductors which do not conduct electricity very good. Metalloids are brittle, and this can be easily seen while handling a thin and brittle, glass-like silicon solarcell.

The density (d = m / V) of metals is generally or universally a constant and-or average value with not much deviation from it, however the density of gasses greatly depends on the heat and-or pressure applied to them, such as by an atmosphere and-or a heat source such as it being deep in the ground and-or a volcano chamber. We see that the density of gasses can vary widely by the physical conditions applied to it, and so their density is usually expressed as its density at a **standard temperature and pressure (STP)**.

(The reader may skip over this discussion if it is too complex right now and-or may view it at another time.)

An example of comparing density (p) and atomic mass (g/mol) values of two elements:

	P	(g/mol)	p
Aluminum , Al	13	26.982	2.698
Iron , Fe	26	55.845	7.87

: P = number of protons ,

Iron has twice the number of atomic mass particles in each atom as compared to aluminum:

Calculated here using just the given number of protons for each atom:

$$\frac{\text{\# of protons in an atom of iron}}{\text{\# of protons in an atom of aluminum}} = \frac{26}{13} = 2$$

: iron has twice the mass , or divide the amu in each element atom

Now comparing the corresponding densities, (g/cc):

$$\frac{\text{density of iron}}{\text{density of aluminum}} = \frac{7.87 \text{ g/cc}}{2.698 \text{ g/cc}} \sim= 2.91\underline{7} =\sim 3.0$$

: about three times as much per unit volume. A cubic-centimeter of iron will weigh about 3 times more than a cubic-centimeter of aluminum. Also note the equivalent fractions to make for density: 1g / volume = 1g / x cc. Ex. Iron has 7.87g/1 cc = 1g / 0.127 cc

If the mass or amount of a substance or material of something such as a particular element increases by a factor (n), then the weight of that something will also increase by the same factor of (n), and vice-versa. If the mass and-or weight of something increases by a factor (n), then the volume of that something will increase by that same factor of (n), however, the linear physical dimensions (L, W, H, such as for a cube shape) after that increase will only change by the cube-root of (n). For example, given 1 cube (ex, L=1 unit, W=1 unit, H=1unit) that has a mass of 1 gram, if you then make a larger cube of that same substance, say L=2 units, W=2 units, H=2 units, then this cube is: 2 x 2 x 2 cubic units = 2^3 cu. units = 8 cu. units. At t 1 gram/1 cu. unit, this is then 8 grams total mass. The cube root of 8 unit^3 is 2 units^1 = the linear dimensions of it.

Geometrically, mass and weight are one dimensional, linear or a "**scalar**" concept of a unit, and a volume unit is a three dimensional. Consider a unit cube with each side length (L, W and H) of 1 and having a volume of 1 cubic unit. If the length of the side of a cube doubles from 1 to 2, a linear change, the corresponding volume increases from 1 to 4 cubic units, hence the corresponding volume changes are not linear or proportional. If the linear (dimensions, mass, weight) change is (n), the corresponding volume change is (n^2), hence the change is **exponential** (not linear, as in a certain factor or constant) increase.

A doubling of atomic mass units (AMU) does not mean there will be a doubling of the size (width, volume) of a theoretical spherical nucleus of an atom. The sphere-like or shell-like atomic arrangement of the atomic mass units within each atom and the orbiting electrons, and of the atom alignments and-or crystal structure and its atom alignment and spacing of a particular element will affect the amount of substance (ie., mass) in a given volume, and this will then be reflected into the volume and density value of that particular element. **Density of an element is not proportional to the atomic number of that element, but it is usually related to its value. Higher atomic number elements generally have a higher density.**

Consider having 100 atomic mass units such as protons. If you were to arrange them into a side by side square plane (2 dimensional) shape, there would be $\sqrt{100}$ = 10 atomic mass units x 10 atomic mass units. 100 atomic mass units side by side would be 100 units long, but the area would only have 10 mass units per side or dimension. In short, the density and-or volume of an element is not proportional to the number of atomic mass units of an element. Consider "heavier", "more dense" elements with more atomic mass units per atom will then have a smaller volume per gram of mass.

If you were to arrange 100 atomic mass units into a side by side cube shape (3 dimensions), there would be $\sqrt[3]{100}$ =~ $4.64\underline{2}$ atomic mass units for each unit of length, width and height. To complicate matters, various sized atoms having various amounts of mass (amu = atomic mass units which are protons and-or neutrons), and various atomic arrangements and-or crystallization will also affect the volume of a mass, and therefore the amount of atoms needed to fill a given amount of volume such as a 1cc. Generally, entire atoms are worked with since the particles of it are essentially locked into position and cannot be normally isolated and that their mass is too small to be isolated, counted and of practical use. Even the mass of even an atom is too small to be isolated, measured, counted and be of practical use, and a huge number of atoms called a mol (or "mole", an old word for mass) of particles is used as the reference unit for the number of atoms to be worked with in a practical and measurable (by weight) manner.

If you had 10 atomic mass units and increased it by a factor or 10 or "10 times" to 100 atomic mass units, the corresponding weight would increase by 10, but the corresponding volume would only increase about 4.64 times as shown above. 4.64 is considerably less than 10. The volume in this example would have 4.64 units per side or dimension.

Atoms with more **atomic particles** (neutrons and protons) or atomic mass units (amu) have more atomic mass units per atom. Their atomic mass per atom is higher, or in other words, their atomic mass unit density per atom is higher. Atoms with more atomic mass units will correspondingly and proportionally weigh more. Bigger atoms with a larger diameter and volume will require more volume for a given number of atoms, and therefore mathematically, for a given volume, there will be fewer larger atoms per volume than the number of smaller atoms that have fewer atomic particles (amu). As indicated above, volumes for the number of (amu) particles and-or atoms are not proportional. For a given weight, there will be also be fewer larger mass, diameter or volume atoms than the number of smaller mass, diameter or volume atoms, but still, the total number of particles (amu) due to the larger mass (amu) atoms will be the same amount as that of the lower mass (amu) atoms for a given weight. Weight is therefore a better indicator, comparator, or "scale" of determining an amount of mass, material or substance than volume is.

On a scale, if two substances have the same weight, their amu count or total mass is the same, and regardless of the various types of atoms (ie. elements) which have different amu amounts.

As a thought example:

Substance or Element	amu per atom	atomic weight per atom
A	5	5 units of amu weight or "5 weight units"
B	10	10 units of amu weight or "10 weight units" Here, since mass is twice as much, its weight is twice as much. That is, if mass doubles, weight doubles.

Given 1 atom of substance B, it will take 2 atoms of substance A so as to have the same amount of total (amu) mass and weight.

Weight is a property that depends on both the amount mass and the strength of the local gravity influencing it with a force and giving it that weight value. A mass value is universal, however weight values are not. For example, the weight (a force) of an object will be less on the Moon than it is on Earth, and this needs to be considered for various kinds of science research.

A gram was originally defined as a unit of weight, and specifically, it was defined as the weight of 1cc of water at 4°C. If some other substance weighed the same amount, then it has the same mass in terms of the number of amu, but not in terms of the number of atoms which for different substances or elements have a different number of amu per atoms.

For a given weight value, say an ounce of weight, when the amu per atom increase, such as for another element, there will be fewer atoms needed for the same weight.

The more amu particles, substance, or material in a unit volume, the more mass in that volume and the denser that material is said to be. density = mass / volume . As indicated before, given atoms with a larger mass, there will be fewer of them for a certain weight. This is an inverse relationship. For a given number of atoms, larger mass atoms will occupy a larger volume than that of lower mass atoms. More lower mass atoms can be put into a certain volume than larger mass atoms.

For learning more about matter and mass, please see the following discussion called: More About Matter, Mass And Mol,

Fundamentally, for pure samples of an element have the same number of protons and electrons, and without considering the possibility of a small percent of atoms being isotopes. An **isotope** is a **nuclide** (an atom of an element that has a different number of protons and-or neutrons. "ide" is a word suffix with a general meaning of a combination of things) with the same number of protons and a different number of neutrons than the average, common or fundamental atom of the same element. For an example, "atomic" or fundamental hydrogen with one proton is sometimes called **protium**, and hydrogen with 1 neutron (created from a hydrogen proton, during fusion) added is an isotope of hydrogen called **deuterium.** Deuterium is used in "heavy water" that cools and prevents hot nuclear fuel rods from melting, and it also absorbs radiation. Hydrogen (one proton) with 2 neutrons added is called **tritium** which is usually man-man = artificially made = synthetic, often from colliding lithium atoms witih neutrons, and of which is ("low energy" beta) radioactive with a half life of 12.3 years. Tritiuim decays (or "reduces or converts to" after releasing radiation) to **helium-3** which is stable, and which has 2 protons and 1 neutron. Helium-3 is very valuable as a future energy fuel, and there is a large amount of it on the Moon's surface. The radiation from tritium can also be used to cause a phosphor coating to glow (ie., gain energy and will then emit that energy as visible light) and can then be used in indication lamps for low-light and-or night-time usage. The cost of tritium is about $30 USD per milligram as of the year 2024.

Atomic Mass (matter) = (2)(Atomic Number) = (atm) of each atom of that element
= (2)(number of protons)
= (number of protons) + (number of neutrons) = atomic mass units = amu

When the probable or actual number of neutrons are considered, the atomic weight or mass of an atom is, at minimum, twice the atomic (proton) number plus some small percentage of that atomic number due to a high probability of some isotopes (have extra neutron(s)) of that element that may be present in the sample. This small increase generally increases as the atomic number increases. Though an atomic (proton) number of an element is constant, the more accurate atomic mass is an average or expected value that can be considered. The mass of an electron is very negligible and is generally not considered for the atomic mass (or weight) of any atom. The mass of an electron is sometimes noted as about (1/2000) or more modernly and precisely as about (1/1836) that of 1 proton or 1 neutron. The sum of the mass of all the electrons in an atom is still negligible and does not even come close to the mass of one proton or neutron. With this reasoning, 2kg = 2000g of mass will have about 1g of mass due to electrons.

Ex. The most common or pure form of carbon has an atomic (proton) number of 6 has an atomic mass of 12 and is identified as C12 ("carbon-twelve") and has a fundamental atomic mass of 12amu (atomic mass units = protons + neutrons). When considering a small percent of those carbon atoms in the sample being probable isotopes, such as C14 ("carbon-14") which has 2 extra neutrons and which increases the total number of atomic mass units in that atom, and the "weighted" or average mass is slightly higher than 12, is considered as 12.0107amu. Though this is only a small percent increase, but when considering many millions of probable isotope atoms in the sample of the element, this small percentage may need to be considered. Certainly, a pure (all similar atoms) sample of C14, having slightly more mass than C12, weighs slightly more than C12 of the same volume.

Ex. Iron atomic (proton) number is 26, and its atomic mass is therefore (2)(26 amu)=52 amu, however due to isotopes often being present in most (practical) samples, its atomic mass or "molar mass" (g/mol) is listed as 55.845. The concept of mol ("mole", unit of the amount of matter) is given a robust discussion ahead of this topic. Taking the reciprocal of this value we can find (mol/g), and it is: 1 / (55.845g/1mol) = 0.017906706 mol per gram. If 1 mol of atoms is to 6.023 (10^23) atoms, then 0.017906706 mol is to (x) atoms, after solving for (x), x atoms = (mol)(atoms / mol) = (0.017906706)(6.023)(10^23) atoms = 0.10785 (10^23) atoms , in 1 gram of iron. or: 55.845g = 1 mol atoms = (6.023)(10^23) atoms , after dividing both sides by 55.845: 1g iron = 1.0785 (10^22) atoms.

For stable, (electrically) balanced or neutral atoms, the number of electrons (-, neg. charge) equals the number of protons (+, charge). Neutrons have approximately the same mass as that of the protons, but neutrons do not have an electric charge to consider for electric and electro-chemical reactions.

Natural isotopes of elements that have a very long half-life and are said to be stable and naturally emit none or very low radiation. Unstable or radioactive isotopes (or a specific "nuclide" form of an atom with a certain number of neutrons or protons) decay into other atoms. Isotopes can also be artificially ("man-made", not naturally, "synthetically") produced by using the high energy and speed of atomic particle collisions such as in particle colliders.

Ex. C12 is "carbon twelve" which is the fundamental form and atomic mass of carbon. C14 is a (radioactive) isotope of carbon or C12. It has two more neutrons, and is made naturally in relatively small quantities (about 1 in a trillion atoms of carbon) due to cosmic radiation, and can be absorbed (ie., breathed, etc) by living things until they no longer are alive. C14 has a half life of about 5700 years, and can be used to help determine the age of the material which contains it. C14 has two extra neutrons as compared to C12. Much of the weight of living plant matter and trees is due to the presence of water, but the solid matter remaining is mostly carbon due to carbon-dioxide gas from the air that the plant matter "breathed" as part of their **photosynthesis** process to produce sugar from sunlight and carbon-dioxide. The photons from the sunlight will split apart the **carbon-dioxide (CO2)** molecule into carbon and oxygen atoms, and produce a sugar fuel for the plant. The water in living matter gives it substance for growth, nutrient and process fluidity and mobility (or "transport"), and is also used to as part of its circulation (ie., transportation, distribution) of nutrients and-or waste removal, and temperature control. All the **life** that we know of is said to be mostly hydrocarbon (a water and carbon molecule and-or compound) based with other various atoms (minerals, elements) used to create other molecules such as for vitamins (nutrition) that the body uses for certain necessary processes for its sustenance and energy, growth and repair. Natural substances that compose and-or promote living organisms are called **organic**. C14 radioactively decays naturally (back) into N14 = nitrogen14 and which is the most common and stable form of nitrogen. Plants absorb carbon dioxide from the atmosphere and convert it into sugar, carbon and oxygen. A dry piece of wood has a high carbon content of about 50% and about 40% oxygen by mass or weight, and the remaining 10% is trace minerals. About 1% of a dry piece of wood is converted to wood ash after it is burned (combustion). The dry ash contains forms of about 50% calcium, 25% potassium and 7% magnesium, and reasonable trace-levels of sodium, phosphorous, silicon, and iron. The type of the plants or trees, and-or its soil and environment will help determine what minerals it contains. If the heat was high during the combustion of the wood, then some elements may be turned into gas and essentially "vaporized" into the atmosphere if not collected, and this is what happens to most of the carbon mass. It is usually converted into carbon dioxide (CO2) gas, and-or is converted to poisonous **carbon monoxide** (CO1 = CO) gas and soot (mostly carbon particles) if it was weakly (**incomplete combustion** such as due to a low amount of oxygen) burned (combusted with oxygen). Soot, a fine particle, carbon byproduct of combustion can dangerously clog or block a chimney and-or reduce its performance of getting the fumes outside into the air, and away from your lungs to breath. It is part of the visible "smoke". Carbon monoxide is flammable. It can also be a health and fire hazard. Carbon monoxide (CO1 = CO) with one oxygen atom per molecule is very similar to **carbon dioxide** (CO2) which has two oxygen atoms in its molecule.

Carbon monoxide (CO) can attach itself (connect, bind) to hemoglobin in the blood which carries oxygen to the body, and therefore, it can deprive the body of oxygen it needs, and this can cause sickness and-or can be fatal. People have fallen asleep and later died when the concentration of CO in the blood increased. Carbon dioxide is also produced by people exhaling, and this can be a health problem if there is not a sufficient amount (% per volume) of oxygen available in the local area, room, etc, and some symptoms are dizziness and concentration issues. If a person has carbon monoxide or carbon dioxide poisoning, remove them from the local environment, and-or ventilate the area so as to breath in less CO or CO2. Seek medical attention, dial 911 if in the United States, and one treatment is to breath in pure oxygen for an amount of prescribed time. Carbon dioxide can also lower the pH in the blood and body, and therefore it can cause an acidity issue.

Plants enjoy carbon dioxide, and release (ie., essentially exhale) oxygen. Carbon monoxide and carbon dioxide are odorless colorless. Some sensitive people can smell a high level of carbon dioxide as an acid-like smell, but not carbon monoxide. Even very low concentrations of carbon monoxide can cause health issues. CO is sometimes used in the chemical industry to make products. Dry-ice is the frozen, solidified form or state of matter of carbon dioxide gas. There are electrical devices and-or alarms (much like a smoke and-or fire alarm) that are available which can sense the level of carbon monoxide or carbon dioxide in the local environment.

> The density of carbon dioxide is: 0.00198 g/cc , and the density of carbon monoxide is: 0.00145 g/cc
> Since air has a typical density of about 0.00124 g/cc, = 1.24g/L both carbon dioxide and carbon monoxide are heavier than air gas (mostly nitrogen and oxygen) and will tend to be at a lower level in a room with no fan circulating and mixing the gasses in that room.

A **candle**, when ignited (ignition, "started") by another heat source, and becomes lit (ie., has a "flame", self ignition, chain or continuous reaction process, once it is started) is a form of combustion of the carbon, hydrogen and oxygen in the wax. This chain reaction continues until the fuel, here wax, a hydrocarbon, is used up or gone. Heat and light energy is released. The heat energy is due to the energy stored in the oil or hydrocarbon molecules that get separated during the combustion process, and the light is due to electrons that have gained kinetic energy due to the combustion process, and then those electrons convert and give off (ie., radiate) that energy as light energy when they join with an atom that needs an electron. A byproduct of the combustion or burning of a hydrocarbon (ie., a water and carbon molecule) in the air (usually containing O2 molecules = a molecule of two oxygen atoms bonded or joined together) is a small amount of water steam (H20 as its gas state), and carbon dioxide (CO2).

The international system (SI or S.I.) unit of mass or matter is the mole (mol) unit. The number of atomic mass units (protons and neutrons) in a hydrogen atom is 1amu. 1 mol of hydrogen atoms or protons will weigh about 1 gram. The number of atomic mass units (protons and neutrons) in a carbon atom is: 12amu. 1 mol of carbon atoms will weigh about 12 grams since it has 12 times more atomic mass units or particles than that of hydrogen which only has 1 proton for its nucleus. It can be said that there are 12 grams of weight / mol of carbon atoms. The atomic mass or molar mass (matter) number or rating of C12 in grams per mol = **grams / mol** = 12 grams / mol or 1 mol / 12 g . Dividing both the num. and den. by the atomic number we can find the number of mols per gram, or matter per gram weight = **mols / gram,** which is essentially the reciprocal of the atomic weight: (1/12) mol / 1g = 0.0833 mol of carbon atoms / 1g. The larger the atom, the more heavier and more massive it is having more atomic mass units or particles of mass, and therefore a lower number of atoms needed to make 1 gram of matter.

The (weight, not mass) density of carbon is: 2.26g / 1 cc . If 1 mol of carbon is to 12 grams, how many mols of carbon are in just 2.26g of it? First, 1 mol carbon atoms / 12 g = (1/12)mol carbon atoms / 1g : after dividing both num. and den. by 12 so as to create an equivalent fraction. The result is:
0.083333 mol / g , then: (2.26g)(0.083333 mol / g) = 0.18833 mol In general:

mols / gram = 1 / (grams per mol) = 1 / atomic weight rating **: g / mol = atomic weight rating**
atomic weight = molecular weight

x mol = (grams of an element) (mols / gram)

If a formula said to use 0.2217 mol of carbon, how much would that amount of carbon weigh? Since 1 mol of carbon is to 12 grams, and creating a proportion type of equation:

$$\frac{\text{1 mol carbon atoms}}{\text{12 grams of carbon atoms}} = \frac{\text{0.18833 mol carbon atoms}}{\text{x grams of carbon atoms}} \qquad \text{mathematically:}$$

$$\text{x grams of carbon atoms} = \frac{\text{(0.18833 mol carbon atoms)(12 grams carbon atoms)}}{\text{(1 mol carbon atoms)}} \approx 2.26 \text{ grams}$$

In general:

x grams of an element = (mols of the element) (grams / mol) : converting mols of an element to grams

Due to that a substance can be compacted and-or compressed to a smaller volume, and that also increases its density for that unit volume, such as with a powdered form of a substance such as carbon dust or flour, it is generally not recommended to determine the weight of something by using a volume of that something. Depending on how much it is compacted or not, 1cc of carbon powder may not weigh exactly 2.66 grams. It is usually best to always use a substance's known weight so as to measure the weight or mass of a substance, rather than use the volume of it. If known measurements were previously made and if you do use a consistent substance and volume of it in a repetitive manner to measure mass or weight, then it is possible to get practical, but not necessarily precise or scientific results with that method of using a volume of a substance.

Since: density = (g/cc) and molecular weight = (g/mol) , multiplying the left equation by the reciprocal of the corresponding sides of the right equation, or= dividing the corresponding sides:

$$\frac{\text{density}}{\text{molecular weight}} = \frac{(g / cc)}{(g / mol)} = (g / cc)(mol / g) = (mol / cc)$$

: **mol per cubic centimeter of an element**

mol = (cc)(density) / (molecular weight)

$d = m / V$, $m = d V$

Electrons and their orbit about the nucleus of an atom

In 1913, **Neils Bohr** conceived the basic model of an atom that we commonly know of and accept. The basic model is that electrons orbit the nucleus which is composed of neutrons and protons. Since larger, more dense and-or heavier atoms have many electrons, some of those electrons will then be in less crowded, more distant orbits where there is not too much of negative charge from other electrons to repel them out of orbit. These orbits having the same radius distance from the nucleus are called (orbital or electron) **shells**, and they are spaced apart at precise distances from the nucleus and each other. These shells can be considered as like the surface of a sphere, and the farther from the center, the surface area increases and then giving much space for electrons to coexist in that same orbit.

The negatively charged electron orbits the positively charged nucleus which contains protons, and is due to the attraction of those charges rather than the very negligible amount of gravity. The minimum distance for an electron to orbit from the nucleus is called the **Bohr radius,** and therefore it is also the closest shell. This distance was found with the aid of Planck's constant (h). Max Planck is discussed in this book in a few areas. Each other shell is at a integer multiple of this distance. This Bohr radius distance is due to the wavelength or distance that this closest electron orbits about the nucleus. For an electron to break free from its orbit and become a free electron, some energy (kinetic and-or electric force) must be applied to it.

The orbital shells are given a letter and-or a number such as: K=1 , L=2 , M=3 , N=4 , and so on. Each shell has a maximum number of electrons, and that shell is then said as being fully filled. The first shell can have a maximum of 2 electrons since there is a relatively low amount of "room" and-or surface area for those electrons from not interfering with each other electrically (ie., here, the repelling charge and its corresponding force to nearby other charges).

The surface area of a sphere is As = 4 (pi) r^2 , if the radius =r doubles to a value of (2r), then (2r)^2 = 4r , hence the surface area will double when the radius doubles. The maximum number of electrons in the second shell will be 4 times more, hence (2 electrons) (4) = 8 electrons maximum in the second shell. If the radius increases by one more unit to (3r), then (3r)^2 = 9r, hence the surface area will increase by 9. (2 electrons)(9) = 18 electrons maximum in the third shell. Due to this calculation process and observing the results, the maximum number of electrons in a shell is:

maximum number of electrons in a electron orbit shell = (2 electrons)(shell number)^2

In the standard Periodic Table of elements, each next row downwards shows elements that have one more electron shell.

Electrons in the shell that is the farthest distance from the nucleus are called valence electrons, and they are said to reside in the valence shell. These electrons are relatively loosely bound to the nucleus since the electric force greatly reduces when the distance increases, and in an inverse square way. In a pseudo formula:
(electric field strength2 at r2) = (electric field strength1 at r1) / (r2)^2

The electrons in a primary shell n may be concentrated in what is called a **subshell** of a shell. Subshells are assigned the letters and-or number: s=1 , p=2 , d=3 , f=4 , and g=5. The maximum number of electrons in these shells is:
2 for s , 6 for p , 10 for d , 14 for f , and 18 for g. We can notice that each new shell can have 4 more electrons.
To then identify the second subshell of shell 3 , this notation would be used: 3p , but another possible notation to consider might be: (shell number, subshell number) , and then 3p = (3 , 2) or= (3-2) or= (s3,ss2)

Subshells are also associated with the energy level of those electrons, and a subshell does not need to be filled in order to begin having electrons in the next shell. Subshell s or 1, is for lower energy, specifically lower angular momentum (p=mv), lower velocity electrons which then reside slightly closer to the nucleus. The orbits of several electrons in some subshells can compose a unique shape, and when they are elliptical orbits. Subshells are usually filled with electrons starting at the first subshell (s), and then proceeding to be filled into higher numbered subshells..

This book will generally not further discuss electron shells or orbits because it is beyond the scope of this book, however, some people might appreciate a basic mention of them as given here. If interested further, you can also research the Aufbau principle for electron orbits, shells, etc.

Some other helpful formulas to remember for finding some needed values are :

weight density = weight / volume : (weight-density / g) = mass density , g=a=9.81 m/s^2
mass density = mass / volume : mass or matter density , mass = force / acceleration = weight / g
mol density = atomic mass rating of an element = g / mol or mol / g : "atomic density" or "mol density"

Elements that are less dense (less mass and-or weight per volume) are said to be "lite elements", and their atom size is very small due to having a low number of atomic mass units (amu). To make a gram (weight) of this element will require many more atoms than that when using heavier atoms which have more atomic mass units per atom.

The identity of a (pure) element can be found by weighing a known volume size or amount of it and comparing it to what is listed in a table of elements. Mass density = mass / volume = mass / cc and Weight density = weight / cc

To help identify a metallic element, if a metal contains iron or is pure nickel, a magnet will stick to it. Usually stainless steel which does contain iron will not attract a magnet, but there is a certain type that will. Color and-or hardness (or softness) are good metal identifiers. When a metal is heated in a flame or other mechanical process such as a grinder, it can emit a certain color which can identify it. Fireworks are colorful displays that often use metals to produce the various colors. Some metals are toxic, so it is best to handle metals and any dust, fumes and-or smoke with caution, and do not breath in any of that. Use proper ventilation, eye and breathing protection. **Spectrometry** is a field of study to determine substances in a sample by using and observing (with a spectrometer instrument) various frequencies (ie., seen as colors, for example, a green color when copper is heated hot, such as for a "flame test", "(light) emission" spectrometry to identify an element) of light emitted when a substance is heated and **emits** certain colors and-or frequencies of light. This light is produced when the electrons gain kinetic energy and become free electrons, and then will radiate that excess energy as a frequency of light when it "falls" back into an orbit about the atom. The electron is then said to be in its ground state, hence 0 excess energy than normal. Some ther materials and the colors seen: sodium = yellow , iron = yellow-orange , calcium = red-orange, potassium = violet. When light such as starlight passes through a gas, that gas will **absorb** a particular light frequency and is an indication of what that gas is. The word-prefix of "spect" is related to vision, and a rainbow of colors is sometimes called the (visible) spectrum of colors, and an event to see is sometimes called a spectacle.

For the number of mol particles, such as atoms of a gas, in a volume of a gas = molar-volume

It was previously noted that 1 mol of gas atoms at standard temperature and pressure (STP = 0°C =32°F, and 14.7psi =
= 1 atm = 1 bar = ~100000Pa) will naturally (no additional temperature and-or pressure) occupy or be in the volume of 22.4L of that gas. This concept is also for a gas of a particular element and not for a mixture of gases. 1 atm = 1 **atm**osphere unit of air pressure = 1 bar. **Bar** is an old unit for weight, and then for pressure, and which for air, its pressure became called as **bar**ometric pressure. "Bar" comes from the old Greek and Hebrew word "baros" meaning weight, burden and-or a load, and of which brought about the word "bear" as in "to bear of hold a weight" and is the same as the English word (letter) spelling for the bear animal. A similar sounding word of "bare" has a general meaning of "without".

1 atm = 14.7 psi =~ 6.668 kg / in^2 = 6.668 kg / 6.4526 cm^2 = 1.0335421 kg / cm^2 =~ **1 kg / cm^2**

24.4L =~ 5.92 gallons =~ 1367 in^3 = a cube shape of about: (11.1 in.)^3 which is nearly a cubic foot. When 24.4L of gas is put into a container, and at STP conditions, the inside of that container walls and the internal gas will have 1 atm =14.7 psi of pressure. As you can imagine, if you try to fit any volume of gas into a smaller container, both the density and pressure of that gas will increase.

Ex. The density of helium = 0.0001785 g/cc. Since the volume of a liter is defined as 1000cc, and after multiplying both the numerator and denominator of this value by 1000, we have: helium = 0.1785 g / 1L = 1g/5.602241L. This is for grams of atoms of helium. Note that a helium atom has 2 protons and 2 neutrons, and therefore has 4 atomic mass unit per atom. The molar mass of hydrogen atoms is listed as about 4 grams of mass / mol. Setting up a proportion type of equation:

If: it is known that there is a density of: $\frac{0.1785\ g}{1L}$ then: $= \frac{4g}{XL}$ with: X =~ 22.4 L
1L = 1000 cc = 1000mL
: Equivalent ratios and-or proportions

And:

$$\frac{0.1785\ g}{1L} = \frac{Xg}{22.4L} \quad : \text{with } Xg = 4g$$

Extra: As the temperature of a gas increases, it will have more kinetic energy and will occupy (if able to expand outwards) a larger volume and will get less condensed, more dispersed, and have less matter, less weight, and less density (of matter) per unit volume. It will therefore take a larger volume of that gas and its new current state (status, conditions, temperature, pressure) so as to have 1 mole atoms of it. A common example of a gas trying to occupy a larger volume is in the cylinder of a combustion (gas, petrol) engine when the fuel ("gas") and air (ie., oxygen) mixture combusts which is a quick release of stored chemical (bonded atoms) energy. Combustion is a chemical reaction causing a high pressurized expansion or "explosion" due to excited hot gas atoms that have a high kinetic energy. This energy will create a force that will greatly increase the internal pressure in the cylinder (ie., a strong metal, combustion and containment chamber) space, and the hot gases will push downward on the (movable) metal piston within the cylinder inside the engine. This energy and-or force applied to the piston will eventually be applied to the wheels of the vehicle or to some other machine so as to provide a rotational force (ie., a torque) such as the wheels pushing against the road surface so as to produce a forward movement of the vehicle. **Combustion**, essentially a form of burning or "consuming", is a chemical reaction of the (carbon) fuel and (oxygen, or "oxidizer" substance) air mixture. Combustion can be described as (rapid, fast) oxidation where oxygen or some other element removes electron from another element and-or substance. During combustion, heat (ie., atoms with kinetic energy) and its resulting pressure (ie., force) will form. If the fuel is a **hydrocarbon (ie., a hydrogen and carbon molecule)** combusting in the air (ie., with oxygen), there will also be a substances formed such as hydrogen, carbon dioxide (a carbon and oxygen molecule) and water (hydrogen and oxygen) in the (initial) form of hot steam (ie., water gas). To start ("ignite", initiate) the chemical reaction of combustion, a source of high heat is needed, and an example of this is when the air temperature inside a piston goes to a high temperature value when it is being compressed and has a high pressure. This initial compression, to essentially "start" (begin the cycle of combustions) the self-running, chain-reaction of compressions and combustions was used with the first type of automobiles manufactured. Here, a person would start a car (automobile) by manually (physically) turning a crank lever with some force so as to move (or "turn") and compress a piston(s) in the engine so as to begin an initial combustion inside that engine of the vehicle. Later, by 1911, geared, high torque, mechanical power and-or force, electric "starter motors" began to be used to "turn-over" (move, cycle) the engines pistons and start a vehicle.

Combustion (ie., oxidation) can also happen slowly ("slow combustion") such as with aging wood or paper after a long time, and it will get darker and have a higher percentage of carbon as the water evaporates. Combustion can happen very quickly as during the explosive combustion with "fireworks" displays. The rusting on iron is due to oxidation. Rust particles are iron-oxide (a molecule of iron and oxygen, and with the aid of water) and it usually has a brown-red or dark-orange color. A candle or a fire with burning sticks is a form of combustion, and the smoke is a steamy mix of hydrocarbon (mostly water and carbon) with some other trace gases and minerals. It is even possible to collect this "fire gas" substance(s) so as to produce a high energy liquid fuel, and which may be called something like "wood-gas". Charcoal is wood that has been already been "cooked" or processed so as to have a higher carbon content, and then it is used as a portable and popular fuel to cook food without much smoke, however, in the process of making charcoal, much potential energy of that wood slow combustion is lost into the surrounding air, and charcoal is then a questionable item in terms of being energy wasteful. The price of charcoal purchased at stores is relatively high as compared to unprocessed dry wood, and therefore it is only purchased occasionally by most people who use it. Oxygen is needed for combustion to occur, and sometimes some substances are added to a fuel to increase its combustion efficiency, and these are called oxygenates, and are said as increasing the "octane" of a fuel.

UV Light

Also of note is that sunlight (especially high frequency, high energy ultraviolet light) can i**onize** [when enough energy is applied to cause electrons to leave their orbit] things and actually promote rusting. **Ultraviolet (UV) light** is generally dangerous to many materials and eyesight. UV light is composed of high frequency, high energy wave of photons. Since ultraviolet light was mentioned, here is a further note about it:

UVA is a (relatively) lower frequency ultraviolet (ie., if it could be seen as an approximate color) light. UVB is medium frequency ultraviolet light, and UVC is high frequency, ultraviolet light. UV-A will pass through regular plate glass, and block most of the higher in frequency, UV-B and UV-C radiation. Laminated glass with the plastic between two layers will block UVA light. Amber and blue colored containers block much of UV light, and is often used for medicine or "pill" containers. Welders wear eye shields made of (usually) dark green glass which blocks both infrared (ie., low frequency light, heat rays) and (**ionization** [can give much (kinetic) energy to an electron(s), and so as to remove them from an atom and-or molecule, and this also then creates positive charged ions], damaging) UV (high frequency) light such as UV-C. These electrons can then travel, and are called "free electrons" meaning it is unbound to an atom. Sometimes molecules of these ions will form due to UV light UVA and UVB can cause sunburn, and typically in just an hour of exposure to direct sunlight and-or sunlight reflected off of bright snow. Having clothing and a hat on, a tan and-or **sunscreen** ("sunblock") lotion helps prevent sunburn and-or UV exposure. Eye protection such as UV rated sunglasses can block much UV light, and sunglasses also reduce the typical bright light, and helping your eyes to maintain normal light sensitivity.

Some electric lamps produce some UV light, intended for specific use (such as sterilization of nearby surfaces). UV light can also help make safer drinking water. Some modern glues can be "cured" (ie., dry faster, crystalize) when exposed to UV light, and modern dentistry and some craftsmen often use such glues and UV light.

Prolonged exposure to UV light can cause skin cancer (melanoma) because of then having a higher chance of ionization and resulting damage to cells and DNA mutations that were not eliminated from the body but rather caused cancer cell growth. Cancer can spread to other parts of a persons body and become even more dangerous. Sunlight in a limited and-or well regulated sense is generally known to help promote the body to create vitamin-D3. Under legal supervision and prescription by a doctor, there are light-therapy, UV light treatments and-or lamps for treating some skin diseases, and the patient must know when and how to use them, such as how close and for how long without causing unintended UV damage and-or other health issues. **Pets, guests and family members need to be aware of a potentially dangerous UV lamp, and to never turn it on.** Vitamin-D3 can be recommended by a doctor, and is often available "over the counter" (ie., without a medical prescription required). If you are sensitive to the sunlight or not, it is recommended to wear a wide brim hat, or at least a "baseball" type of hat. It is also recommended to wear bright colored clothing in the summer so as to reflect a good percentage of the light to limit your UV light exposure and to prevent sunburn. Sunglasses are a good option to consider for any time of the year. **Inform others,** such as your children, about prolonged sun exposure and its dangers. For example, for people who have not come outside routinley for at least a few minutes at a time during the springtime for a slight protective tan to prepare for summer, and then easily get sunburnt in the bright and intense summer sunlight and its energy. It is even possible to get a suntan and-or sunburnt in the winter when the conditions are just right, such as a bright sun reflecting off of the snow around midday (noon, 12pm) time. Light reflecting off of water or other bright surface can also contribute to a suntan and-or sunburn.

In space near the upper atmosphere of Earth, about 10% of the Sun's radiated energy is UV light and-or energy, and with **3%** of it reaching the surface of the Earth at the Equator at noon and after the other 7% was already absorbed by the atmosphere. The higher the altitude, the density of the atmosphere decreases, and the greater amount of Solar radiation received there. Of that 3% mentioned, 95% of it is UVA, and 5% is UVB. At the surface of the Earth, about 45% of the received energy is visible light, and with abut 52% of it being infrared light (ie. heat energy). A small amount of microwaves and x-rays from the Sun will reach the surface of the Earth.

Mohs Scale = The Mohs Scale Is a type of a "molecular hardness" (resistance to visible scratching) scale invented in 1822 by **Friedrich Mohs**, (1773-1839), from Germany, who studied rocks and geologic landforms. The values could be thought of as a measure of the amount of force needed to scratch a sample piece, however, the scale is not exactly linear, and is more of a slight exponential-like scale or mathematical relationship of the amount of force needed to scratch the element. **Note that hardness and density are not necessarily directly related,** for example, lead is very dense and heavy, but is also soft, melts easy and has a low Mohs Scale rating. For an element to be visibly scratched (technically, not a repeated cut or plowed groove), it must be done by another element with a higher Mohs Scale rating. Generally, elements and materials that have stronger atomic bonds will have a higher Mohs rating, and it could be said that those elements are more crystallized at the atomic (atom) level. The Mohs scale was developed to determine what element a rock and-or material may be composed of.

When a Mohs Scale value for an element is greater than 1, the amount of force needed to scratch it is roughly proportional to the square or cube of that value. Here are some typical Mohs Scale values:

Potassium = 0.4 , Sodium = 0.5 , Lithium = 0.6 : low hardness , **soft metals**

Talc ("soapstone", which is similar to plaster ("paste, layer", a pre-word for (bendable) "plastic"), and talc is a mineral compound of magnesium, silicon and oxygen. gypsum = Calcium-sulfate , chalk = calcium-carbonate = **1.0**

Lead , Gallium , Calcium , Tin = 1.5 : lead is quite dense, but has low hardness (ie. "soft") , lead melts at 621°F , gallium melts at 85.6°F , tin melts at 450°F

Plastic = 1.75 typ , Alabaster (crystalline, calcium-sulfate) = 1.5

Alabaster = a denser, crystalline calcium-carbonate stone = 2.0 , Amber (a hard tree sap) = 2.25 typ
Bismuth = 2.25 has a relatively low melting point of about 521°F , Sulfur = 2.0 typ. (= typical)
Zinc = Magnesium = Silver = Gold = Table-Salt , 2.5 : gold is quite dense (mass/volume) and therefore relatively heavy, but it is only as hard as zinc , hence relatively soft. zinc melts at 420°F , magnesium melts at 1202°F , silver melts at 1763°F , gold melts at 1946°F
Aluminum = 2.75 , aluminum melts at 1220°F
Copper = 2.85 av. , copper melts at 1985°F

Calcite (calcium carbonate) = Coral = Antimony = 3.0 , Platinum = 3.5 , Brass = Pearl = Limestone = 3.5 typ. Bronze=3.7 typ. , Mother Of Pearl (Abalone , animal shell from the ocean) = 3.7 typ.

Iron = Nickel = 4.5 , Platinum = 4.25 av. , Marble = 4.0 typ. [essentially a dense limestone]

Apatite = 5.0 : often a green to blue colored stone containing a compound of phosphorous
Steel = 5.25 av. , Glass = bone = 5 typ. , Opal = 5.7 typical, somewhat brittle (will often have a chonchoidal (curved) fracture, and not cleaved along a flat plane) if bumped. Opal has an internal iridescence or reflective shine of colors when light is reflected from it. , Manganese = Cobalt = 5.0
Turquoise (or Turquois) = 5.5 av. which is a copper-aluminum-phosphorous-oxygen (oxide) mineral
Stainless Steel = 5.7 typical - note that tempering the steel to alter its crystal structure will change its hardness, the more harder, the more brittle usually.

Pyrex glass = 6 typ (borosilicate glass, thermally annealed, withstands high heat, low thermal expansion, but can still shatter due to a high temperature differences - thermal stress).
Titanium , Feldspar = 6.0 (a crystal mixture of elements: potassium, calcium, sodium, aluminum, silicon) = berryllium (has crystals of aquamarine and emerald) = 6 , hematite = 6 typ.,an iron oxide , Manganese = Germanium = Uranium = 6.
Silicon = Iridium = 6.5 typ.

Ceramic = 7.0 , a man made stone from mostly clay which is mostly silicon dioxide, mixed with water, shaped, dried and fused into a solid using high heat. Porcelain (a more dense ceramic) ~ 8
Quartz (a silicate crystal mineral of silicon dioxide) = garnet = diorite = granite = flint = vanadium = 7 , Hardened Steel = Tungsten = Amethyst = Emerald 7.5

Topaz = 8 , a silicate (silicon and oxygen molecule) mineral with aluminum and fluorine, a gemstone
Chromium = 8.75 typ

Corundum (is aluminum oxide, abrasives, crystals with some trace elements such as chromium oxide are called sapphire and ruby, can be made artificially with high heat from current) = Tungsten Carbide = 9
Moissanite = a natural silicon-carbide mineral, a diamond-like gem substitute, can be man made = 9.25
Boron = 9.3 is quite dense and hard, but brittle , Silicon Carbide (carborundum, silicon and carbon) = 9.5

Diamond = 10 : very hard form of graphite carbon = 0.5 , but diamonds are also very brittle due to the crystalline atomic bond structure, and will shatter or cleave rather than bend or absorb-store applied mechanical energy. 10 is the highest value in the Mohs scale.

Chromium is the hardest metal known. Corundum is about 2 times harder than quartz. Boron is about two 2 times harder than corundum. Diamond is about 3 times harder than corundum and about 2 times harder than boron. Cubic-zirconia is the (diamond-like) crystal form of zirconium (a metal) dioxide (being part oxygen, here specifically 2 oxygen atoms in the molecule) and has a Mohs hardness rating of 8.5

Besides using the Mohs scale, there are some other newer methods and scales created to more accurately measure and represent the physical properties of elements or materials such as the **Rockwell scale** which is a tensile strength test that uses indentation (such as an indent from a moving or dropped weight of specific dimensions) which also indicates a materials hardness by the depth of the dent. Harder materials will simply have a smaller and lesser amount indentation. Softer material will have a larger and-or deeper indentation. The **Vickers scale** and **Brinell scale** are somewhat similar to the Rockwell scale, and also uses an indentation (depth of a dent) method.

The Rockwell scale and the initial indentation machine was invented by Hugh and Stanley Rockwell from the U.S.A. in 1914. Though this entire subject is beyond the scope or range of this book, and is rather useful when and where needed such as at some factory or for material production, here are some examples of the Rockwell scales that can be used to test a materials hardness:

For the Rockwell A hardness scale = HRA, a diamond tipped cone, and with an applied force of 60kg is used.

For harder materials, the Rockwell B hardness scale = HRB, a sphere tip having a 1/16 inch diameter, and with an applied force of 100kg is used.

For more harder materials, the Rockwell C hardness scale = HRC, a diamond tipped cone, and with an applied force of 150kg is used.

The Rockwell Hardness of a material is then expressed as: HR = (N - hd) , where d is the depth in millimeters. For the Rockwell A scale: h = 500 and N = 100, For the Rockwell B scale: h = 500 and N = 130. For the Rockwell C scale:
h= 500 and N = 100. This HR equation has the form of:

> Rockwell Hardness value = HR = (Arbitrary Initial Standard Reference Value) - (multiplier)(indentation depth in mm). The less the depth of the indentation, the higher the Rockwell Hardness value. The recommended scale to use depends on the specific material(s) being tested.

A scale for wood hardness:

Gabriel Janka (1864-1932), from Austria, made a test and resulting **Janka measurement scale** to determine the relative surface hardness, compression and-or general strength of various species (ie., types) of wood. The amount of natural density, drying (water reduction), grain direction(s), and age ("seasoning", dryness, "carbonization") will also effect this value. The test is standardized for wood having a moisture content of 12%. The Janka measurement is done using a dent test using a 11.28 mm = 0.01128 cm (= slightly greater than 1 cm) =~ (7/16)in =~ nearly a (0.5 in) steel ball and the amount of force or more specifically, the Torque (= Force x distance from rotation point) to place half of it into that wood. The circular area (pi x r^2) at the diameter of this sphere and-or produced dent is **1 cm^2**. First, **lbf = pound-force =** (equivalent, weight) **pounds of force,** and here its also for a certain amount of defined area, hence a pressure (P = F/A) value.

Ex. Buloke (Bull-Oak) = 3700 lbf to 5000 lbf , Ebony = 3500 lbf , Bamboo = 3500 lbf or more typ. , Hickory = 1800 lbf , Apple = 1700 lbf , Hard-Maple = 1448 lbf , Oak - 1350 lbf , Ash - 1330 lbf , Walnut = 1000 lbf typ. , Cherry = 970 lbf , Paper Birch = 900 lbf , Sycamore = 750 lbf , Yellow Pine = 600 lbf , Poplar = 540 lbf , Pine (soft, Fir) = 500 lbf typical , Basswood - 430 lbf , (common) Aspen = 360 lbf typ. , Cedar = 350 lbf , Balsa = 70 lbf.

The price of wood often depends on both its rarity and-or hardness. Woods such as ebony and rosewood are endangered trees, and it is advised to seek alternative woods and-or materials such as carbon fiber or hard maple. Trees that have fallen naturally are generally sought after as a fair resource, and so as to obtain its wood for practical use before it decays naturally and is then much of valued resource.

If wood dries out further, and then having a lower moisture content per volume, and a higher carbon content per volume, it will tend to then have a higher Janka value for the same type of wood. This wood has bwecome denser.

Some of the following are mostly new book discussions, and it includes some brief, additional and-or alternate discussions of previous and-or further book discussions. Definitions and some general history of the commonly recognized discoverers and inventors are mentioned, and so as to help the reader have a further understanding of a concept and-or formula.

Torque = (**Force Applied) x (Lever-Arm Distance)** : this is not exactly the same as Work = force x distance, and as described below, torque is essentially the resulting or effective amount of force output after a change or transformation (ie. here, an effective amplification, or growth) of a given applied or input force. With the Work equation, the force is not amplified as it is with the torque concept and equation.

Torque is a measure of the resulting and effective rotating, turning or "twisting" **force** (ie., a force that will cause a rotation about a center point), and if that force is constantly applied, it will cause something to accelerate about a fixed point. An example is a long wrench tool being pushed or pulled so as to loosen or tighten a screw or a nut on a bolt. Another example is a rod, beam or lever which has a pivot (turning or rotation) point or "fulcrum" (support, post) set at some distance along it, of which the rod, beam or lever is able to rotate on or about, including up and down vertically. Levers are used as simple (mechanical) machines to have a "mechanical advantage (gain, increase, amplification)" so as a small force or weight can lift objects that have a heavier weight, although requiring more time and-or distance to do so. Torque may sometimes be mentioned as "moment" or "moment force". Often, once a bolt and-or nut is "broken free" or "loosened" from applying its ("clamping") pressure to mechanically join things together, the torque needed to completely remove it will be much less than that used to tighten it.

Lever-arm is a term associated with torque forces, and is the distance from the point a force is applied on the lever, beam or bar, to the point of pivot or rotation of that lever. A regular lever, or compound pulley, as mentioned in the book are well known as force multiplier, but taking longer to do so. With the concept of torque, the lever material rather transfers the input force to the center point of rotation, and applies the output force there. The Lever-arm distance is essentially like a radius or distance value from the pivot point as if that point was the center point of a circle. Since force is (mass x acceleration), we see in the torque equation that the lever-arm distance is essentially a multiplier to the force applied, and technically, this is because the lever-arm (or radius) distance essentially increases or multiplies the acceleration. Given a constant value of applied force, if you increase the lever-arm distance, then the output torque (twisting force) will increase by the same factor the lever-arm was increased. The equation shown above assumes that the applied force is perpendicular (at a right angle, or 90° to it) to the lever arm, otherwise, when the force is not applied in a perpendicular manner, the applied force is actually less, and the more general equation to use for such conditions is:

Torque = (**F**orce) (**L**ever-arm) (Sin ¢) : where the angle is the angle between the lever and the applied force. When the applied force is perpendicular (90°), Sin angle is at it's maximum possible value of Sin 90°= 1, and all the force is being applied to produce torque and the equation simplifies to the previous one shown: **T** = **F L**

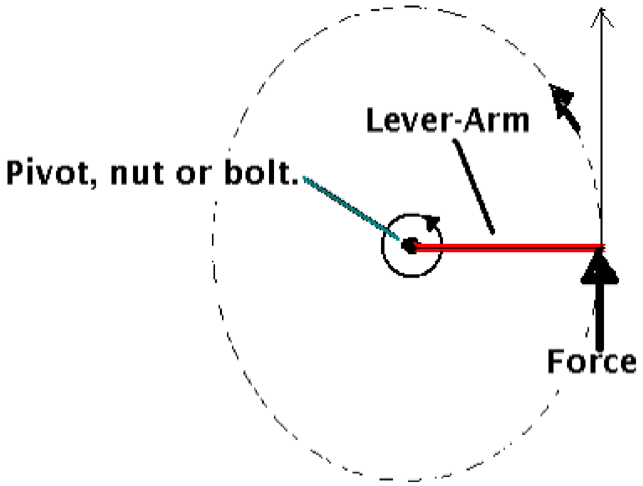
[SEE FIG 228 below]

Increasing lever-arm increases or amplifies torque (force) because the acceleration of a point (where the force is applied) on the lever is greater when it is farther from the (center) point of rotation, and that the velocity and distance traveled about the point (center of rotation) is greater per same amt. of time. Force (f = ma) is directly related to acceleration, and since acceleration is a change in speed (velocity) per change in time, and speed (velocity) is a change in distance per change in time, therefore, acceleration is directly related to the distance traversed per unit time. If acceleration increases, or is desired to increase, force must be increased. Acceleration will essentially become a multiplying factor to the mass when force is being considered since:

f = ma = force = mass x acceleration. Using substitution we see how these factors affect the torque equation:

Torque = (Force)(Lever-Arm) = (mass)(acceleration)(Lever-Arm) with units of **Newton-meters** = Nm

A longer lever-arm (such as that of a long wrench tool, ratchet, or machine lever) increases the acceleration which increases the output or torque force. If the lever arm or radius distance increases by a factor of (n), the torque will also increase by that same factor of (n). It is incorrect to think that a common, long screwdriver will provide torque. [FIG 228]



Ex. Here, all these conditions will apply the same torque or "twisting force" of 100 ft-lbs:

100lbs of force at 1ft = 50lbs of force at 2ft = 10lbs at 10ft = 1lb at 100ft.

A note about the units to use or express for torque:

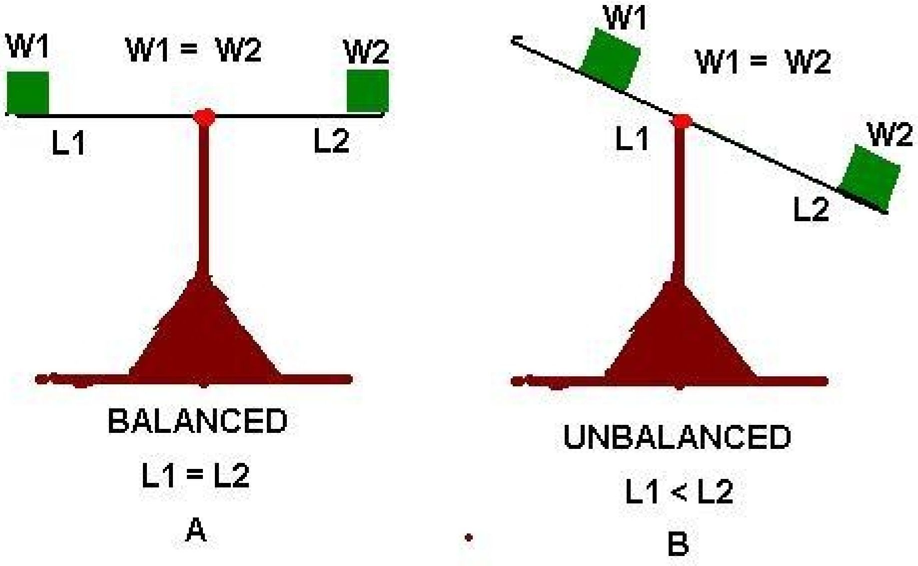
More correctly, 100 ft.-lbs of torque should be expressed as: 100 lbs-ft. = 100 pound-foot. That is, the force should be expressed first in the units of torque. The expression or units of: Fd = (force)(distance) is actually an amount of work or energy in Joules. This value does of (Fd) does equal (Nm) which is considered the standardized unit for torque, but don't consider a torque value equal to a joule value of energy or work. Note that (torque)(distance) would rather be equal to: (force)(lever-arm)(distance) and this is clearly a different value than work or energy. For the units of torque as (Nm), the value of m=distance in meters) is not the arc distance moved, but is rather the distance the force was applied from the center of rotation, hence the lever-arm distance. You may still sometimes see torque expressed inunits of ft-lbs = (foot)(pounds), hence the distance expressed first. 1ft-lb = 12 in-lbs

From the Torque equation, we have: $\text{Force} = \frac{(\text{Torque})\ \text{Nm}}{(\text{Lever-Arm})\text{m}}$: with units of Newtons = N

$\text{Lever-Arm} = \frac{(\text{Torque})\ \text{Nm}}{(\text{Force})\text{N}}$: with units of meters = m

An example of where torque is used is for a stated, recommended (for safety) "tightening" or "tightness" value for a nut or bolt. Once tightened, this but or bolt will compress two or more piece of material together like a strong clamp applying force and-or pressure (force/area) on each side of it, and it will give that structure much rigidity and-or stability at that location. Note that a nut may have a specified and-or rated amount of torque to apply to it for safety and legal reasons, and so as to not damage that nut and-or bolt by excessive force, and also to prevent injury of the user. There are various torque-wrenches manufactured and are available in the tool sections of some stores. They are often a type of ratchet wrench which accepts a socket adapter of the size that will fit the dimensions of the nut being tightened. The specific torque value needed can be set on these wrenches, and a click-sound will be heard and-or indicated when the nut has been tightened enough.

Some considerations about torque by using the concepts of a balance scale that is used to measure mass and-or weight of objects. The balance mechanism is essentially two levers of the same length on both sides of a pivot point. A calibrated reverence weight and-or mass may be utilized for this measurement depending on the specific balance scale used. [FIG 228B]



For both part A and part B of the above figure, the weight values (W1 and W2) have the same value, therefore, W1 = W2. As mentioned, weight is a force in the downward direction due to the force of gravity constantly attracting and accelerating a mass. Weight = Force = (mass)(acceleration) = m a .

In part A of the figure, since the lever arm distances (L1 and L2) of the weights are both the same length from the pivot point, this system is in balance and is not moving, and specifically here, not rotating due to gravity pulling upon the weights. The "balance beam" of which weights are upon will be horizontal and-or level with the ground. The torque = T = (Force)(Lever-Arm distance) = FL or rotation force produced by each side is the same value, and the result of these opposite signed torque values is zero net torque as if no weight or force was applied to either or both side. Another value is that the support structure is holding up or supporting the sum of the two weights and beam.

In part B of the figure, the weights are still the same value, but one is moved closer to the pivot point, and has a lesser value for its lever arm. Although the weights are the same value, L1 is now less than L2, and this system is now unbalanced and is rotating. It is now as if W2 is greater than W1, but again, they are still the same value. What is actually less is the torque or rotation force produced by W1 and its corresponding lever arm distance. The torque of W2 has not changed, but it is now greater than the torque produced by W1 and its lever arm. The lesser that L1 is, the less the resulting torque. An actual balance scale for measuring weights and-or mass will usually have some type of springs or physical stops so as to prevent too much rotation and possible damage to the scale.

Torque or torque force is the rotation force around the pivot point. For this unbalanced system shown above, the result is that W1 and W2, and their supporting beam structure will be vertical, and where W2 at the bottom due to its greater torque force. The net or total torque upon the pivot point is the difference between the two torques applied:
Tt = (T2 - T1).

When given any two weights of any value, their torques can be balanced (ie., produce and equal torque value) or set equal by adjusting their corresponding lever arm lengths. In general, for this to happen, the larger weight will need to have a shorter lever arm distance.

Archimedes discovered the **Lever Law** that states: **(M1 L1) = (M2 L2)** , and for the lever to be balanced, both sides are equal, and-or that mathematically: (M1 / M2) = (L2 / L1) , and these are reverse ratios. Note that due to gravity, the mass (M) results in a force or weight of (Ma = Mg), and that torque = (F L). For the lever to balance and-or be set to no net torque: (T1 = T2). Archimedes did knot know Newtons specific equation (F = ma) for force at that time.

When using a wrench upon a nut or bolt - essentially being the pivot point or axis of rotation, and if there is no second weight or force involved, all the input energy, force and torque (T= F L = m a L = m (v / t) L) created is applied about the pivot point, nut or bolt. As can be seen in the formula, the greater L is, and even if the input force is the same, the greater the (effective linear) velocity will be about the center point. This also effectively gives a higher value of acceleration. Note that the angular velocity (= ¢ / t) is the same at every point along the lever arm distance. Technically, for an object to change direction, there must be a force applied, but in the case of orbits, the force applied is gravitational force (= ma = mg) pulling upon the spacecraft, and the result is a circular orbit.

Another way to explain the force increase upon a nut or bolt due to a long wrench applying torque is:

Energy In = Energy Out : and-or: Work In = Work Out
F in D in = F out D out : Energy = Work = (Force) (Distance) with units of Nm = Joules

Given a long wrench, the radius distance from the center will be long, and the distance a point on its far end will travel is a much further effective linear distance about that center point for any given angle of rotation. Mathematically:

$\text{Fout} = \dfrac{\text{Fin D in}}{\text{D out}}$: since D out is a relatively low value, and less than D in, F out will be larger than F in.

Also: Power out = Power in : or more correctly: Work in = Work out , or Energy in = Energy out , : joules
F2 d2 = F1 d1 : F1 = input force , F2 = output Force = amplified input force
$(n\ F1) \dfrac{d2}{n} = F1\ d1$: showing that F2 is a factor of (n) times more than F1, and actually (n) is the lever arm distance (L). (d2 / n) = d1 , hence: d2 = n (d1)

Weight is a resulting force due to the constantly applied force of gravity (causing g = a = an acceleration in velocity = 9.81m/s^2 = 32.2 ft/s^2 on Earth) upon a mass. This force of gravity gives the mass an acceleration of (g) and increases the energy of that mass. Essentially, mass and gravity are amplifying each other, and are expressed as multiplying factors of each other, and the resulting force or weight is:

F = weight = (mass)(acceleration) = (m)(a) = (mass)(g) : g = a = 9.81 m/s^2 = 32.2 ft/s^2 Note that:

1lb of weight is 1lb of force = about 4.4482N of force =~ 4.45N of force =~ 0.45359kg of force =~ 454g of force
1 kg of mass will have a weight of 9.80665 newtons of force = 9.80665N of force ~= 9.81N of force = 2.2046 lbs
1 lb = 0.45359 kg = 453g . 1N =~ 0.22481 lbs = roughly a quarter of a pound , 1N =~ 102g =~ 0.1kg

Here are the derivations of the above conversions:

$\text{F newtons} = (\text{mass})(\text{acceleration}) = (m)(a) = (\text{kg}) \left(\dfrac{m}{(s^2)}\right) = \dfrac{\text{kg-m}}{s^2}$: N = newtons = force units

1N = (m)(a) = (1kg) (1m / 1s^2) = 1 kg-m/s^2

When the acceleration (a) = (g) = 9.80665 m/s^2 , such as for weight force:
9.80665N = (m)(a) = (1kg)(9.80665 m/s^2) = 9.80665 kg-m/s^2 = 2.2046 lbs of force

1kg of mass will weigh 9.80665N when in the gravitational field ("force field" or "field of force") of Earth.

If the weight of a mass or object is 1lb = 16 dry-ounces, the corresponding mass in kilogram units is 0.45359 kg:
4.448$\underline{2}$N = (m)(a) = (0.45359 kg)(9.80665 m/s^2) = 4.448$\underline{2}$ kg-m/s^2 = 1lb of force

100lbs =~ (4.45N / lb)(100 lbs) = 445N , 1000 lbs = 4445 N , 1 ton = 2000 lbs = 8890 N

1ft = 0.3048m ~= 0.3m.
1lb-ft =~ 1.355817Nm :derived from: (1lb)(1ft) =~ (4.44822N)(0.3048m)=~ 1.355817Nm , therefore mathematically:
1Nm =~ 0.7375624 ft-lb

Though kilograms are often thought of as a weight value, it is actually an amount of mass, and the corresponding weight or force of an amount of kilograms of mass is shown above as:

F = weight = (m)(a) = (kg)(m/s^2).

The reason for thinking a kilogram is a weight value is that for example, a 1cc = 1 gram of water is said to have a "weight" of 1gram or gram-weight. Most scales will actually display the corresponding mass value and it is commonly said or spoken as being a weight value, and which is a loose way of saying it was a measured value from a device (scale) that initially senses the weight of the mass. Most weight scales are calibrated to show an equivalent amount of mass of the object. Therefore, if a scale indicates 1 gram, you will know that the mass of that object is equivalent to 1 gram of mass. As mentioned several times in this book, weight and mass are mathematically proportional to each other, if one variable increases or decreases by a factor (n), the other will also increase or decrease by that same factor. A mass value of 1 gram of any type of atom (ie., element), object, or substance will also have the same weight, and this is how **the total mass of an object can be determined, and that is by measuring its corresponding total weight.** If you know the volume of the object, then its density = (mass / volume), and then you can find what (if consistent) element it may be from an element density list. (weight / volume) = (force / volume) =(ma / V) = (mg / V) could be defined as a "weight density" of an object.

Since letting mass density = d = (m / V) , and letting: weight density = (mg / V) , we can see that if we divide the weight density of an object by (g = 9.81 m/s^2) , we will then have its corresponding mass density = (m / V) and this is very useful if you do not know the volume of an object.

Energy can be defined as the ability to do something such as work. Therefore, a measure of energy is a measure of this ability to do work. The units of energy are Joules (=J). A force (ie., influence) can be used to apply and transfers energy from one object to another. For a force to apply and transfer energy, there must first be energy to create that force. Energy can be accumulated, concentrated and stored, such as for example: in batteries, fuels, and our muscles.

Work can be measured as equal to the total amount of energy used up and-or transferred, and therefore, its units are also the same as that for energy, and that is Joules. In term of forces (the application of energy) and distance:
Work = (force)(distance) with units of the energy needed and-or used, and that is **Joules (J)**.

Power is a measurement of the rate of using energy or doing work, hence power is a "work-rate", and therefore it is equal to the total amount of energy used per unit of time.

power = energy / time = work / time : with units of joules/second = J/s , and is a rate value; the rate of, and-or using energy

The units of power are **joules per second** which is also called watts (w). 1 **Watt** is 1 Joule of energy used and-or transferred per second of time.

1watt = 1w = 1J/s.

From the above formula, we can derive that 1 Joule of energy is equivalent to 1 watt of energy used or applied for or during 1 second of time.

J = w-s. : 1 Joule of energy is equal to 1 ws = "one watt-second" of energy =
1 ws = an energy rate of 1 watt = 1J/s applied for a length of time equal to 1 second of time.
Ex. 5ws = 5 Joules , could be from an energy rate of 1 watt = 1J/s applied for a time length of 5 seconds, or 5 watts = 5 J/s applied for a time length of 1 second.

Another form of this equation is: **Joules = energy = (power)(time)** **: total joules or energy**

For electricity or electronics, 1 watt of energy usage is equivalent to 1J/1second which is equivalent to 1 volt = 1V of electrical pressure or force (emf = electro-magnetic force due to charges repelling or attracting) causing and moving 1 ampere (= 1A) of charge (current, electrons) past a point in a circuit. The equation for watts then becomes:

Power = Watts = (energy/second) = (joules / second) = (voltage)(current) = V I , and this is derived in this book.

A joule of energy is also equivalent to the energy needed to apply 1 Newton of force for or through 1 meter of distance:

1J = energy = work = (force)(distance) = (Newtons)(meters) = N-m = 1 w-s

1J = N-m = (force)(distance) = (mass)(acceleration)(m) =
= Mam = M(m/s^2)m = M (m^2/s^2) = M(m/s)^2 = Mv^2

Mv^2 is nearly the same equation of kinetic energy = KE = Mv^2 / 2 = joules / 2 , and one way to consider this value be half, is that it is due to equal and opposites forces which limit the energy transfer by half.

Extra: Also of note: J = (force)(distance) = F v t = M a v t

Horsepower (hp) is an old and large unit of power = (energy / time) with units of watts. Power is essentially the average amount of energy or work used during a time period or amount of time.

1 horsepower (hp) is 746 watts. 1 hp = 746w = 746 J/s = 178.3 calories/s.
$1hp = 748w = \frac{746\ J}{s} = \frac{746\ N\text{-}m}{s}$

Work is a measure of applying a constant force (F) or energy to something (object) over a length (distance) of movement. The units of work are the same as the units of the measurement of energy, and that is Joules (J). Since work is measured with units of energy, work is also a measure of the total amount of energy used and-or transferred to something(s) else:

Work (W) = (Force) x (Distance) :Joules (J) of energy , mathematically:

Note that here, distance is the distance of which the constant force was applied and the time needed to do so. Also, note that mathematically. and expressed like an average ratio or rate:

Force = Work / Distance = energy applied per unit of distance.

$\text{Force} = \frac{\text{work}}{\text{distance}} = \frac{\text{energy}}{\text{distance}} = \frac{J}{m} = N$: mathematically, force is the rate of energy used per unit distance, or the rate of applying energy over a distance, and for this example it is how much energy was used or applied for each meter. For an object to accelerate, the force must be constantly applied, and therefore, the energy used and-or needed must be constant.

Work = (force)(distance) = (Newtons)(meters) = Nm Joules of energy. , Mathematically:
Work = (mass)(acceleration)(distance) Joules
Work = (mass)(acceleration)(speed)(time) = mavt Joules : acceleration = a = change in v / change in t,

a = change in v / change in t , and if the initial values were: t=0, and v=0 , a = v / t = (d/t) / t = d / t^2

Since d = (speed)(time) = vt, and the initial velocity was 0, then that speed or velocity was not always applied during that amount of time (t), and the value of v= (d / t) is not then actually correct to use for (v). What value of (v) should then be used? The average value of the two velocities can be used: v av = (V final - v Initial) / 2 , and this assumes there was a steady increase in the velocity during that amount of time due to the (constant) acceleration during that time:

$$\text{Work} = (m)(a)\frac{(v)}{(2)}(t) =$$

$$\text{Work} = (m)\frac{(v)}{(t)}\frac{(v)}{(2)}(t)\ \text{Joules} = \frac{mv^2}{2}\ \text{Joules} =$$

Which is a measure of the total energy needed to do that work and-or the gain in kinetic energy (KE) of an object in motion due an applied force and-or work upon it. mass (m) has units of kg, and velocity (v) has units of m/s.

An object just moving in space at a fixed velocity and without accelerating (a=0), then the factors of acceleration and time are not influencing factors of its ("stored", "potential") equivalent energy value, and therefore are not even considered as factors in the equation. The object has energy due to just its mass and velocity. Because the object has mass and velocity, the object has momentum which is set as being equal to this value. Momentum p = mv = (mass)(velocity), and it is defined as a measure of an objects ability to keep moving and-or its resistance to changes in velocity and-or direction. The momentum of an object is directly related to the kinetic energy (KE) of that object. In short, it takes more energy or force to influence (change [increase or decrease]) the speed, and-or direction of a more massive object. Since v = d / t, momentum can also be describe as a measure of a mass through a distance during an amount of time: mv = (mass) (distance) / t

Ex. A mass of 1 kg which has a velocity of 3m/s^2 has $\text{KE} = \frac{(1\text{kg})(3\text{m/s})^2}{2} = \frac{(1\text{kg})\ (9\ \text{m}^2/\text{s}^2)}{2} = 4.5$ Joules

If this energy was to be used to apply a force to a second object, and due to equal and opposite forces being applied to the first and from the second object, only half of that energy is actually transferred to the second object, and the amount of energy transferred is: KE / 2 Joules. It is as if half the energy was not transferred due to the resistance or inertia of the second object. Another explanation of this formula is that when an object1 initially collides with object2, object1 will begin to decelerate, and its velocity and energy will decrease. Object1 will start to loose energy, and since object1 is applying a force = (m)(a) to object2, object2 will gain energy, increase its speed and-or possibly be compressed. This formula is also mathematically derived in this book.

As a "thought concept or experiment", if object1 somehow transferred all of its energy to object2, then surely that amount of energy increase would be equal to the KE of object1. Since an amount of KE is related to the square of the velocity, if the velocity changes by a factor of n, then the KE increase (added) of object2 will also be a factor of n^2. This also implies that to increase the velocity of an object by a factor of (n), then n^2 more Joules of KE energy must be applied to that object. Likewise, if the mass of an object increases by a factor of (n), then the amount of its potential energy increases by that same factor if it is still moving at the same velocity.

If you were applying a force (f=ma) pushing a box across the room on the floor, surely the box must experience an acceleration so as to have a velocity and move. At the same time, the force of friction or drag between the box and the floor causes the box to loose energy, decelerate and essentially loose any acceleration and energy it had. If the same pushing force and drag force is constantly applied and the velocity of the box appears to be the same, this is due to very brief, nearly instantaneous, periodic acceleration and deceleration of the box. It will be as if only half the acceleration, or average accelerate is effectively being used.

Assuming no energy losses during applying energy so as to produce a force upon an object through a distance, which is the work, the energy used and transferred to an object is equal to the increase in that objects kinetic energy.

Our muscles store energy and it can be used to apply force so as to do work and-or apply energy to another object, and due to the "equal and opposite force" concept, some of the total amount of energy needed to move an object will essentially be "used up" or lost in our muscles as heat energy and wont be transferred to the object as a gain in its momentum. The energy gained by the object is equal to: work = (force)(distance) joules, but this equation does not consider any losses and the total amount of energy actually required by the person or a machine, and this value of work is rather the energy gained by the object and-or the minimal amount of energy required by the person or machine. Essentially, only half the total energy involved will be applied to the object.

If a force is applied to an object for a certain distance and-or time in space, that object will gain energy in the form of momentum. The force and-the (limited) amount of energy used will actually move it an infinite distance and also at the same speed if there is no other forces applied to it. For the work formula , work = (force)(distance) joules, the force and distance values for this equation are only for when the force and energy was initially applied to the object so as it to give it that supply of energy.

If a meteor has a speed of 15000 mph, it is calculated that it will take about 25 seconds for it to go 100 miles of distance, and which is about the thickness of Earth's atmosphere. If the meteor does not come in (ie., travels, moves, enters) at a direct (perpendicular to Earth's surface, a 0° angle) course, that length will be longer than 100 miles and the time needed to travel that distance will be longer, say 1 minute on average. Once the meteorite enters Earths atmosphere it, will collide with the air and compress it and loose much momentum and energy due to the "friction" and "drag" resistance of the air. Much of the energy will be converted to heat energy, and the meteorite may "burn up" and become many small bits of dust and gas. This can be seen, and it is often called a "shooting-star". Its speed will decrease further, and therefore it will take even more time to reach the surface of the Earth. Since the surface area of the Earth is about 75% water, a meteor will reach land (solid surface, non-water) about 25% of the time on average, and generally away from populated areas.

Ex. Since KE = mv^2 / 2, if the speed of the wind (which has mass due to the air gases) doubles, its instantaneous kinetic energy for an instant of time will increase by 4 if it is considered as a single mass or object:

KE = mv^2 / 2 = 0.5 mv^2 , and if the velocity of a thin layer or mass of air or wind doubles:

KE = m(2v)^2 / 2 = m4v^2 / 2 = 2mv^2 and this is 4 times more KE, but more needs to be considered since we need to consider the KE in a volume of air that will pass a point and-or be available to the wind-blades of the wind electric generator every second.

Kinetic Energy (KE) of the wind is being used to power a wind- turbine so as to make electricity or power some mechanical equipment such as a mill or grinder, and the result would be 8 times the power if the wind speed doubles. An instant of air mass can be considered as a thin, two dimensional layer of air, such as the bottom layer of a cube, however over time such as 1 second, this thin layer of air becomes a volume of air which has three dimensions, and the total KE of the air during that time would be the sum of all these layers of KE during.

Consider: power = energy / time = KE / time = joules / second

The thin layer or area of the air can be considered as an instance, bit or "differential" of a larger volume, and noted as dV. To find that volume, we can take the anti-derivative of it; and here in this example: dV = 2mv^2 (which is the energy in each thin layer of air and-or instantaneous or bit of volume of that air per second, and when the speed had only doubled) and get the total or sum of all those thin areas or bits of volume so as to have the full volume (V) of air, and the full KE value of that volume of air during 1unit of time (here it is 1 second).

Consider: Volume = a^3, and that the derivative of it is dV / da = 3a^2 = an area (A) equal to a thin layer (ie., an area) of, and instantaneous bit of that volume. From this it can also be inferred that a higher dimension is equivalent to and-or composed of an infinite number of bits or layers of the next lesser dimension.
Volume = a^3 = (aaa) = (a)(a^2) = (a)(Area). As a side note, Volume is mathematically equivalent to Area times the square root of that Area. Ex. If Area = (2)(2) = 4, Volume = (Area)(Area^0.5) = Area^1.5 = 4^1.5 = 8 =
= 2^3 = (4)(2) = 8.

Also note mathematically: Volume / a = Area, and that as mentioned above or taking an infinitesimally small change, called a differential (d), in each variable, we have:

d Volume / da = dV / da = d Area = same ratio value of Area = Volume / a , or:
From: Volume / a = Area , we have: Volume = (Area)(a) , and after taking the differential of each side:
d Volume = d ((Area)(a)) and mathematically:
dV = d ((A)(a)) = d A da

The sum of each calculated, real bit and-or segment of volume = Sum of (dV) = equals the whole volume (V).

For our equation above of 2mv^2 , and if we take the anti-derivative (ie. summing up all these derivative, bit, component or instantaneous layers of area, which equals dV for each bit or layer), we have:
2mv^(2 + 1) / 2 = mv^3, and if speed doubles, KE will increase by the cube of that factor value, and here it is the cube of 2, and it is: 2^3 = 8 times more KE per second, or power than the KE at the half the speed or velocity.

What is the mass of air passing a point in 1 second. The density = (mass / volume) of air is noted at about:
Ma = 0.001225 g/cc. Multiplying both the numerator and denominator by 1000, we have:

Ma = (0.001225 g / 1 cc)(1000 . 1000) = 1.225 g/1000 cc = 1.225 g / L .
A cubic meter = 1m^3 = 100cc x 100cc x 100 cc = 1,000,000 cc , after dividing by 1000cc / L:
A cubic meter = m^3 = 1000L .
A cubic meter of air has a mass of: (mass / 1 L)(1000 L / 1 m^3) = (1.225 g / L)(1000L / 1 m^3) = 1225g / m^3 = 1.225 kg / m^3 .

If the windspeed was 1 m/s, then (1.225 kg of air / m^3) will pass by a point per second.
This could also be expressed as a mass rate per time of:
(mass / volume) / time = (mass)(time) / (volume): 1.225kg / 1m^3 / 1s = 1.225kg-s / m^3 , or = (density / time)

Setting up a proportion to find the volume of air that will pass a point per second in the windspeed is 10 m/s:

$$\frac{\text{speed}}{\text{density}} = \frac{1\text{ m/s}}{1.225\text{ kg / m\^{}3}} \quad \text{as} = \frac{10\text{ m/s}}{\text{X kg/m\^{}3}} \quad \text{we have:} \quad \text{X kg/m\^{}3} = (1.225\text{ kg/m\^{}3})(10\text{m/s}) / 1(\text{m/s}) = (1.225\text{kg/m\^{}3})(10) = 12.25\text{ kg/m\^{}3}$$

Power, which is the rate of using energy which is: energy / time can also be expressed as work done per unit time: Pw = Work / time , hence power is a measure of the rate of doing work and-or the using energy per unit of time. The derived or combined units for power is called watts (w).

Pw = (energy / time) = (joules / time) = (work / t) = (force)(distance) / (time) = (Nm / t) = (J / t) = (V C / t) = V A watts

In terms of torque: power (Pw) = (torque) x (rotation speed) : rotational speed = w = angular velocity = radians / s
Pw = (torque)(w)
Or: w = 1 revolution / s = 1 rev / s = (2)(pi) rads / s
w = (2)(pi)(revs) radians / second .

rpm = rev per min = revolutions / minute = (rps)(60)
rps = rev per sec = revolutions / second = rpm / 60
w = (2)(pi) (rps) = (2)(pi) (rpm/60) = (pi)(rpm/30)

This type of equation above is often found in the study of wheel and gear systems, and is derived below. A discussion of basic gear systems is given in this book. The units of force are usually called Newtons, the units of energy is Joules, and the units of power are Newton-meters per second = Nm/s = Joules/second. We see in this equation of power, that torque and speed are mathematically inversely related for a given (fixed, constant, limited) amount of power, and such as for the input and output power of gears or wheels. Note, that even though they are inversely related, they are generally not mathematical reciprocal in value to each other. It is also important to note that in a gear system, that the corresponding gains (multiplying factors) in torque and speed are actually mathematical reciprocals. The equation may look unique in terms of the variables used, but it is actually related to the previous equation shown. Torque is related to force, and speed is related to distance and time.

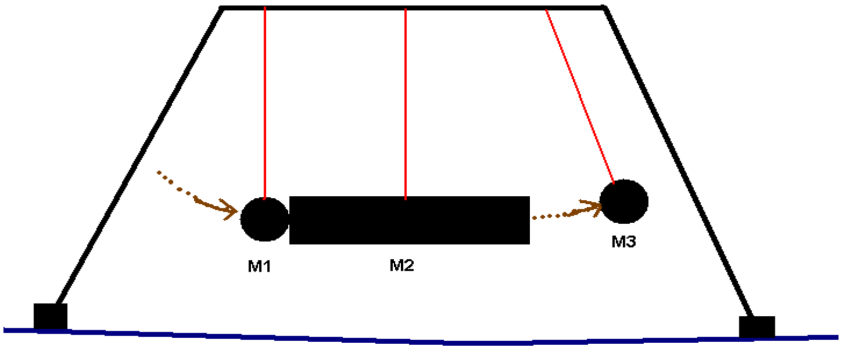
For the above equation: As derived in the **angles and rotation** section this book:

linear velocity = v = angular velocity / radius = w / r
distance = v t = (w r) t

Power = energy / time = work / time = (force) (distance) / time = ((torque) / r) ((wr)t) / t simplifying:
Power = (Torque)(w) joules

A BASIC ANALYSIS OF COLLISIONS OF MASS AND THE TRANSFER OF ENERGY

Below is a mechanical system of 3 masses at rest without any initial motion and having energy: M1, M2, and M3. M1 and M3 have the same value of mass, and M2 has many more times the mass of either M1or M3. [FIG 229]



This device shown in the above figure is very similar to a device called "Newton's Cradle", "Newton's Balls" or "Newton's Pendulums" and where it has only solid metal balls (ie., spheres), and with each having the same mass. That device is also credited to Abbe Marriot, and Christiaan Huygens to study the collisions or impacts of masses in about the mid 1600's. Today, Newton receives most of the credit because of his famous equations for motion such as force = (mass)(acceleration) = f = ma. Fundamentally, this device is also an image of how mechanical (ie., physical and-or motional) forces are transferred even through a single piece of material, atom by atom, from the input to the output at a high speed.

When M1 is swung and let go, it will collide into M2. The energy of M1 will be transferred to M2 via the applied force of M1 due to its mass and velocity, and which is its **momentum** (p or P = mv). With this system shown in the figure, there will be a small energy loss for each collision, and due to a transfer of some energy into sound and (KE) movement losses due to friction.

The since the mass of M2 is much larger than M1, M2 will not accelerate and then move much due to that its mass is larger and therefore has larger inertia or resistance to change. Then M2 will transfer nearly all of its newly gained energy to M3 by applying a force to it. After M3 reaches its maximum height, it will swing back in the reverse direction, and a cycle of these collisions will keep happening until the loss of energy due to the small amounts of friction and sound deplete the input energy to 0 Joules.

Energy in = Energy out : conservation of energy , theoretically 0 losses, full transfer of energy
KEm1 = KEm2 = KEm3 : In reality, there is a small amount of friction losses for each cycle.

Since: $KE = \frac{mv^2}{2}$ for a given, constant or limited amount of kinetic energy (KE), the relationship of (m) and (v^2) is an inverse relationship. When the mass (m) increases, its velocity will be less. When the mass (m) decreases or is less, its velocity will be more. Note that this equation has a quadratic equation form with a squared independent variable.

If all the kinetic energy (KE) of a mass such as M1 is transferred to a larger mass at rest such as M2, the velocity or movement of M2 will be less, but its amount of KE will be still the same. When M2 applies force to M3, it will transfer its KE to M3. Since M3 is a smaller mass, its KE will still be the same, but its velocity or movement will be more:

Momentum in = Momentum out : conservation of momentum (p, here using P), theoretically 0 losses,
Pm1 = Pm2 = Pm3 full transfer of momentum. Whereas (KE) is a quadratic type of
(M1)(V1) = (M2)(V2) = (M3)(V3) relationship to (v), momentum is a linear relationship to (v).

Work in = Work out
Work due to M1 on M2 = Work due to M2 on M3
(force)(distance) = (force)(distance)

When M1 strikes M2, M1 will apply a pulse of force to M2. M1 will loose energy and decelerate, and this is also due to the concept of equal and opposite forces. The inertia of the large mass of M2 will be like a resistance in the path of M1, and so the force applied to M2 is as if it was "reflected" (by compression and expansion of the atoms) back to and upon M1, especially when the velocity of M2 is very low, such as 0, and it will take some time for it to accelerate to a velocity. Since this "reflected force" is in the opposite direction and upon M1, M1 will decelerate and loose velocity and momentum (ie. energy). The momentum and energy that M1 transferred or "lost" will be gained by M2.

An "**elastic collision**" or impact is when much of the applied energy or momentum is "reflected" back to the object(s) of the same mass, and their KE will be, or nearly be, the same as before the collision as if none was lost and-or transferred to something else. In short, their momentums will be exchanged, and there is no loss of momentum and-or energy.

Forces cause motion, but forces also often causes a very high speed compression (force, pressure or "shock") wave of matter (ie., atoms) that transmit the energy from one atom to the next via force, much like how sound is a compressed wave or vibration of air that transmits the pulse of energy, atom by atom through the air.

When M1 collides or impacts with M2, the force and available amount of energy is quickly transmitted in what is described as a pulse of energy and-or an impact force. Here, quickly transmitted means a very short, almost imperceptible, amount of time to do so. The change in velocity with respect to time is high, therefore, the acceleration (here, in the form of a deceleration) is also very high during that short amount of time.

$$a = \frac{\text{change in velocity}}{\text{change in time}} = \frac{\text{Vtraveling} - 0}{\text{a fraction of a second}}$$

: at impact the velocity is 0, especially if the object that got impacted did not move much

Since: F = ma , and if (a) is a very large value, the impulse (a quick impact) force will be a very high value, but only briefly in time, and over a very short distance. Because the force is high, and force is the application of energy, the energy "release" or transfer (joules/second) will be a very high rate. We see that a quick acceleration and-or deceleration can effectively increase or amplify the force created to a very high value for a short amount or pulse of time. This high force value can cause metal to bend in a high speed collision, and especially mores so when the objects are traveling toward each other and with each having their own kinetic energy (KE=mv^2 / 2) and momentum (p=mv) which will increase the resulting decelerations and (impulse, quick-impact) forces during the collision. As a thought concept, when the objects area headed toward each other at the same velocity, if the velocity of one object was then twice as much, its KE increases by 4.

If an object collides with another object that is already moving, such as in the same direction and slower so as there is actually a collision, then only some of its KE will be converted to force upon colliding with that object, therefore, it will keep the energy that was not transferred to the object. The energy transferred to the object will increase its KE (joules) and momentum (movement, p = mv).

Since: Work = (force)(distance) = W = (F)(d) = (ma)(d) , we can mathematically derive:

$$F = ma = \frac{W}{d} = \frac{\text{Joules}}{d}$$

: force expressed as a rate of using energy per unit of distance,
and:
Mathematically: a = F / m = J / md and:
mad = Joules and: Fd = work = Joules and: Fvt = Joules and:
Fv = Joules / t = energy / time = Power in watts and
F = Joules / (vt) and: momentum = p = mv = m (d / t) = md / t

The change in momentum (p) of an object just before collision and after collision where its momentum is 0 because all of its energy has been transferred or released to something else is:

(change in momentum) = (change in p1) = (m1)(v2) - (m1)(v1) = (m1)(0) - (m1)(v1) = - (m1)(v2)

The negative sign indicates the change in momentum (p , a change in movement) was a decrease.

From: a = (change in velocity) / (change in time) = $\Delta V / \Delta t$: extra: (change in v) = a (change in time)

$$F = ma = m\frac{\Delta v}{\Delta t} = \frac{\Delta p}{\Delta t} = \frac{\text{(change in momentum)}}{\text{(change in time)}}$$

: force can be measured as a rate of change in momentum with respect to a change in time. The units could also be expressed as energy / distance = = joules / distance .

$F = \Delta p / \Delta t$, also , $\Delta v = F \Delta t / m = a \Delta t$ and $F = ma = m v / t = p / t$ and $F t = mv = p$

If there is no change in momentum or motion such as a change in velocity, then no force has been applied and v is the same.

The greater the change in momentum and-or the shorter the time of that change, the greater the resulting brief pulse or impact force applied. During a collision, velocity and momentum will change since p = mv.
Also: v = p / m = momentum / mass

$\Delta p = F \Delta t$: (change in momentum) = (force applied) (change in time) = a measure of an **impulse**
(the application energy by a force)

The longer the time that a force is applied to an object , the greater the change (increase or decrease) in its momentum. The greater the force applied to an object, the greater the change in its momentum during a given amount of time. Δp may sometime be symbolized with letter J, but it does not mean Joules of energy.

Force can be described as the application of energy to an object and-or which changes the momentum of an object.

p = momentum = mv with units of: (kg)(m/s)

If one Newton of force is applied for 1 second of time, it is called a Newton-Second = N-s and is the unit of impulse (I), and which is a measure of the force applied and the time it is applied.

Impulse = (Force)(change in time) = (change in momentum) = (mass)(change in velocity) = (Newtons)(seconds) = N-s = (m)(a)(s) = (kg-m / s^2)(s) = (kg-m / s) = mv = momentum. From this we can also have: mv = Ft and F = mv / t = momentum / t = m a

Impulse = I = F t = m a t = m v

If energy is used up by a person trying to apply a force to something very massive and it does not move (ie., change its momentum = mv), and since none of that input energy was transferred to that massive object, there was no actual, apparent or useful work=energy done in the terms of transferring energy to that object. Surely, a force was used and energy was applied, but none of it was apparently transferred, and-or saved (ie., gained) by the massive object, and the energy used up by the person is lost and-or wasted as other forms of energy. In the equation: Work = (force)(distance), if the distance is small or 0, then the work is small or 0 regardless of how much energy (Joules) was used. Work is rather an amount of transferred energy to something else. This is one reason why W = (F t)Joules is not used for the transfer of energy, but rather W = (Fd) Joules is used. Using: (Work)(time) = (force)(distance)(time) = Fdt = (Joules / time)(time) = (power)(time) = Joules , would be the total energy input, and including any losses to the (useful, desired) momentum of an object moving a distance.

A moving object such as an automobile or bicycle have wheels which will experience friction with the road. This can be thought of as a type of collision between the wheel and the roadway. Due to this the moving object will continually loose a certain amount of its kinetic energy each second, hence a certain amount of power each second, and the moving object velocity will continually be reduced unless more kinetic energy is given to the object by a force. If the energy input is equal to the friction losses, the objects speed will remain constant. If the energy input is greater than the friction losses, then the object will accelerate and continually increase in velocity. The effective input force given to the object and-or its mass is:
(effective input force) = (input force) - (friction force) , $F = ma$, $a = F / m$ = (effective input force) / (mass of object)
The effective energy input is: (effective energy input) = (energy applied) - (energy losses due to friction).
As the object slows, the graph of its velocity and KE with respect to time will decline downward just like a downward parabola, and have a high negative slope value. This is so since kinetic energy = $mv^2 / 2$ has the squared variable in it and it is therefore a quadratic and-or parabolic equation.

The mathematical relationship between kinetic energy and momentum:

First: Momentum is a measure of the total movement, motional and-or ability of an object to either keep moving or stopped. $p = mv = vm$ is a linear equation

Kinetic energy is a measure of the stored energy of a moving object, and which therefore has an equivalent amount of potential or stored energy. Its units like other forms of energy are joules. $KE = mv^2 / 2$ is a quadratic equation, and that KE greatly increases when v increases. It will also, for example, take 4 times more KE and-or applied force so as to double an objects velocity.

A falling object will increase in motional (ie., momentum, p) and kinetic energy (KE) due to gravity accelerating it.

$KE = \frac{mv^2}{2}$ and **p = momentum** = mv , we have $v = p/m$ and by squaring both sides: $v^2 = p^2/m^2$, we have:

$KE = m v^2 / 2 = m (p^2 / m^2) / 2 = p^2 / 2m$ = (momentum)^2 / 2 (mass) , solving for p = momentum:

$p^2 = 2 m KE$, taking the square root of both sides:

$p = \sqrt{2 m KE} = 1.414 \sqrt{m KE}$

Also, from $KE = (mv^2) / 2 = (mv)(v) / 2 = p v / 2$

Before moving on to another topic, lets see how the values of mass and velocity will vary if the kinetic energy (KE) remains (nearly, and practically) a constant value such as in the Newtons Cradle, (KE) device.

From: $KE = \frac{mv^2}{2}$ we have: $m = \frac{2(KE)}{v^2}$ and $v = \sqrt{\frac{2 (KE)}{m}}$

If we set (KE) equal to 1=100% of some value, we can create a relative analysis so as to see how the variables related to (KE) will change in a relative way, such as by what factor, and so as to have a more intuitive approach to how (KE) will change when one of these variables changes.

$1 = \frac{mv^2}{2}$, since we are rather interested in changes, * we can consider this analysis without the denominator of 2, and we see that these are factors of the product of 1, and are then mathematical reciprocals of each other:

$m = \frac{1}{v^2}$ * , if one factor increases or changes by a factor or (n), the other changes by the factor of (1/n) which is the the inverse of that factor. Ex.:

$$1 = \frac{(n)}{(n)}\,\frac{mv^2}{1} = (nm)\,\frac{(v^2)}{n} = \frac{m}{n}\,\frac{(n)(v^2)}{(1)}$$

It could be said that the relative changes to each factor are also reciprocal in value, and expressing this as another equation:

1 = (relative change in m)(relative change in v^2) mathematically:

$$\text{(relative change in m)} = \frac{1}{\text{(relative change in } v^2\text{)}}$$

: relative change in v = $(v2 / v1)$ = result v. / starting v.

$$\text{(relative change in } v^2\text{)} = \frac{1}{\text{(relative change in m)}}$$

: relative change in m = $(m2 / m1)$ = result m. / starting m.

$$\text{(relative change in m)} = \frac{m2}{m1} = \frac{1}{\left(\frac{v2}{v1}\right)^2} = \frac{1}{\text{(relative change in v)}^2}$$

$$\text{(relative change in v)} = \frac{v2}{v1} = \sqrt{\frac{1}{\left(\frac{m2}{m1}\right)}} = \sqrt{\frac{1}{\text{(relative change in m)}}} = \frac{1}{\text{sqrt (relative change in m)}}$$

Ex. If the KE of a mass1 of 1kg is being transferred to a mass2 of 10kg, how will the velocity of mass1 change?

(relative change in mass) = (mass2 / mass1) = $(10 / 1) = 10$

(relative change in velocity) = $\sqrt{1 / \text{(relative change in m)}} = \sqrt{1 / 10} = \sqrt{0.1} \approx 0.316$

Its velocity, whatever it may be, will change by a factor of 0.316 . That is $(v2 / v1) = 0.316$
For example, if its velocity = $v1 = 5$m/s , $v2 = (0.316)(v1) = (0.316)(5\text{m/s}) = 1.58$m/s

$KE = mv^2 / 2 = (1)(5)^2 / 2 = (10)(1.58)^2 / 2 = 12.5$ joules : When (KE) in = (KE) out , due to no energy losses, and a complete energy transfer and conservation of energy.

The discussion about Bernoulli's equation in this book has a similar analysis to the above.

Momentum is conserved for two objects that collide

total momentum before a collision = total momentum after a collision

total momentum = momentum of object1 + momentum of object2 = $(m1\ v1) + (m2\ v2)$, mathematically:

$v1 = [\ (\text{total momentum}) - (\text{momentum of object2})\ ]\ /\ m1$
$v2 = [\ (\text{total momentum}) - (\text{momentum of object1})\ ]\ /\ m2$

If after a collision where object2 collided with object1, and if object2 stopped moving, all of the energy and-or momentum of object 2 was transferred to object1, and the momentum of object1 will then be the total momentum of the system (here, of the two objects). This conservation of momentum (ie., the total momentum being conserved and not reduced or lost) is similar to the conservation of energy concept.

How much (kinetic) energy is transferred during a collision depends on the amount of force and the distance (and time, since to go a distance takes time) it was applied.

energy = work = (force) (distance) , Joules
energy = work = (mass)(acceleration) (distance) , Joules

Note that (KE) is a second-order or quadratic equation, and momentum is a linear equation. When velocity changes by a factor of (n), the (KE) is significantly changes by the square of that factor , and the momentum (p) changes in a linear manner by the same factor:

$KE1 = mv^2 / 2$ and $KE2 = m\,(nv)^2 / 2 = (m\,n^2\,v^2 / 2) = n^2\,(mv^2 / 2) = K1\,n^2$

$p1 = mv1$ and $p2 = m\,(nv1) = n\,mv1 = n\,p1$

From: $KE = mv^2 / 2$ and momentum $= p = mv$ and $m = p / v$ and $v = p / m$

$$\mathbf{KE} = p\,v^2 / 2v = \mathbf{pv / 2} = p\,p / 2m = \mathbf{p^2 / 2m} \quad \text{and} \quad \mathbf{p = 2\,KE / v = \sqrt{2m\,KE}}$$

Sometimes an **impact force** is described in terms of the (impact) energy in joules = (force in newtons)(distance in meters), rather than Newtons of force. For example: "the object impacted with a force of 1000 joules", and this rather means: "the object impacted with 1000 joules of energy (ie., KE = kinetic energy).

Energy = KE = Work = (Force)(distance) = Fd joules = $ma\,d = \frac{mvd}{t^2}$, and mathematically:
: in an impact (a) is a deceleration for the object that looses energy

Force = F = Energy / distance = Joules / distance = $KE / d = \frac{mv^2}{2\,d} = \frac{m\,v\,v}{2\,d} = \frac{mv}{2t}$: $d = v\,t$, $t = d / v$
$1 / t = v / d$

If the given energy is transferred in a shorter distance and-or shorter time, the impact force will be higher. An object with a greater mass and or velocity will have a greater amount of kinetic energy, and will produce a higher impact force.

One way to actually measure a force is by using a force gauge which can indicate the highest force encountered during an impact.

If an object is dropped from a height from above ground level, and due to the concept of equal and opposite forces, there will also be a force placed upon that object during the impact, and the value of 2 in the denominator of the impact force expresses that the (KE) energy available will apply and-or create (ie., induce) an equal amount of force to both the object and the ground it lands upon. The ground may obtain a dent in it, and the object may break apart. In other words, the energy got divided, some used to make the dent in the ground, and some used to break apart the object.

Some extra equation for consideration:

From: KE = mv^2 / 2 , we have: m = 2 KE / v^2

From: F = m a , we have: F = 2 KE a / v^2 = 2 KE g / v^2

KE = mv^2 / 2 = F v^2 / 2g

When KE = GPE , KE = GPE = mgh = mv^2 / 2

v^2 = 2 g h and $v = \sqrt{2 g h}$:

Such as for a falling object just before it reaches the ground . Notice that mass is not a factor in this equation, hence various masses will have both the same velocity and time of impact when dropped from the same height (ie., distance). Due to the constant force of gravity accelerating the mass, the linear equation: distance = height = (velocity) (time) is not valid due to that the velocity is not a constant value due to the force of gravity constantly applied to the object and accelerating the velocity of the object which starts from v=0 units of distance/second and continuously increases.

Calories = An indicated calorie number or level is basically the total energy available, and in these modern times, it is usually in reference to food(s) substances only, and for the specific food(s) in question since the total calorie value will vary for each different food substance or mixture and the amount of it being considered. This energy can be used by the body to do things, such as the fuel for moving muscles so as to move or do things which will require some energy (ie., fuel) to do. Any of the available calorie energy that is not used immediately by the body is either stored (perhaps as some fat, muscle or other tissue for a future use by the body) and-or eliminated from the body. 1 calorie of energy is formally defined (ie., its calculation and measurement) as the amount of energy needed to raise the temperature of 1 gram of water to 1°C higher than a given temperature. The English unit conversion of this is: 1 gram of water = 0.038814 fluid ounces of volume , and 1 °C increase = 1.8 °F increase or change. 1 calorie is equivalent to about: **1 cal = 4.187 J =~ 4.2 joules** of energy. Note, that to heat a gram of a certain substance or element other than water, it may take more or less than 1 calorie, and the specific value is called the thermal ability or thermal capacity of a substance. Also this equation assumes that all of the input energy to try to increase the thermal energy of the water or substance will increase of the thermal energy of the water or substance by that input amount, and this is generally not the case due to the specific situation and its inefficiencies of the energy transfer. For example, with a flame heating a pot on a stove, some of that energy is wasted as hot air around the side of the pot and it will then not heat any water in the pot. **1J = 0.239 cal**

In the cells of our body and other life forms are smaller structures called organelles that make and-or do things. One organelle type is called **Mitochondria**, and these produce **ATP** (**A**denosine **T**ri-**P**hosphate, a nitrogen, hydrocarbon sugar and phosphate molecule) from chemical reactions from the foods we eat, and this ATP molecule with stored chemical energy and-or ability provides chemical energy for the body to make and-or do things. In short, it takes energy from food to create other forms of energy that our body needs. You can tell by it's name, phosphate (**phosphorous**) is part of this ATP molecule. A typical cola soda may contain about 30mg to 55mg of phosphorous in the form of phosphoric acid, and too much soda will usually decrease the vital calcium level in the body and interfere with some other essential minerals. People with kidney disease will have trouble removing any unnecessary phosphorous from the body. Because white phosphorous can radiate a green light when in contact with warm air, its name is based on the words "photon bearer". White or yellow phosphorous can cause caustic burns and ignite in air, and is the toxic form of phosphorous. Red phosphorous is made by heating white phosphorous to about 500°F in an airless (ie.,no oxygen) container, and is not toxic, but it is flammable and is used in the production of fire matches.

The average human adult at rest, say sitting and-or lite activities, will use about 100 watts of energy = 100 Joules of energy per second for powering all their body processes (blood flow, digestion, breathing, etc.) of which much is eventually converted to heat and keeping the body's internal temperature at a comfortable 98.6°F = 37°C, and of which some of this heat energy is constantly being lost to the cooler air that is in contact with the skin and the body then needs to keep reheating itself. 100 W = 100 Joules of energy / 1 s =~ 23.88 cal / s =~ 24 cal / s , and this would total to 2063232 cal / day =~ 2000 kcal = 2Mcal = 8640000 J / day . It is often, though technically incorrect in terms of units, commonly said that adults should consume a scientifically estimated, **"2000 cal / day diet"** so as to replace this (estimated, averaged) amount of energy used up and converted to mostly heat energy. For a person doing moderate exercising and-or doing general work, this 100W = (100 Joules of energy used / 1s) of power value can increase to say 300 W of power, and these people will then require three times more food, calories and its corresponding energy so as to replace this used up (ie.., converted to heat, etc) energy and to sustain and power their work ability. Many animals have a similar or slightly higher body temperature than that of humans.

A calorie in terms of food: A calorie value or level is not an indication of a food's nutritional (nutrients= vitamins [elemental compounds] and minerals [elements]) content or value. A food may be high in calories, but low in nutrition. Many diets include some physical exercise and limit the number of calories you should eat, and then you will therefore need to get your proper nutrition (vitamins and minerals, and with at least the minimal daily amounts recommended) in that food you do eat, and assuming your body actually did absorbed all the available nutrition in what you did eat. Some people eat well to get their nutrition, but have digestion problems, and so that nutrition available may not actually be getting absorbed into them, and they should therefore consider deliberate supplementation (ie., a vitamin pill(s)) after consulting with their doctor. For people having some difficultly loosing weight, it is still better to at least not gain any more weight, and which is a very positive start of controlling their weight. Having food is comforting and life maintaining, however it can actually become detrimental to our health if it contains inadequate, low nutrition, and-or if we are already overweight and not controlling our weight gain. Try to always stay aware and consider these matters every time you shop for and-or eat foods. Too much sugar, oils (fried foods, chips) dairy (cow milk, cheese, sour creme, etc.), salt, and bread (wheat) products have been a problem for many people. Vegetables, some fruit, and a general variety of foods are usually recommended. Some foods are also more enjoyable, depending on how they were prepared and cooked. For example, finely shredded raw carrots are easy to eat, are somewhat sweet and make a wonderful addition along with some other available shredded vegetables into ramen ("quick-noodles" [cook quickly]) or a "veggie sandwich" with a small amount of your favorite salad dressing.

Ex. A certain bag of potato chips that has a total of 252g indicates that 1 serving for a person is 28g = 1oz, and that it has 150 calories. How many grams and calories would 3 servings be? 3 servings would be (3 servings) (28g/serving) = 84g. 150 calories is to 28g as is x calories is to 84g. 150 cal/28g = x cal/84g. After solving for x, we have x= (3)(150 cal) = 450 cal. A 252 gram bag of these chips will have: 252g / (28g/1 serving) = 9 defined or standard servings. This bag will also have at total of: (252g)(150 cal / 28g) = 1350 cal.

Examples of calories in common foods:

Food	**Calories (averaged over a variety) / gram**	**: 1 gram = 1g = 0.035274 oz (weight ounce, wtoz)** **1 oz =~ 28.3495g =~ (30g food 1 oz.)** **1g = weight of 1cc volume of liquid water** **1 fluid oz. water = 29.573555 grams = 30g food oz**
Water	**0**	**1 fl. oz. Water =~ 29.57 cc volume**
Food Salt = Table Salt =	0	
Food Oils	9	= about (9 cal/g) (30g/oz) = 270 cal. / oz
White Sugar	3.8	, about 112 cal./oz
Instant Dried Potatoes	3.5	, about 100 cal./oz dry : can rehydrated with plain water, hence 0 added calories
Popcorn	3.8	, about 110 cal. / oz
Rice	3.55	, about 100 cal. / oz dry
Peanuts	5.63	, about 160 cal. / oz : about 50% of the mass and-orweight of a peanut is due to its oil
Peanut Butter	5.85	, about 166 cal. / oz
Meats	13	, (13 = 4 calories protein + 9 calories fats) = about (400 cal./oz) = 6400 cal/16oz = 6400 cal/lb
Breads	2.75	: (2.75cal)(30g/oz) = 82.5 cal / oz = 1320 cal / 16 oz = 1320 cal / 1 lb
Pasta (noodles)	3.55	=~ 100 cal./oz = 1600 cal / 16oz = 1600 cal / lb
Vegetables	0.5	
An Olive	1.3	:a green olive weighs about 4 grams. About 15% on average of the weight or mass of a green olive is oil. A back, ripe olive can have about 22% oil on average.
Cola Soda	~ 0.38	, (mostly from white or cane sugar) , 12 fl.oz can =~ 355cc =~ 360g , having ~ 140 cal / .can
Vodca , 100%	7.5	, (about 210 cal./oz = 210 cal./28g = 7.5 cal./g)
Average Beer	~ 0.43	, (a 12 floz can will have about: (12 floz)(12.3 cal/oz) = 148 cal. / 1 can of beer
Chicken Egg	1.3	, 65 cal./ medium size chicken egg =~ 50g , hence : 65 cal. / 50g =~ 1.3 cal./g
Mozzarella Cheese	2.71	, 76 cal. / 1 oz = 76 cal. / 28g : from cow milk , slightly aged , mild taste
American Cheese	3.68	, 103 cal. / 1 oz = 103 cal. / 28g : Usually a blend of mild cheddar, Colby, and may have other common cheeses , made from milk

Specific Heat Capacity is the amount of energy rating to raise the temperature of 1 Kg of a substance by 1 °C, and when no losses are considered. Water has a specific heat capacity of 4186 J/Kg/°C = 4.186 J/g/°C , and it will have this much more thermal energy when no losses are considered.

Mass-Energy Equivalence : E = Mc^2

First, **energy does not have a specific form, material or shape, and is rather an ability, "the potential" or "power" to do things**. Materials can store and-or release energy such as to apply it and release it to other materials that will absorb it. Energy is measured in standard units called Joules (J) or Joules of energy.

There is a concept or theory that since we can use matter or "mass" to store and-or release some energy, in a reverse manner, that energy can be condensed into some mass, hence effectively as being a "matter battery" or "battery of matter" which can contain energy. A good example is a fuel to release its energy and make heat, light or motion (such as in a vehicles gas combustion engine) so as to have and give useful energy to another mass so as to do other things. There is a famous equation for the mathematical relationship of mass and energy, and it was developed by the German physicist **Albert Einstein** (1879-1955) in about the year 1905:

E = M c^2 : E = energy in joules , M = mass in kilograms , c = speed of light in meters/second =~ 3(10^8) m/s
c^2 ~= (3(10^8))^2 m/s =~ 9 (10^16) m^2/s^2

This formula indicates that even a small mass, such as 1 gram, has a very large energy capacity, storage, potential or ability within it. The energy is stored as the **strong nuclear force** that is much like the stored energy of a compressed spring. This force holds the quark particles together that compose each proton and neutron. This force will also keep the protons from electrically (ie., charge force) repelling each other in the nucleus. The strong nuclear force is much greater than the electric force, but it only acts strongly at the nucleus area of the atom, hence for a short distance only. According to the formula, the density of the mass, or the type of element(s) the mass is composed of, does not have an effect on the resulting energy equivalence. From the formula, since (c) is a constant, if M is increases by a factor of (n), then E increases by that same factor of (n), and vice-versa. (c) is a constant of proportionality in the mathematical relationship between (of) M and E, and specifically, its value is how many times E is numerically always greater than M. (E / M) = c^2. The ratio of the value of E to M is always the same constant of (c). The reciprocal of c^2 is how many times M is numerically less than E.

Another consideration is that the smaller the mass, the less energy needed to make it go at a certain or given speed, and here, the speed of light. It takes little energy for an atomic particle, which has a very small mass and momentum, so as to be highly accelerated and have a high velocity such as the speed of light. E / M = c^2 , and if M is changed or amplified by a factor, E is also changed by that same factor so as to have an equivalent fraction with the same ratio value, here c^2.

According to this formula and theory, 1 gram of mass which equals 0.001kg can (theoretically) be converted to 9(10^13)J = 90 (10^12) J = 90 trillion joules = 90 Tera-Joules = 90 TJ . This is enough energy for a 1 MW = 1 mega-watt = 1 million watts = (1) (10^6)J / s = 1 MJ / s power station to supply full (100%) and continuous power for 2**.**854 years:

From: watts = joules / s = J / s , we have: time = joules / W = (energy available) / (rate of using the energy)
90 TJ / (1MJ / s) = 90 (10^12) **/** 1 (10^6) / s = 90 (10^6) s = 90,000,000 s = 90 million seconds of time
Since 1 year = 31,536,000 s : 90,000,000s **/** 31536000s/1yr = 2**.**854 years

Einstein's equation shown above is actually very similar to the (older, and more useful) kinetic energy equation: **KE = mv^2 / 2** , and it could be thought that the if the matter itself also turned into pure energy, then this KE value would be twice or double as it is expressed in Einstein's equation: mv^2 = mc^2. Even though Einstein's mass-energy equation contains the speed of light variable (c), his equation actually considers the mass when it is at rest and does not have any extra or kinetic energy associated with it and which would increase its total energy. His equation rather considers the energy as potential or stored energy due to the matter only.

It was previously shown in this book that force = mv^2 / d , hence: fd = mv^2 = work = energy , joules
If v = c , the speed of light , we have energy = mc^2

Again , this is the kinetic energy formula without the 2 in the denominator. What can we make of this? Consider when you lift an object a height to give it an amount of (gravitational) potential energy, your muscles have used and converted an equivalent amount of work and-or energy but have lost it as heat energy, hence this is a reason why the common KE formula equals mv^2 / 2 or half of the total energy used in the system as indicated by the 2 in the denominator. This is much like the concept of equal and opposite force, and perhaps could be considered equal and opposite work = energy , joules.

When atoms are made, tremendous kinetic energy and force is needed to force together, and essentially fuse together, the protons, neutrons and electrons of an atom. Even each neutron and proton are now understood (after research beginning 1964) to be composed of three quark (with mass a mas of 1/3 of a proton or neutron) particles each, and with gluons holding the quarks together with what is called the "strong atomic or nuclear force". Don't confuse this force with magnetic or electric force. This energy used to force particles so as to be together as an atom, is stored in that atom as strong atomic or nuclear forces and this could be thought of as being like a compressed spring with stored energy, and if the spring is cut, the stored energy is released. The more particles in a particular type (ie., element) of atom, the more total energy need to make it, and the more stored, potential energy in it.

A helpful theory of what causes gravity. The field of gravity from a mass, unlike that of electric and magnetic fields, does not seem to curve around to itself an-or have two poles of attraction and-or repulsion. If mass is associated with energy, a larger mass has a larger amount of energy, and therefore a smaller mass has a less amount of energy. The force of gravity seems to be proportional to the amount of mass, hence therefore proportional to the energy within that mass. Surely, it takes more energy to split and-or create atoms having more mass particles (atomic mass units = protons, neutrons, etc.) because they took more energy to create and they can therefore store more energy, much like atom sized springs compressed together at the nucleus and storing the energy it took to do so, and particularly for protons which have the same (positive) electric charge and repel each other. Gravity could then be said as due to that energy (or energy and mass) attracts other energy (or energy and mass), and is commonly said as (just) the matter, and not the conceptual energy it has that attracts each other. With this theory of gravity, and object with more mass will have a higher "gravitational [potential] energy" potential and-or ability to attract other mass. In short, gravity is then a form of stored and-or accumulated energy, much like how the strength of magnetism and electricity are.

The concept of **relativity** takes into effect of how the observer (apparently) sees, experiences, and-or understands (or assumes) things. For example, if you were in some type of vehicle, such as a car going 50 miles and hour, or even going 1 million miles an hour, you would generally not even notice how fast that vehicle is going. With respect, reference, relative, or in relationship to you, it would seem or appears as that you and the vehicle and all the objects in it are going 0 miles per hour or not moving in reference to you and each other. This all happens because you and the vehicle are both going the same speed and direction, and there isn't any difference in speed between you and the spaceship your in. To a distant stationary observer on a planet, they would indeed see the spaceship vehicle with you in it traveling quite fast with respect or relative to them and their own corresponding position (location), speed and direction. It is often said that speed or velocity is "relative", or "relative to the observer (and their own speed)". Due to this fact, is not to difficult to then image that distance and time are also relative to the observer. Now consider the possibility that gravity is also relative to the observer, surely, for two astronauts or objects falling at the same rate inside a spacecraft orbiting about the Earth, they will sense no downward force of gravity upon them, and it is as if g=0m/s^2 , but it is the relative or apparent value to them. It will still require energy to make a force and apply it (the energy) so as move an object in "weightless" space, but once it is applied, the object will keep moving unless another force acts upon it. Extra: While on this subject, due to the mass value of an object, it will still have an inertia (ie., effective resistance to the change in motion, and-or that an amount of time may be needed to transfer the applied or input energy) value, and its value is relative to the amount of mass. If an orbiting spacecraft were to reduce speed and-or stop in its orbit, it will begin to feel the effects of gravity and it will be pulled closer to the Earth by not having enough velocity to maintain the altitude of orbit, and the spacecraft will reduce in altitude, such as needed for landing the spacecraft.

Some conversions for energy, work and power

BTU = **B**ritish **T**hermal **U**nit. If the temperature of 1 pound (the weight of 16 fl or volume ounce of water) of water is increased by 1 degree Fahrenheit, it is gained 1 BTU of (thermal) energy. 1lb = 1 pound =~ 453.592374g = = ~ 454g =! 0.454kg. 1°F = 0.555°C , 1°C = 1.8°F . 1 BTU = 0.293 watts, therefore 1 watt = 3.413 BTU

Calorie = A (thermal, energy) calorie or cal is a unit of (thermal energy) measurement when the temperature of 1 gram (= 1cc) of water increases by 1 degree Celsius or Kelvin. 1 cal =~ 4.184 Joules of energy.

Foot-pound = A unit for the amount of energy to lift or move a weight of 1 pound upward by 1 foot of distance. In terms of torque or twisting force, 1ft-lb is the (perpendicular applied) force of 1 pound on a lever arm that is 1 foot long. If the force is still 1 pound, but the lever arm is now 2 feet long, then the torque or twisting force is 2 ft-lbs, and this is also equivalent to a weight of 2lbs on a lever arm of 1 ft. Torque = (F)(L).

1 Joule of energy = about 0.000948 BTU = 0.239 calories = 1 watt-seconds = 1Nm = = 1 Newton-meters , (ie., the energy = work of 1 Newton of constantly applied force to an object through 1 meter of distance). 1BTU =~ $1054.8\underline{5}$J =~ 1000J = (~ 1000 kJ) = 0.293w

Note that force = (mass)(acceleration)
1N = (1kg)(m/2^2) = the force that can accelerate 1kg of mass 1 meter per second/per second that it is applied.

1 Joule in terms of electricity is the amount of energy needed or used to force or move a total of 1 ampere or 1 coulomb of charges / 1 second of current through a resistance of 1 ohm for a duration of 1 second. `V = J / C , therefore: J = VC = fd = work = energy. The voltage drop across and-or through this resistance is IR = (1A)(1ohm) = 1V. If the resistance was then 10 times more at 10 ohms, and the current was still 1 ampere, the voltage drop across and-or through this resistance is IR = (1A)(10ohms) = 10V and the energy needed, used up (or wasted as heat) would be 10 times more in that 1 second of time, and that would be 10 Joules. An equation to find the amount of electrical energy is:

From: **V = J / C and 1A = 1C/s** we have: **J = VC = VAs** , Ex., as described above: J = (10v)(1A)(1s) = 10
Note that VA = power = P watts , and 1J = 1W-s
VAs = Ws = (Power)(time) = (J/s)(s) = J = Joules

Pw = $\frac{\text{joules}}{\text{time}}$ = (voltage) (current) = $\frac{(J)\ I}{(C)} = \frac{J\ I}{I\ s} = \frac{J}{s}$: 1W = 1J/s
: From: Ia = 1C/1s , 1C = (1a)(1s) = "1 amp-second"

joules = J = (Pw)(t) = (V)(I)(t) : also by Ohm's Law: V = (I)(R) and I = V/R ,

joules = (I^2)(R)(t) = (V^2 / R)(t)

Work = (force)(distance) joules = (mass)(acceleration)(distance) joules = Energy to do that work

The relationship between these energy units:

1 BTU = about $1055.05\underline{6}$ joules = 252 calories . : Consider: 1 BTU = $\frac{454g}{1°F} = \frac{Xg}{1°C}$ and $\frac{454g}{1.8°C} = \frac{Xg}{1°C}$ and:

(1°C / 1.8° C) 454g = Xg = 0.555(454g) = 252.2g

Or by considering a (mass)(temperature) product:

(454g)(1°F) = (454g)(0.5555C°) or:
(454g)(1.8C°) = (Xg)(1°C) and:

454g = (Xg) (1°C / 1.8°C) = Xg (0.5555) , solving for Xg:
Xg = 252.2g

1BTU is = 454g raised 1F° = 252g raised 1°C = 252 calories = 1055.05$\underline{6}$ joules , mathematically:
1 joule = 0.0009478$\underline{2}$ BTU =~ roughly 0.001 BTU =~ a thousandth of a BTU
1 calorie = 4.184 Joules = about 0.003966 BTU =~ 0.004BTU =~ 4 thousandths of a BTU

1 watt (W) of power (ie., energy used up or converted to another over form time = an energy rate) = 1 Joule per second = = 1 J/s . From this we have: 1W = 1J/s , therefore: 1J = 1 (W)(s) = 1 W-s = 1 watt of power applied for 1 second

1 watt = 1J/s , if we multiply both sides by 1000, we have 1kW = 1000 J/s
Hence, mathematically: (1kW)(1s) = 1000J , and if we multiply each side by 1hr = 3600s, we have:
(1kW)(3600s) = (1000J/s)(3600s) = (power)(time) = **PwTs = Total Energy**
1 kWh = 3600000 J = 3.6 (10^6) J = 3.6MJ = 3.6 mega-joules

1 horse power = 1HP = 550 foot-pounds = 746 watts = 745J/s = 0.746Kw. 1Kw = 1000w = 1.34$\underline{1}$hp

Energy = Work = (force)(distance) = 1 ft-lb or 1 lb-ft = about 1.3558 Nm = 1.3558 joules of energy

Other related considerations:

Power = "strength applied or needed" = $\frac{\text{Energy}}{\text{time}}$ = $\frac{\text{Work}}{\text{time}}$ = when the fractions are reduced = $\frac{\text{Joules}}{\text{second}}$ = J/s : like an average

Total Power used or needed = $\frac{\text{Total Energy}}{\text{Total Time}}$

Power = $\frac{\text{Energy}}{\text{time}}$ = Joules / time = Work / time = (force)(distance) / time = (force)(velocity) : d=vt , v=d/t , t=d/v

Force = $\frac{\text{Power}}{\text{velocity}}$ = (mass)(acceleration) , velocity = $\frac{\text{Power}}{\text{Force}}$ = $\frac{\text{Joules / s}}{\text{Force}}$ = $\frac{\text{Joules}}{(m)(a)(s)}$

time = $\frac{\text{Total Energy Used}}{\text{Energy Use or Rate}}$ = $\frac{\text{Joules}}{\text{Power}}$: = Ts = time to deliver, acquire or use an amount of power

velocity = distance / time = meters / second

acceleration = change in velocity / time = (change in d/t) = (meters / second) / second = meters / second^2 = m/s^2

Force = (mass)(acceleration) = (mass)$\frac{(\text{meters})}{(\ s^2\ )}$, mass = $\frac{\text{Force}}{\text{acceleration}}$ = $\frac{\text{Force}}{m/s^2}$ = $\frac{\text{Force } s^2}{\text{distance}}$

Force = $\frac{(\text{mass})(\text{distance})}{s^2}$ = (mass)$\left(\frac{d}{(s)(s)}\right)$ = $\frac{(\text{mass})(v)}{s}$: (Force)(s) = (m)(v) = momentum, or change in momentum

An object having (n) times more mass will take (n) times the force and-or energy to move it the same given distance, for example lifting a mass and-or weight a height. For a given amount of mass, if the force and-or energy applied is reduced by (n), the acceleration is reduced by (n), and the time needed to move it a given distance will increase by (n).
If the mass increases by (n), Energy applied and-or stored / unit mass is still the same ratio.

Work = Energy = (Force)(distance) = lb-ft = Nm = (mass)(acceleration)(distance) = (m)(a)(v)(t) , Joules

(**n**) Work = (**n**) Energy = (**n**) lb-ft = (**n**) Nm = (**n**) (force) (distance) , Joules

Ways that thermal or heat energy can be transferred from one object or place to another.

In general, the density of a substance is a major contributor to its ability to conduct heat. Metals have a high thermal energy conduction, liquids are not as good, and gasses are poor thermal energy conductors. Materials having much air space or "gaps" in them are often used for insulating (ie., protect, separate, make of no effect) objects from both higher and lower temperatures by greatly reducing the thermal conduction around an object. The study of heat effects in materials, and the spread and-or transfer of thermal energy is called **thermo-dynamics**.

1. **Conduction** = Direct contact, such as from the atoms of a hot object in contact with the atoms of a cooler object. The cooler object will increase in temperature, while the hot object will therefore decrease in temperature. Friction or mechanical resistance is an example where some kinetic energy is converted into thermal energy, friction is usually a sign of wasted energy, an energy loss. Fluids and substance blended or rated at high speed in a container can actually increase in temperature due to friction.

2. **Convection** = To convey or transfer of heat energy by a medium such as a liquid or gas. This transfer can be assisted by pumps and fans. The warm air from an electric heater is an example. Hot. low density and weight air rises upward like a flowing current, and heavier weight and density cool air falls downward (ie. sinking) like a "draft" (flow) of current. This warm air can then transfer its heat to another object via conduction or direct contact.

3. **Radiation** = Transmission through space. An example is solar (sun) heat (thermal) radiation (energy transmission). Thermal radiation is actually a form of light which itself is a form of electromagnetic radiation.. Invisible radio waves are another example of electromagnetic radiation and is often called "RF" or Radio Frequency energy. The energy in this radiation can then heat up objects. A solar air heater can convert solar radiation into warm air, heat convection after the heat is first conducted to the air at the collectors surface.

"Saving heat" energy is preventing heated objects from cooling down and wasting the energy and money it took to heat it up initially. **Insulation** (ie., a separation from) is the general method to prevent thermal energy loss, and insulation basically slows down and-or prevents thermal transfer, that is, it does not easily absorb and-or transfer heat energy.

Friction is a direct contact, (slight) collision or (slight) impact between two objects and-or surfaces and will cause heat to be created due to the forces applied to the atoms in those surfaces. Friction will also cause some of the (kinetic = motion) energy of a moving object to be transferred to that which is causing the friction, and the energy (KE, motional) of that moving object will be reduced, and therefore, its speed will reduce. An example is when you push a box on a floor, it may move fast with a high kinetic energy at first, but friction will reduce or decay (ie., slowly loose) all of its KE to 0 joules. Force and-or friction can even cause the direction of an object to change, and this could be considered as a deflection in motion. Friction can cause an object to turn in its direction of contact as can be seen by slowing (perhaps by the friction of a piece of wood against it, the left wheel or motion of vehicle and it will want to turn somewhat leftward as the right side of the vehicle tries to continue forward. If the left side movement was to stop completely, the right side would pivot or rotate about the left side. A rudder (a thin, flat, vertical and steerable piece of wood or metal) in the water beneath the end of a boat can be used to steer that boat by slowing one side of that boat. The collision between the rudder and the water will also cause the boat to loose some kinetic energy and its velocity will also slow. That energy will be transferred to the water.

For an example of direct contact or conduction of thermal energy:

A piece of ice such as an "ice-cube" is a solid piece of water. Is crystallized water (H20), a crystal of water, or water crystal, and with atoms bonded, held or locked together. For this to happen, the liquid state or condition of that water must be changed to a solid state, and this is done by cooling that water to its freezing or solidifying temperature of 32°F = 0°C or less. When the water cools, its molecules loose thermal or kinetic energy, and can no longer stay loosely moving about due to the energy they had at a higher temperature.
If a piece of ice is placed into a liquid that has a temperature higher than the freezing temperature of water, the frozen

molecules in the ice will start to gain kinetic energy and move about. The ice will melt or dissolve to be liquid water. Since the liquid of which the ice was placed in has used up or lost some of its thermal energy to melt the ice and increases the thermal energy in the ice. The temperature of that liquid that the ice was place in will decrease or cool, especially if it was a small volume and-or mass, and there will be less of a temperature difference between the liquid and the ice, and the rate or speed of the amount or volume of the ice melting will decrease. To make a cool drink or substance to a lower temperature, ice can be placed into the liquid, and the melt water of the ice will become part of that liquid solution, and dilute it. Some of the dense cool water will also sink into the liquid, and this is a form of convection which transfers (here, cooler) thermal energy.

Usually, an object that is dense, having many particles, is more able to more gain kinetic or thermal energy and can then store much thermal or heat energy. That object is said to have a high **thermal mass**. Thermal mass can be considered as: energy / mass . Ex. joules / gram.

Just like a large mass that is difficult to move, a large mass will take longer to move and-or heat up, but when it does, it is difficult to reduce since it contains a lot of energy and-or motion. It could be considered as like a "thermal momentum" or "thermal inertial" of that substance. A flywheel is a large rotating mass to store kinetic (motional) energy, and its energy value is directly determined by the amount of mass and its rotational speed. A small solid mass cannot store as much thermal energy as a larger mass of the same material, and the smaller mass has a lower total thermal mass or energy in it, and it will "cool off" or reduce (or gain) in temperature much more quickly than a large mass of the same material. A larger surface area for the same given mass will also increase the rate at which an object can change in temperature due to having more ability to conduct heat into the air (or other material) due to the larger contact area between those substances..

A **thermal capacity, heat capacity** or **specific heat** rating of a mass or object is the amount of energy needed to raise its temperature by 1 degree, usually in Celsius temperature. The word "specific" in specific heat, is in reference to the specific, unique substance and-or element being considered, which has a specific associated thermal capacity and rating.

$$\text{Heat or Thermal Capacity rating of a mass or object} = \frac{\text{energy needed per mass}}{\text{degree change in temperature}} = \frac{\text{Joules}}{1\text{C}^\circ\ 1\text{g}} = \text{J} \ / \ \text{g}.1\text{C}^\circ$$

Ex. Water has a high heat capacity of about (4.2 J / C°) per gram of mass , hence (4.2J / g) / 1°C = (4.2J / g-°C). It could also be said that water has 4.2J of energy per gram for each degree rise in Celsius temperature. It will also take 4.2 joules of energy to raise the temperature of 1 gram of water by 1 degree Celsius, and if there was no energy losses doing so. If there are (4.2J/C) / (1 gram), and if we multiply the numerator and denominator of this fraction by 1000, we have there are (4200J/C) of energy per kilogram of water. Water has a density of 1 gram / cc. This value of 4.187J =~ 4.2J is also defined as the **calorie** energy unit.

Ex. Copper, which is much denser than water has a low heat capacity of about 0.385 J / C° per gram of mass. Copper has a density of nearly 9 grams/ cc, and this is 9 times more than the density of water, and the ratio of their heat capacities is that water is about 11 times more, and-or copper is 11 times less.

Compared to other substances, water is fairly difficult to heat or change in temperature due to its strong atomic bonds, and that its density is fairly low at 1g/cc, and as compared to the much higher densities of metals, and yet it therefore retains heat very well, and is a fluid which can transport thermal energy in a practical manner through a pipe, etc. To much thermal energy applied to water will cause it to change its physical state to a gas called steam or water vapor when it boils. The higher the temperature of water, the lower its density.

If the water being heated is (N) grams, it will take (N) times more energy to raise its temperature by 1°C :

$$\text{Total energy needed for 1°C in temperature in N grams of water} = \text{Ng} \ \frac{(4.2\text{J})}{\text{g}} = \text{Ng } (4.2) \text{ Joules}$$

The above value is for a 1°C change in temperature, and if the change in temperature is Tc times higher, it will take Tc times more energy to do so. This is so since the energy needed is the same for each degree change, step or increase in temperature, and the total energy is the sum of energy needed per degree change. This sum can be expressed as a multiplication by the number of degrees change in temperature = Tc.

Total energy needed for a change in temperature of Tc of N grams of water $= Tc\ Ng \left(\frac{Joules / g}{1\ C°} \right)$ Joules =

= Tc Ng (4.2) Joules for water

4.2 Joules is also called a **calorie** of thermal energy. 1 calorie will raise the temperature of 1 gram of water by 1 degree Celsius. 1 calorie = 4.2 joules = 3.96567 **BTU** (British Thermal Units) ~= 4 BTU. A BTU is the amount of energy needed to raise 1 pound (about 16 fl. oz = 454 cc) of water by 1 degree Fahrenheit. 1lb = 0.454kg = 454g. 1J =~ 0.0009478 BTU , and 1 BTU =~ 1055.075 J : 1 BTU can be roughly considered as equal to about 1000J. It will take about 4220J =~ 4 BTU of energy to raise the temperature of 1kg = 1000g = 1000cc of water by 1 degree Celsius. 4BTU will also raise the temperature of 1 pound of water by 4F° , or 4 pounds of water by 1°F.

This above example also assumes all of the energy used to heat the water was converted to thermal energy of that water, and with no wasted energy or energy losses. The equation presented was theoretical, and there will be some loss of energy. For an object to retain its thermal energy, temperature or heat value, it must be insulated from its surroundings by something that does not remove or conduct heat or thermal energy away from it. This is the case as for thermal energy storage, where that energy is stored until it is needed. A Thermos (tm, R) or other similar device is a double walled glass container that is insulated by a **vacuum** between each wall, and can keep and-or cook foods if a process known as "thermal (retention) cooking". Here, hot water and the item to bee cooked such as noodles is placed within the container, and all that is needed is time to cook and soften the noodles rather than more energy. Likewise, in theory, a well insulated house would not have to use any more energy to be heated to a comfortable temperature once it was warmed up. If there are no energy losses in a container, the substance within it can be heated by using just a small amount of power, but it may take considerable time depending on its mass and-or volume: From: Energy input = Power = Joules / time = P = J / t, we mathematically have: J = Pt, and for heating purposes, this must be thermal or heat energy.

A vacuum is the best thermal insulator due to the lack of direct material contact, but it will allow radiation such as infrared thermal energy (ie., a form of light that we can not see) to pass through it. Due to this, a Thermos (tm, R) type of container is often coated on its outer surface with a reflective material, and this will help maintain the internal temperature at a stable higher temperature, and from reducing due to that type of thermal energy loss. The thermal energy loss per second is a very small amount of joules, and this can be replaced by a small amount of joules of thermal energy directly applied to the substance - perhaps by a small, low-power electric heater. Just the same, a thermal insulator can also keep things within it at a stable cooler temperature and from absorbing external thermal energy.

How much total thermal energy does a mass of water have? It depends on the amount of mass, its temperature, and its energy storage capacity per gram. From the above discussion, we know that for each degree change in Celsius temperature, a mass of water will require and then acquire 4.2 Joules of energy per gram. Let the temperature value (To) of an object be its change in temperature from the "absolute zero" (zero thermal energy) and where there is no (0) kinetic and-or thermal energy of any use in that mass or object:

Consider: $\frac{\text{Total thermal energy}}{\text{Total mass}} = \frac{\text{Joules}}{1\ g}$: equivalent ratios or fractions, and after the division of just the numeric parts of the values. From this we have:

Total thermal energy = (mass) (energy / gram of mass) = Ng (joules / g) = joules

We will now consider a given temperature of the mass:

Total thermal energy in a object or mass of N grams = To (Ng) $\left(\frac{\text{Joules / g}}{1\ \text{C}^\circ}\right)$ = Joules :for **To**, see the note below

K = C° + 273.15 : K = kelvin temperature , C = Celsius temperature
C° = K - 273.15 F = Fahrenheit temperature , C = (5/9) (F° - 32) , F = 1.8C + 32

At absolute 0 = K = 0 = -273.15° C = -459.67° F : temperature, and-or thermal heat, start at 0°K, and not 0°C.
Change or difference in temperature Celsius above absolute 0 = Temperature - (-273.15°) = Tc + 273.15°

Let **To** in the above equation be the total temperature change or difference above absolute 0: To = Tc + 273.15°
Tc is the current temperature of the substance. Both values have units of Celsius degrees.

Ex. If the mass is 1g of hot, near boiling liquid water, and its temperature is 212°F, = 100°C, how much thermal energy (Et) does it have?

K = 100°C + 273.15 = 373.15 : ie, equivalent Celsius degrees above absolute 0

Et = (Ng)(change in temperature)(thermal energy per gram per degree Kelvin)
Et = (1g)(373.15°C)(4.186J/gC) = 1562J

Element or Substance	**Density (g / cc) At STP**	**Heat Capacity Rating (J / C° / g) = (J / g C°)**	**: (essentially a "thermal mass" rating) Typical or Average Values**
Water	1.0	4.186	: slow or difficult to heat , but hot steam has great KE energy,
Lithium	0.534	3.6	
Paraffin Wax	0.87	2.48	: a wax made from petroleum (ie.,crude oil)
Water Steam	0.006	2.0	: at 100°C
Water Ice	0.917	2.1	: at 32°F = 0°C , and 1.4 for -100°F = -73°C
Alcohol	0.79	2.2	
Sodium	0.97	1.2	
Magnesium	1.74	1.05	
Air	0.0013	1.012	: =~ 1.0
PVC	1.38	1.67	: Polyvinyl-Chloride
oils	0.93	1.75	: averaged, for food oils, petroleum is 2.1
clay	1.5	0.91	: for the denser clays
Aluminum	2.7	0.9	
Salt	2.16	0.88	: sodium-chloride = "table salt" = "food salt"
Concrete	2.3	0.88	
Glass	2.89	0.82	
Granite	2.7	0.79	
Carbon	2.25	0.71	
Steel	8.05	0.48	: doesn't store too much thermal energy, but is easy to heat
Copper	8.96	0.39	
Silver	10.49	0.23	: very easy to heat, its atoms have a high thermal transfer in it
Gold	19.3	0.13	
Lead	11.35	0.128	: easy to heat and melt (at 621°F) to a liquid

1g mass of water = 1cc volume = 1mL volume or water that has gained 4.186 Joules of energy will have increased 1°C higher in temperature. Likewise, it could then be said that if 1cc = 1mL of water was now 1°C higher in temperature, then it has gained 4.186J of energy. As seen above, metals with high density, dense crystal-like atomic (ie., atom) structure, can be heated relatively easily due to their thermal transfer from atom to atom. The above could be also stated as:
(4.186J / 1°C) / 1g = (4.186 ((J / g) / C°))

From this information, if 1L = 1000cc = 1000mL = 1000g of water was 1°C higher in temperature, that water has gained: (1000cc)(4.186 J / 1°C) = 4186 J of energy.

If 1L of water changed by 10°C higher, that water has gained: First, 1L = 1000cc = 1000mL = 1000g if water: (1000g)((4.186 J / g) / 1°C)(10°C) = (4186 J)(10) = 41860J of energy.

For water: $\frac{4.186\text{J}}{1°\text{C}}$ is to , then $\frac{1\text{J}}{0.2389°\text{C}}$ is to , : after dividing both the num. and den. by 4.186

If the temperature of an amount of water decreased by 1°C, then it has lost 4.186J / 1cc = 4.186J / 1g if water.
If 1L = 1000cc = 1000g if water decreased in temperature by 1°c then it has lost: (1000g)(4.186J/g) = 4168J of energy

A **thermal conductivity** rating of a material is how well (ie. how fast) heat or thermal energy can be transferred or flow through it over a time period. It is the rate of heat or energy transfer within itself. A thermal conductivity rating is essentially based on the amount of energy needed per unit time which is power or watts, and so as to change the temperature within the substance at a distance of 1 unit away and by 1 degree increase in temperature.

Some metals have a very high **thermal conductivity rating**. Silver, copper and aluminum have a high thermal conductivity rating, and they also conduct electricity very well and therefore have a low electrical resistance to the flow of electricity (electrons, current). Air and-or insulation foam have a low thermal conductivity and is used help keep things (objects, a volume) remaining at a certain temperature, and to also minimize wasted heat and-or energy. A vacuum has no thermal conductivity and is the best temperature or heat insulator. Here are some approximate thermal conductivity ratings (W / m k°) of some materials, and they can be considered as considered relative values. For example, silver has a rated value of 410, and it therefore transfers heat 410 times faster than that of glass which has a rating of 1. Although water can store much thermal energy, it is not a good thermal conductor of thermal energy within itself. Hot water can rather be transferred to where it is needed via pipes such as to deliver thermal energy. Hot steam (ie., water vapor substance, gas), rather than its temperature can do much work due to its high (gas) pressure and-or kinetic energy.

air=0.024 , pine wood=0.15 , water=0.6 , glass=1 , concrete=1.6 , ice=1.58 , lead=35, steel=48 , iron=80 , aluminum=210 , gold=310 , copper=390 , silver=410 , diamond (dense, crystallized carbon) =1500 av.

Note that lead is very dense, and yet has a very low thermal conductivity.

thermal conductivity = (thermal or heat power transferred) / (degree change / unit area) / unit distance

The formula may also be expressed as:

thermal conductivity = (joules / time) / 1 C° / m : 1C° change in temperature = 1°K change in temperature

thermal conductivity = $\frac{\text{(watts)}}{1\text{C}°\ \text{m}}$: the reference distance may be for example, 1cm, hence over that distance, a reference volume that the heat must pass through is 1cm^3 = 1cc. The reference distance is usually expressed with units of centimeters or meters. If centimeters, the resulting digits are the same, but are a thousand times less.

Ex. How much energy will be needed to heat a fluid ounce of "tap water" from a pipe to boiling temperature?

A fluid ounce volume of water = about 30cc of volume, and has a mass of about 30 grams
The average temperature of tap-water is about: 55°F =~ 13°C.
When water begins to boil, it has a temperature of: 212°F =~ 100°C

From this data, the water will require a temperature increase or change of: 100°C - 13°C = 87°C

From: Total energy needed for 1°C in temperature in N grams of water = $Ng \frac{(4.2J)}{g}$ = N(4.2) Joules

Energy needed = (mass)(J /g C°) (change in temperature) : (J/g) / C° = J / gC° , or simply:
Energy needed = (mass) (energy per gram / degree) (number of degrees)

Energy needed = $30g \frac{(4.2J)}{g} \frac{(87C°)}{1C°}$ = 10962 J = 10.962kJ =~ 11kJ : (number of degrees) can also be noted as the (change in temp.).

This could be considered as that it takes about 11 kJ / 1oz or= 11 kJ / 30g, to heat tap water to a boiling temperature. Hence, for 2 ounces, or twice as much water, it will take: (2 oz / 1)(11kJ / 1oz) = 22k J or twice as much energy.

Power = $\frac{\text{energy}}{\text{time}}$ watts : power is the rate of using energy, mathematically, Energy = (Power)(time) J

If that water requires 2 minutes to boil: time = 2 minutes = (60s/min)(2min/1) = 120s, the rate of the input power needed and applied to the water is on average:

$$P = \frac{10962J}{120s} = \frac{91.35\ J}{1s} = 91.35 \text{ watts}$$

For the above example and values, regardless of any possible inefficiency or energy losses and that value during this change of temperature process, when the mass of water has reached a certain temperature, that mass has gained 11kJ of energy, and in the form of thermal heat (kinetic motion of the molecules and-or atoms).

If the temperature of a mass increases by (n), the total thermal energy within that mass will increase by (n). If the amount of mass with a given temperature increases by (n), the total thermal energy within that mass increases by (n).

If given two different metals with the same mass, say 1g, and if they are placed in an oven with a certain air temperature inside it, those two metals will absorb thermal energy via (heated air) convection until they reach the same temperature of the air in that oven. If the metals have a different density and associated thermal capacity rating, then the amount of thermal energy that each will then have or store in its atoms, will be a different value. Metals with a higher thermal capacity can store more thermal energy per gram. Metals with a higher thermal conductivity will heat up or increase in temperature at a quicker or increased rate with respect to time than a metal with a lower thermal conductivity. Silver will heat up much faster than steel will, and this is because silver has a higher thermal conductivity rating and this is determined by its density, atom and crystal structure. Note also that silver has a lower thermal capacity than that of steel. In general, it could be considered that silver rather conducts thermal energy better than it stores it.

Extra: **John William Draper**, (1811 - 1882), from England, discovered in 1847 what he named the **Draper Point** temperature at which all solid matter starts to produce (ie. make, "glow", "infrared" thermal radiation) some visible, faint red light at about 977 °F = 525 °C =~ 798 °K. This is roughly about 1000°F. This color of relatively low frequency of light in the visible "spectrum" (frequency range or bandwidth of frequencies) has a frequency of about 83 (10^12) hz = 83 trillion hertz = 83 Thz. If this temperature is placed into the Stefan-Boltzman equation as shown in this book, the result is about 22000 watts of (rf, light, thermal radiation) energy per square meter of surface area. Some examples of where thermal radiation is needed is for cooling via heat-sinks ("draws or absorbs heat from a nearby object, and radiates it away), and cooling in shaded regions of a spacecraft to prevent overheating.

When heat retention is needed, then the loss of energy and-or heat via thermal radiation is to be avoided. If you had an object or dwelling that requires (x) joules of energy per second (hence a power value = x J/s = x watts) to maintain a certain temperature, then surely, that object or dwelling is loosing and-or radiating (x) joules of energy per second. A well constructed, perfectly insulated (ie., via a vacuum, etc) object or structure will maintain or slowly (J/t) and (°T/t) reduce in temperature.

A SIMPLIFIED THERMAL ENERGY TRANSFER EXAMPLE

In this example we will be given two different masses or objects of the same metal, say iron or copper, hence they will have the same density. If it helps, you can consider these pieces of metal as being cube shaped. We are to find the resultant or final temperature ("the thermal equilibrium temperature") of the combined masses after the two metals are joined together at a side, and considering no external heat energy losses.

Helpful considerations for when the masses are joined together at their surfaces:

1. If given an evenly heated mass or object of the same element and-or density, it has a total amount of thermal energy associated with it. Any portion of that amount of mass has the same portion of the total thermal energy of the total amount of mass. For example, 10% of a mass will contain 10% of the total thermal energy of the total mass. Each different sized portions or samples will still have the same temperature, but the mass and temperature products ($m\ °T$) will be different, hence having a different total thermal energy.

2. Heat or thermal energy will transfer from the hotter mass to the cooler mass. There must be a temperature difference for heat to be transferred. A temperature difference can be considered as the resulting "heat pressure" which will cause a transfer of thermal energy. Hotter substances or elements have atoms and-or molecules that have an increase in (thermal) energy, and they are then moving and-or vibrating faster and will have a higher kinetic (ie., movement) energy, and which can be transferred to other atoms and-or molecules during a collision, and thereby loosing some of its kinetic energy and then getting cooler as the object it collided with gains (thermal and-or kinetic) energy. Remember that when and object collides with another other, each is effectively colliding with the other and will affect each other in some way.

3. The hotter mass will get cooler, and the cooler mass will get hotter, and the amount of temperature change for each depends on the amount of mass for each. If the two masses have the same temperature before being joined, the larger amount of mass tends to then have a slightly lower temperature, and a smaller amount of mass tends to change more and quicker in temperature. Over time, the rate of the change in the temperatures of the masses with respect to time will decrease, and then those two objects will eventually be at the same temperature or "equilibrium temperature". The equilibrium temperature will have a value that is between the two temperatures, and will be closer in value to the temperature of the largest mass.

4. The more area of surface contact of the two masses, the faster that the heat can transfer or conduct from one to the other. An example is with the construction of a "heatt-sink" and-or radiator, such as to cool a motor or electronic part, or to heat a room quickly. A heat sink will absorb heat from a device, and that heat can be transferred, radiated to, and-or absorbed by a cooler air mass. This will cause the heated air to become less dense and it will then rise upward and allow more (cooler) air to then come into contact with the heat sink which may sometimes be called a (heat) radiator.

5. When the masses or objects become the same temperature, there is no temperature difference or imbalance, and therefore, there is no "thermal (energy) pressure" to cause a transfer of thermal energy. Their temperature are at equilibrium or balance.

6. The total amount of thermal energy is the sum of the thermal energy in each mass. If there are no losses due to air and or infra-red thermal radiation, this amount of energy will be the same value after the two masses are joined together.

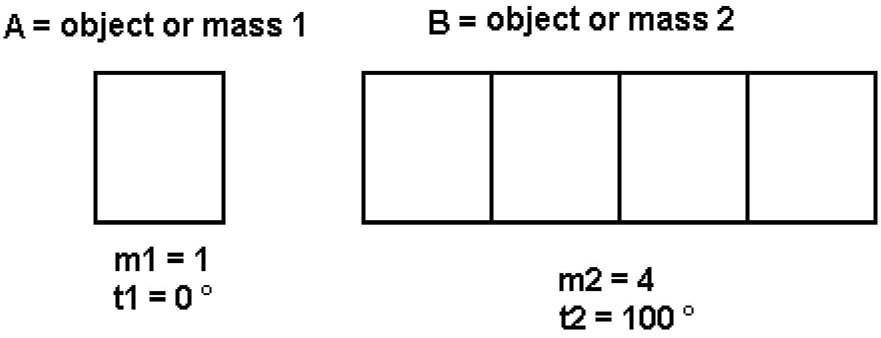
Et = E1 + E2 : starting and ending total amount of thermal energy
Mt = M1 + M2 : total mass

7. At thermal equilibrium the temperatures of the joined objects are the same. The amount of energy (ie., Joules) in each object depends upon its mass. A larger mass at a give temperature will have more thermal energy associated with it than a smaller mass at that same temperature. Given a certain temperature, if the mass is twice as much, its thermal energy is twice as much, hence mass and energy are directly proportional when the temperature is constant. The ratio of the energy in each mass will equal the ratio of their corresponding masses when they are the same temperature. E1 / E2 = M1 / M2 or= V1 / V2 = since volume is directly proportional to mass.

8. A larger mass will take longer to heat up to a certain temperature, and will then have more total thermal energy, and this value could be described as its "thermal mass" and-or ability. A larger mass will take longer to heat up to a certain temperature, and this could be described as "thermal inertia" or the slowness or resistance to a temperature change.

9. The amount of Joules in an object may be difficult to calculate by some, and so another practical way that energy can be measured is what can be called the "mass-temperature" product or thermal-mass product. The more mass, the more thermal energy at a certain temperature. The more the temperature of a certain mass, the more thermal energy it has.

   For this analysis, we will let: E = energy in joules= thermal-mass product = (mass)(temperature) , [FIG 230]



When m1 and m2 are combined together at their flat edge area, what will the resulting or equilibrium temperature of their total mass be if there are no losses in thermal energy? .

The total energy of this system is the energy of mass1 plus the energy of mass2:

Et = Em1 + Em2
Et = (m1)(t1) + (m2)(t2) = (1)(0) + (4)(100) = 0 + 400 = 400 : at the both start and end at equilibrium
: (m)(t) = "mass-temperature product" and can use (v)(t) = "volume-temperature product"

The total mass of this system is:
Mt = m1 + m2 = 1 + 4 = 5

The total amount of energy at equilibrium temperature (Te):

Et = (Mt)(Te) or can use: **Et = (Vt)(Te)** :if you have measured volumes (V), such as water fluid.
400 = (5)(Te) , solving for Te:
Te = Et / Mt = 400 / 5 = 80 considering each mass having this new temperature, their energy is:

Em1 = (m1)(t1) = (1)(80) = 80
Em2 = (m2)(t2) = (4)(80) = 320

As a check, the ratio of these two masses is:

m1 / m2 = 1 / 4 = 0.25

Mass2 had 4 times the mass as that of mass1, and at equilibrium, mass2 will have 4 times the energy as that of mass1. The ratio of their corresponding thermal energy is:

E1 / E2 = 80 / 320 = 1 / 4 = 0.25

The author has tested the above formula using 1 container of cool water at 63°F, mixed with 4 containers of hot water at 114°F, and the measured temperature was about 103°F, and the calculated temperature, using the above method, was about 103.8°F The slight error was probably due to both a slight measurement error and some minimal heat losses in the large combining and mixing container, and of which probably absorbed some thermal energy.

Solving for the temperature needed for a volume and-or mass so as to have a certain equilibrium temperature of two volumes (V) and-or masses :

Ex. If V1 = 4, T1 = 100°F, and V2 = 1 , what is T2 if the equilibrium temperature (Te) after mixing these two volumes of water is to be 120°F ?

Et = Vt Te = (V1 + V2) 120°F = (4 + 1) 120° = (5) 120° = 600° : total thermal energy

Et = Vt Te = E1 + E2 = (V1)(T1) + (V2)(T2) , solving for T2:

$$T2 = \frac{Et - (V1\ T1)}{V2}$$

$$T2 = \frac{600° - (\ (4)(100°)\ )}{1} = \frac{600° - 400°}{1} = 200°F$$: this temperature is close to water boiling at 212°F

How is the specific heat rating of an element determined? In brief, it is done by performing an experiment, often by immersing the metal in question into a volume of water and noting all the changes, and then making a calculation. The mass and temperature of both the water and metal are also measured before this takes place. A loss in temperature and-or (thermal) energy of one is a gain in temperature and-or (thermal) energy of the other.

Let **Hs = Specific Heat of an element = (J / gC°)**

When an object is heated by a certain number of degrees higher, it gains thermal energy or heat, and therefore, there was a change in energy:

(change in thermal Energy) = (mass)(change in Temperature)(Hs) = (m)(Hs) ,* and note that mathematically:

$$\frac{\text{(change in thermal Energy)}}{\text{(change in Temperature)}} = \frac{(E2 - E1)}{(T2 - T1)} = (m)(Hs)$$:**for a given object and element, (m) and (Hs) are constants**

The thermal energy and temperature of an object or mass are linear and-or proportional, and for a certain mass, they will always have the same ratio value:

$\frac{E1}{T1} = \frac{E2}{T2} = \text{ratio}$, * Mathematically:

$Hs = \frac{\text{(change in thermal Energy)}}{\text{(change in Temperature) (mass)}}$, with units of : J / g °C , and the loss of thermal energy in the water is equal to the change, gain or increase, of thermal energy in the metal

Thermal Expansion

When a metal is heated, it will cause that area of the metal to expand due to the excited or energized (vibrating) atoms and the forces created when they expand, and this is particularly seen by heating a long thin metals strip in its middle, and its cooler ends will effectively bent in an arc shape toward the source of heat.

A bi-metallic strip is created when two pieces of different metal are welded together along their length. Each metal has a different amount of thermal expansion due to the heat applied, and the rated value of the expansion is called its thermal expansion coefficient value (CTE). Due to the heat applied, this will cause the ends of the metal with a higher thermal expansion value to bend or arc towards the other metal. Obviously, a device than can bend due to heat can be used as the temperature sensor for various temperature measuring devices. Lengths, widths, areas, and volumes are affected by thermal expansion. Much like water freezing to ice, the forces involved in thermal expansion can be high, and devices and structures can crack and then be a potential functional and-or safety problem.

When an object such as a strip of metal is heated uniformly, it will expand by a certain percentage uniformly and then it will be longer as long as its temperature remains the same. When the object cools, it will contract and eventually be the size it was before it was heated.

Coefficient Of Thermal Expansion (CTE) = $\frac{\text{(percent increase in any length of the material)}}{\text{(1 degree increase in temperature)}}$

A Short Note On The Thermal Affects of The Air Temperature On The Human Body

Our body temperature is 98.6°F on average, and this is considered a healthy body temperature, however it does not necessarily indicate any medical condition or problems. We actually feel most comfortable on average when the air temperature is near to 72°F and which is called "room temperature". We feel comfortable at that temperature and it is most likely due to that any excess internal body thermal (heat) energy created due to internal functions and also to keep us warm in cooler weather is more easily transferred to the air, and our bodies do not have to create any more internal heat (if possible) to keep us warm. Clothing helps insulate us and keeps us warm in cooler weather, and several layers of shirts, a hat, socks, shoes and-or slippers will help keep a person stay warm. As for pants, the author has found that "blue-jeans" (ie., dungarees, durable cotton material) are a poor choice to wear in cool or cold weather. Loose fitting "sweat pants" (ie., a thicker soft cotton) are then a better choice to wear, and two layers of pants can be worn if the temperature is very cold and windy outside. A winter or cold weather coat is also needed in cool or cold weather conditions. A "hoodie" coat is acceptable, but only if the person has layers of shirts on, hence a oversized coat may be necessary for a person to feel comfortable. The author has found that an indoor, dwelling temperature as low as 60°F = 15.5°C is livable and comfortable if people dress properly, and this will also help conserve energy and money needed for it. Keeping active also helps keeps us warm in cooler weather. .

When the air temperature gets lesser than say 72°F or "room temperature", the heat from our body is more easily transferred to cooler (lower temperature) air since the difference is growing, and it is then more easier to transfer thermal energy to it. At cooler air temperatures, our skin in contact with the air will reduce in temperature or "cool down" or "cool off" (ie., reduce in value) as the heat from it is more easily transferred to the cooler air and the it slightly increases its temperature before it rises upward into the more cooler air since warmer air is slightly less dense. Cooler skin will then absorb heat from the body, and this process will eventually cool the body to a lower temperature if there is no thermal or heat energy created by the body to keep it at a constant temperature.

If the air temperature is greater than 72°F, then the higher it is, the more difficult it is for the body to transfer energy to the warmer air since the temperature difference is less, and this is why it feels very warm or hot at say, beginning at about 85°F. Today as of about the year 2010, an electric air-conditioner to reduce a rooms air temperature and-or humidity is no longer an expensive luxury, but nearly an inexpensive necessity since it is often warmer indoors than outdoors during the summer months, and that is no way to live - stay cool, comfortable and be healthy indoors. Being hot often raises people "tempers" and discomfort, and things become more challenging to complete. During hot temperature, people can find shade to stay cooler, drink cool liquids, and-or wear a wide hat and- sunscreen ("sunblock") lotion if necessary.

More About Temperature And Altitude , How Does Air Temperature Change With A Change In Altitude

The troposphere of the Earth is from sea level (0 feet high) to about 30000 feet high, and the air temperature in this zone will decrease at a fairly steady or linear rate as the altitude increases at a fairly steady or linear rate. As altitude increases, the air gets less dense and-or has less mass and thermal or kinetic energy. The air near the Earths surface is denser, and therefore warmer. Some of this warmer air temperate, especially near the ground, and up to about 30000 feet is due to the air being in contact wit the relatively warm surface of the Earth and then rising upward, and also due to warm air temperature mixing and distribution due to the clouds and wind .

For an average value about the Earth, the air temperature will decrease at a rate of about (-0.003566 °F) per foot higher, and-or increase at a rate of about (+0.003566 °F) per foot decrease in elevation. To make an estimated temperature calculation at a certain height above a location, you will need to know the locations current air temperature:

$$\frac{-0.003566\ °F}{1\text{ ft higher}} = \frac{-3.566\ °F}{1000\text{ ft higher}} = \frac{-3.566\ °F}{0.3048\text{ km higher}} =\sim \frac{11.7\ °C}{1\text{ km}}$$

: 1 km = 1000m = 3280.8 ft = 0.621364 mi
1 mile = 5280 ft = 1.609364 km
1m =~ 3.28 ft , 1 ft =~ 0.304878m

Some other equivalent fractions to consider:

- 1°F / 278.86 ft higher = -1°C / 85.5 m higher = 0.0117 °C / 1m higher

°F Air Temperature Above = Air Temperature °F At Your Location - [0.003566 °F (change in feet higher)]
°C Air Temperature Above = Air Temperature °C At Your Location - [0.0117 °C (change in meters higher)]

The above equations is also from and having a linear equation format of: y = mx + b:
Air temperature at your current altitude =
Air temperature above your current altitude + (change in temperature / distance)(change in distance) =
(change in temperature / distance) (change in distance) + air temperature above your current altitude

For some reference: 32 °F = 0°C and 0°F = -17.7778
A change of 1°F corresponds to a change of 0.55555°C
A change of 1°C corresponds to a change of 1.8 °F

The Stefan-Boltzmann Law : **Ludwig Boltzmann**, (1844-1906), from Austria, and who studied energy loss and **entropy** which basically means the eventual disorder of a system, and particularly when studying gas molecules in a container that will eventually collide and go into random directions and velocities, hence a disorder.

This law states that the energy radiated or emitted per unit of surface area of a piece of matter per unit of time is related to the fourth power of its temperature. The simplified general formula is: **Energy = c T^4** , and where **c** is the Stefan-Boltzmann constant =~ 5.6704 (10^-8) W / m^2 K^4 . **T** is the absolute temperature, hence in degrees Kelvin. If T of the matter has doubled, the internal and radiated energy will increase by 2^4 = 16, and this also implies that the object has also gained this much more thermal energy. This formula is for an ideal **black-body** (or **blackbody)** that absorbs all radiation or energy, and that it radiates it very well once it is at the temperature of its environment, and this is called black-body radiation. This black-body radiation factor is equal to 1 = 100%. A "grey-body" rather absorbes and emitts radiation of a llimited range of frequencies. A conceptual "white-body" will reflect all radiation and not rise in temperature. **The full Stefan-Boltzmann Law equation is: Power = c (Area) T^4 , hence P / A = c T^4**

A **heat-sink** is often a piece of aluminum metal with a large surface area in a small volume of space or size, and it is used to protect sensitive electronics by absorbing its heat and then releasing or radiating this excessive heat energy into the surrounding cooler air, and therefore, this system is very similar to an electric air heater.

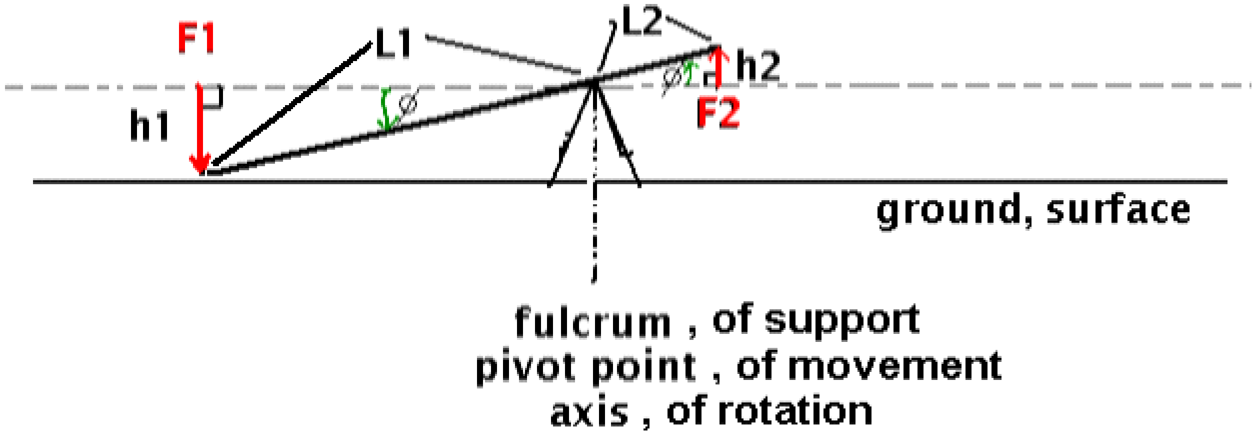
A LEVER ANALYSIS

A lever system can provide a gain in force, but requires more input distance and-or time needed so as to do something such as lifting a heavy weight. A lever is known as a "simple machine" and has a "mechanical advantage" of some sort, and here it is an amplification or "gain" in force. [FIG 231]



Though a lever arm does provide a gain in force, it does not provide a gain in the total amount of energy needed, and the total amount of energy needed to move an object a certain height will be the same as that without using the lever. The red arrows in the image rather show the relative height length moved at the ends (ie., input and output) of the lever and not the relative amount of force. Still, the arrows do show the direction of the input and output forces. F1, the input force is lower than F2, the output force, when a lever is to have a mechanical (ie., force) advantage or gain.

Total Energy Out = Total Energy In	and since power is the energy used per time:
Total Power In = Total Power Out	The input Power is lower with a mechanical (force) gain, but it takes longer, and therefore, the total input power will be the same as the total output power.

The lever machine or system allows the user a lower rate of using or inputting energy or force so as to eventually lift the object, but then the time needed to lift that object a certain height using that low rate of energy input or power will be longer so as to effectively apply or accumulate the necessary total amount of energy needed to lift that object a certain height. Since there is a lower rate of input energy per unit of time needed, the corresponding force needed to apply that input energy is lower, hence its easier for the user.

W out = (force out)(distance out) = W in = (force in)(distance in) : since (force out) > (force in) due to the increase in output force. For equation balance (distance in) > (distance out) Here the distances are the heights moved.

For these two values to be the same, if one factor is multiplied by a certain value (n), the other non-corresponding factor on the other side of the equation must be multiplied by the reciprocal (1/n) of that same value, which is the same as dividing it by that value (n). In short, for a given or constant value such as the value of the above equation, if one factor of it increases, the other factor of it must decrease.

For this analysis of a mechanical lever system, we can, for practical purposes, analyze it with basic right-triangle analysis even though the system actually rotates about a pivot (ie. rotation) point in a circular manner. Levers are mostly used to help lift a heavier, more weighted (ie., a force) object by using a smaller input force for a longer period of time. This almost seems impossible, but it becomes very possible and real when the input leverarm distance (L1) to the fulcrum (pivot or rotation point) is greater than that of the output leverarm distance (L2). L1 is the distance from the fulcrum that the input force (F1) is applied. L2 is the distance from the fulcrum to where that the output force (F2) is applied to the object. The twisting or turning input and output forces or torques will be analyzed using simple direct, linear (non-twisting or rotating) forces. How can a smaller input weight or force lift a larger output weight or force? This will be mathematically shown now.

First consider that using weights (a force) of the same value and distance on each side of the fulcrum point of the lever, that the lever would be in balance and not moving downward or upward (ie., rotating). The effective output torque would equal the input torque, or in simple words, the effective output force would equal the input force:
Tout = Tin and-or Fout = Fin : we will also use: F2 = Fout and F1 = Fin

If the weights or forces are different values, then their distances along the leverarms can be adjusted so as the system is kept in balance and not moving or rotating due to an unbalance of forces and resulting in some net force being applied to and then moving (here, rotating) the lever.

From the concepts of work (W), a measurement of work equals a constant force applied through a distance so as to do that work. For this lever system and analysis, we will let the distance (D) moved equal the height (h) moved:

W = (force)(distance) = (F)(D) = (mass)(acceleration)(distance) = mad : = energy , joules

Win = Wout this is equivalent to: energy in = energy out and power in = power out less any losses

$(F1)(h1) = (F2)(h2)$ from this we have the reverse ratios of: $\frac{F2}{F1} = \frac{h1}{h2}$ mathematically:

$F2 = (F1)\frac{(h1)}{(h2)}$:clearly as h1 increases, the output force F2 increases. The input force (F1) amplification value or factor is equal to the ratio of: (h1/h2). To increase (h1), the length of the leverarm (L1) on that side of the fulcrum must be increased. The longer (h1) and (L1) is, the larger the output force (F2).

In the figure shown, the angles on each side of the fulcrum are equivalent vertical angles, and the lines (h) dropped to the lever create similar right-triangles. The lever arms (L) are effectively a (hypotenuse) side of these right-triangles created. Corresponding sides of right-triangles are proportional (same portions or fractional value of their respective triangles) when one is essentially just a similar triangle or magnified construction of the other:

$\frac{h1}{L1} = \frac{h2}{L2}$ mathematically:

$\frac{L2}{L1} = \frac{h2}{h1}$ or $\frac{L1}{L2} = \frac{h1}{h2} = \frac{F2}{F1}$

We see that the height ratio is equal to the corresponding leverarm ratio which can then be mathematically substituted in the above equation for F2:

$F2 = F1\frac{(L1)}{(L2)}$: * The gain in input force (F1) is equal to the ratio of the input and output lever (L) arms. The greater L1 is and-or the lower L2 is, the greater the input force amplification factor. From this we have the familiar torque (T) equation(s):

$(F2)(L2) = (F1)(L1)$, which can be expressed as a ratio of torque or force values:

$\frac{F2}{F1} = \frac{L1}{L2}$: these are also "reverse ratios" since corresponding values are not in the same numerator and denominator. Consider also for example, the less the output lever arm (L2), the greater the output force (F2)

Here is a related note about actual levers and their lever arms:

torque (force) multiplier = tm = (reverse ratio of lever arm lengths or distances) , (see * above)
torque (force) multiplier = tm = (lever arm length of the input force) / (lever arm length of the output force)

Note that if using a lever arm system to lift something up a height, the height multiplier (h1/h2)=hm or increase is inversely related to the torque or force multiplier (F2/F1) = fm. height multiplier = hm = (1/fm). For example, if the force multiplier is 10, the output height multiplier will only be: hm = 1/fm = 1/10 = 0.10 = a tenth of the force multiplier. If the input height was 10 inches, the output height is: (10 inches)(hm) = 10"(0.10) = 1 inch

Some other helpful relevant equations are similar to those mentioned:

From: work = (force)(distance) = energy : input energy = output work , and with standard units of joules
: input work = output work

W1 = F1D1 = W2 = F2D2 : W1 = Win and W2 = Wout , mathematically:

$F = \frac{W}{D}$, and for a given amount of work or energy, if the distance decreases, the corresponding force value will be higher since these values are mathematically inversely related.

$D = \frac{W}{F}$, and for a given amount of work or energy, if the force increases, the distance to do that work and-or use-up its corresponding amount of energy (Joules) will be less.

Notice that the time it takes a point at the end of L1 to go the distance of h1, is the same amount of time it takes a point on the end of L2 to go the distance of h2:

Since: distance = (speed)(time)

D = VTs

$Ts = \frac{D}{V}$

If the time (Ts) value is the same or a constant, then if a distance (ie., h) is less, such as the output height or distance, then (vertical, linear) velocity will be less on that side of the lever. If the input distance or height is larger, the (vertical, linear) velocity will be more on that side of the lever.

In terms of angles moved per unit time, since the angles are the same value due to being vertical angles, both sides of the lever will rotate at the same rate or angular velocity = degrees or angle per unit time = (¢ / time).

For the lever system, the input and output time of the (input and output) applied forces or resulting amount of work is the same, but the specific time value or amount of time to get the result of lifting the weight a certain height is now longer, but "easier" (less force).

If there is a weight at the end of a lever and you are trying to raise it a height, the torque (ie. an "amplified force") due to that weight must also be considered, and this could be considered as the effective weight that we are trying to move a height. A basic equation for this is: Effective weight = Torque = (Force)(Leverarm) = (Weight)(Leverarm)
To raise that effective weight to a height, we must now provide a torque that is greater than the torque due to that weight. The torque needed to be applied to the opposite side of the lever so as to raise that effective weight will be at least:
Force = (Torque) / (Leverarm) and-or (Leverarm) = (Torque) / (Force)

If a weight is too difficult to lift to a height such as to be used for a lever, many smaller objects can be used such as rocks, bricks, dirt, etc. The gear analysis shown previously in the book is closely related to this lever analysis, and vice versa.

[This space for book edits.]

More About Matter, Mass, And Mol

Chemistry is the study and measurement of matter (ie., chemicals composed of atoms and molecules) and its interactions with other matter and-or energy such as heat, light and-or electricity. The word "chemistry" is rooted in a description of Egypt as "Khemia" which is based on the fertile "kem" (dark or black) soil material called "khem or "kemet" found about the large and fertile Nile river delta near the Mediterranean Ocean. The word "chemical" is based in the word of "khem". khem basically means substance(s), and chemistry basically means the study of substance (ie. matter). From a modern point of view, the ancient Egyptians had much knowledge about chemistry or matter and which then inspired the world in that field of science. **Matter** is a real physical material or substance. The word and meaning of "matter" is based on the words of "mother" and "source". The word "material" is based on the word "matter". **Mass** is a measure of the amount of any type of substance or matter. The word "mass" is a form of the word "material" and which is being combined or assimilated (based on the word "similar") together so as to have a quantity of it. A **mol** is a unit for a defined quantity of similar objects or particles of fundamental units of matter such as for example protons, atoms, or molecules.

We can divide an objects weight (a force) by (g) to find its mass.

From: force = (mass)(acceleration) = weight = (mass)(g)

:g is the amount of local gravitational acceleration caused by the constantly applied gravitational force upon a mass, therefore producing the corresponding force or weight of that mass. (g) at Earth's surface is ~= 9.81 m/s^2.

Force or weight has units of Newtons = (kg m/s^2) = the result of an acceleration applied to a mass

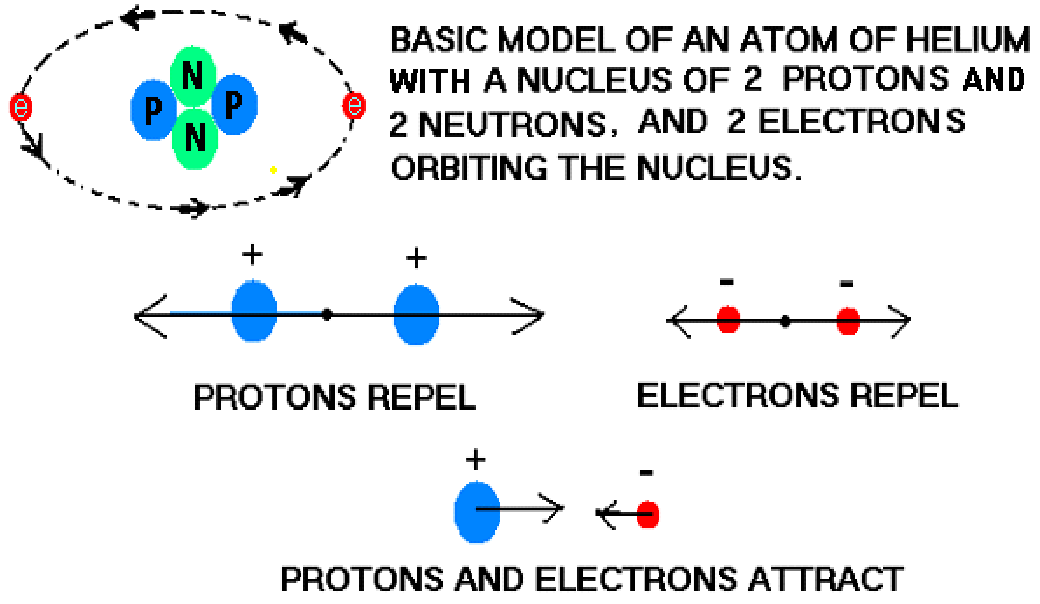
$$\text{mass} = \frac{\text{force}}{\text{acceleration}} = \frac{\text{force}}{\text{g}} = \frac{\text{weight in Newtons}}{9.81 \text{ m/s\^{}2}}$$

, with units of kilograms

Most household scales are calibrated so as to automatically do the above calculation for mass using its weight, and then to display the result in grams or kilograms. Most scales are technically "mass scales" and not "weight or force scales".

Atoms are commonly understood as the building blocks of matter (ie., "mass"), and are the smallest part of a unique material or substance called an element (of matter). An atoms fundamental structure is composed of particles of material (ie,. matter that has a measurement of mass) called protons and neutrons located at the center or nucleus of an atom, and electrons which orbit that nucleus of the atom. The number of protons in an atom is formally and usually equal to the number of neutrons. The number of electrons is equal to the number of protons. Each element (ex., oxygen, iron, gold) has a unique atom or atomic structure because it has a different number of particles than that of an atom of another element. The unique structure of the atoms of a particular element gives that element its unique physical properties such as mass and its corresponding weight, density, color, hardness, bending or twisting strength, melting temperature, electrical conductivity, light energy sensitivity, etc. [FIG 232]

Please note that chemistry experiments can be very toxic and dangerous. Please get an education first, and-or follow the precise rules made by those who have came previously.



The above figure shows a basic representation of the main (atomic) particles of an atom, and their electric forces. The electric force of attraction or repulsion is a much stronger force than gravity at the same distance. For example, static electricity can cause (lightweight) things to be lifted upward, hence against the force of gravity.

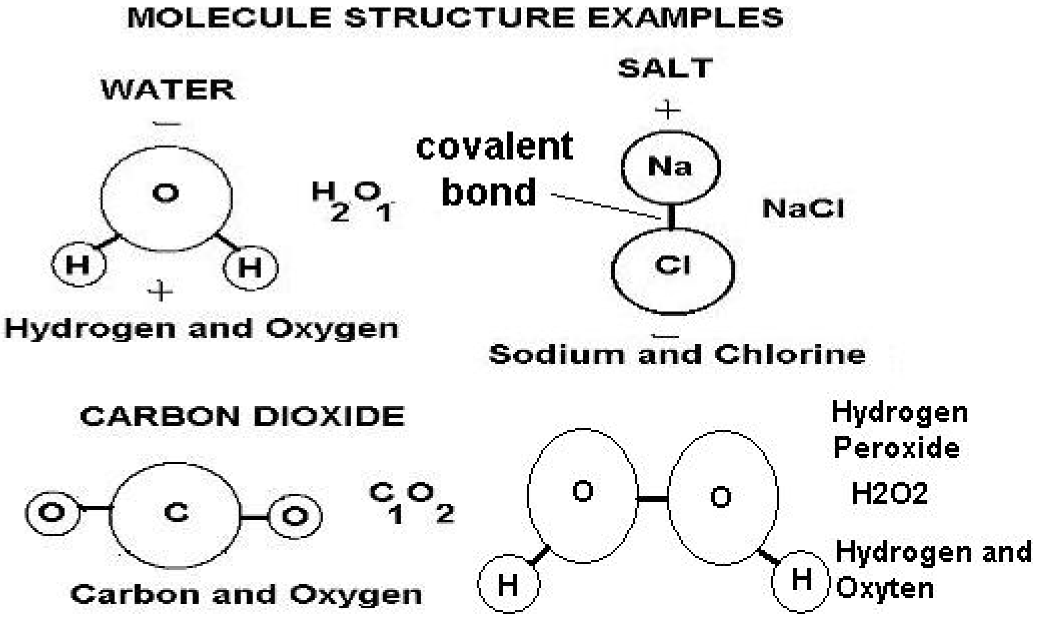
.

Each element is composed of particular atom structure that has a specific amount of (sub-atom or sub-atomic) particles (such as protons, neutrons, and electrons) of mass, and therefore, each atom of a particular element will have a particular amount of total mass to it. The more particles in an atom, the more mass it has and will be "heavier" (more) in weight. If the proton and-or neutron particles in an atom increase by a factor of (n), the total mass and-or weight will also increases by that same factor of (n). When not expressing the unique mass of an atom, a value of mass (matter) generally does not indicate what specific element(s) of matter it is in reference to. For example, 1 gram of copper, and 1 gram of gold both have the same mass of 1 gram, but each different atom of an element has a different number of atomic particles per 1 gram. 1 atomic particle, such as a proton or neutron, is said to have a mass of 1 atomic mass unit (amu). The mass of an electron is so small, it is considered negligible and is usually not considered for most of the basic and useful calculations involving mass.

If we want a specific number of mass particles (usually atoms, but could be its particles of atomic mass units = amu), say from different elements, it is nearly impossible to count them since they are to small to even see, but we can use the corresponding weight of their combined (ie., multiples of) mass (each having a very small weight) to effectively count, know, or closely estimate the number of particles in that mass. Since each element has a different number of atomic mass units (each amu has the same mass, and therefore each amu has the same weight) for each atom, the number of atoms of an element to have a given weight will be different, but the total sum of mass, regardless of what element(s) considered, is still the same for a given weight.

The number of particles (atomic mass units, or atoms) used by chemistry to make a substance is usually in reference to units called mol, and is a specific and large quantity of particles, and which will be discussed shortly. The weight of a mol of particles (usually atoms which contain or are composed of the atomic mass units) of each different element has a corresponding and unique weight, and this information can then used in a equivalent fraction or proportion equation so as to find the number of particles or mol units in question when given the total weight, or to find the total weight when given the number of mol units of those particles.

A **molecule** is two or more different element atoms bonded (joined, usually by sharing electrons) together into one unique unit or structure. The word "molecule" is based on and has the meaning of "massive [mass]" and "small" ["cule", a old word suffix meaning "small"], hence the word "molecule" means a small piece of an object or mass. More modernly and formally (ie., scientifically, standardized), a molecule is the smallest indivisible part of a **compound** (ie., "combined", several, joined as one) of two or more elements joined together. An example of a molecule is a water molecule (H2O) that is made of 2 atoms of hydrogen (H), and 1 oxygen (O) atom joined together into a new substance of matter. Liquid water, a compound substance is therfore composed of two or more water molecules. A **mixture** is two or more substances (elements and-or compounds) mixed together. Note that a mol (a specific numerical amount) and a molecule (a structure of two or more atoms) are two different concepts. [FIG 233]



Also indicated in the above molecules is the "electric polarity" (if its substantial) of the molecule, and this is useful for some chemical and-or electo-chemical reactions. The main common factor of chemistry and electricity is the electron. For a simple example of how this can be is that in chemistry, an electron is shared by atoms when they combine together to form molecules, and in electricity, a moving electron is used to carry energy through a circuit.

In chemistry science, when substances and-or chemical processes and reactions are being made or considered, sometimes a specific (from an existing formula or recipe) amount or mol of the substance(s) are to be used. Having and using a specific number of mol of particles (usually atoms) ensures having enough particles of that material or substance to make another substance, and to reduce waste and prevent making a chemically wrong substance and-or mixture with too much or too less of something. A chemist will easily weigh (rather than count the mass) each substance so as to have a particular number or mol of particles (atoms, electrons, protons, molecules) of it needed for the chemical process, etc.

Some fields of science and work that may include and-or require some chemistry knowledge are healthcare, pharmacy (medicines), agriculture (farming), nutrition, and research. In about the first half of the 1900's, the agricultural scientist, chemist, and teacher **George Washington Carver** (1864-1943), from America, made many significant discoveries in the field of agriculture, chemistry, and new products, with many being plant based, and so as to benefit both industry and mankind. Many of his new products were created from the peanut plant and of which is also said to be a "complete protein(s)" in terms of nutrition. Carver created and promoted the concept of **plant rotation** by periodically planting a different crop(s) in the same location (ie., farm, garden) so as to help replenish (ie., fertilize, replace) surface soil nutrients, particularly the nitrogen compounds created by bacteria on plant roots so as to have "nitrogen fixing" and nitrogen for the plant to grow. Soil nutrients can be depleted and-or lost by plant "takeup" or absorption of nutrients into its roots so as to grow bigger and-or higher. Rain runoff (removal, erosion) from the top layer of soil will also deplete valuable nutrients for land based plants. For a grown food to be nutritional, the soil it was grown in must first be nutritional. Carver, being an African-American, also promoted racial harmony, and his scientific knowledge and expertise was desired by many other scientists and farmers, and of which some new scientific discoveries are still being based upon today.

A unit for counting nearly invisible particles, atoms or molecules by weight and-or mass:

A **mol** (based on the concept and word of "molecule", and sometimes pronounced as "mole", and sometimes referenced as "molar") is a standardized (accepted) unit of measurement (reference, for comparison to) that is essentially just a certain number of objects, much like how the dozen (doz) unit equals a group or count of 12 and is a defined as a specific and accepted (standardized) number of objects, and yet is used and understood as a (single, 1) unit of measurement or reference. For example 5 dozen doughnuts = (5 doz) (12 doughnuts / 1 doz) = 60 doughnuts.

How many things are in a mol unit?

A mol or "mole" (from the word "molecule" meaning small, minute) is simply defined as: **1 mol = (6.02214076)(10^23) particles**. This strictly numeric or unit-less value was found by experiments, measurements, and calculations of charged (electric, and which protons have an atomic mass and weight) particles, and some years after it was proposed. See Coulomb's law or equation about the basic formula for the amount of electric force due to particles with electric charge. This numeric constant and particle count called a **mol** unit is also called **Avogadro's Number (N_A)** or constant since **Amedeo Avogadro** (1776-1856), from Italy, first proposed (ie., a theory) a fundamental particle of matter count (linear, scalar, proportional) relationship to mass (ie., amount of matter) and weight in about the year 1811. It must be mentioned here in this book that it was already known since antiquity that there is a direct or linear relationship between volume and weight of a particular substance. For example, a cubic inch of lead weighs more than a cubic inch of iron, and at twice the volume, these specific cubes of volume of an element would then weigh twice as much, however, the question eventually became: "Is their a fundamental particle count then the same also?". The answer we know of today, after Avogadro's proposal, is that different elements have atoms that have a unique amount of mass, and therefore, given the same weight of two elements, there is a different number of atom particles and with each type of element atom having a different mass. Still, if the weights are the same value, the total mass (due to the amu = atomic mass units or particles) will be the same, but their atom sized particle count per unit of weight and-or volume will be different. Given a mol of atoms of two different elements, a mol of atoms of one element will weigh more and have more total mass than that of a mol of atoms the other element. If an atom has more mass (due to more amu), a mol of those atoms will weight more.

Avogadro proposed (now known as **Avogadro's Gas Law**) that the same volume (such as in an inflated balloon or rigid container) of different gasses (which have different natural densities) at the same temperature and pressure will probably have (on average) the same number of (randomly moving, and smallest of) particles (or what was also called then as "molecules") of matter which will keep each balloon inflated at the same size (ie., volume), and due to it having the same number of particles (with the same average thermal and kinetic energy level) applying pressure to its inside surface. This also indicates that an atom or particle of different elements (here, only gas elements were used) probably have a different mass in their natural, unpressurized state, and therefore, probably have a different size, structure or construction (ie., today, now known as atoms, and with their specific number of smaller parts now understood to be atomic mass units (amu) that are protons and neutrons).

Today, we also know that the kinetic energy of a particle of mass is: KE = (mv^2) / 2, and that temperature can change the kinetic energy of a particle and vice-versa. In the early 1800's, when **electrolysis** was used in water, the volumes of the two gases created was twice as much for hydrogen gas as for the oxygen gas, and hence the chemical formula for a water molecule became H2+O1 = H2O. Water (technically a compound [ie. substance, of many molecules] of or joining of two elements, here into water molecules) was then found to be not a single element, but is composed of two elements which must be joined together to make a particles (here, a molecule) of it. Avogadro did not yet know the actual number, or even an estimate of this particle count per unit volume, mass or weight of the gas, and it took until 1909 when **Jean Perrin** (1870-1942), a scientist from France, made experiments and gave a good estimate of it, and it has been refined in value after many years of research. The numerical constant of Avogadro's number is named in honor of Avogadro. In relationship to mass: **1 mol of protons (atomic mass units) is defined as having a mass of 1 gram**. For example, since each hydrogen atom has just 1 proton, **1 mol of hydrogen atoms has a mass of 1 gram.** The molar mass or mol per gram = mol / gram , of hydrogen atoms is therefore: 1 mol atoms per gram = 1 mol per gram. At the **s**tandard (reference) **t**emperature and **p**ressure (**STP =** 68°F =~ 72°F = 273.15K, and 14.7psi), **1 mol of a gas atoms, and which all have a low density (mass/volume) and which are all greatly spread out and-or colliding due to their containment and movement, will occupy a volume of 22.4 L = 5.917454 gallons =~ 6 gallons of volume.** Note that a gas having some kinetic and-or thermal energy will naturally expand outward and fill a container it is placed in. As it expands to fill the container, its density will decrease if it was initially compressed (ie., pressurized and having a higher density), but its total mass in that entire container and volume will remain the same value.

Note that a mol amount of atoms does not have a general or specific defined weight, and since atoms of different elements have a different structure or atomic (amu) particles in each atom. For example, a mol of iron atoms will weigh more than a mol of hydrogen atoms. This is also true for different gasses of different elements and-or compounds.

The atomic structure of a carbon-12 atom was found to contain 6 protons and 6 neutrons, hence it has 12 atomic mass units per atom = 12 amu / atom. It will be shown in a calculation below that 1g of carbon-12 has 1 mol of amu, and-or that 12g of carbon-12 is 1 mol of atoms = 1 mol-atoms. 1g of any element will have 1 mol of amu, but not atoms, except for hydrogen which has only 1 proton in its nucleus.

Note, as mentioned above, each atom of carbon-12 also has 12 smaller particles of matter (atomic mass units = amu = protons and neutrons) with mass and with each having 1 atomic mass unit (amu). The atomic or molar mass (mass of a mol of it) of carbon-12 atoms is about 12 grams of weight per mol of atoms or= 12 grams per mol-atoms:

12g carbon-12 = 1 mol of carbon-12 atoms : or= 1 mol-atoms of C-12 , and since each C-12 atom has 12 amu:
12g carbon-12 = 1 mol of carbon-12 atoms = (12 amu/atom)(1 mol atoms) = 12 mol-amu : = 12 mol of atomic mass units

If 12g of carbon-12 is to 12 mol-amu, then mathematically:

1g of weight (ie.,1g of mass being displayed on a common "corresponding weight to mass scale") of carbon-12 atoms is to 1 mol-amu = 1 gram of mass = 1 gram unit of mass or= 1 mass-gram

As a reminder, most "weight scales" are actually calibrated to display the objects corresponding mass value associated to its measured corresponding force=weight=Newtons value. A common "weight scale" is more correctly a "mass scale" whose value was automatically calculated (in the scale) from the corresponding weight of that mass.

If another element(s) or substance(s), other than carbon-12, has a weight of 1 gram, then it will have more or less than the number (1 mol) of atoms of carbon-12 in 1 gram of mass, but it will still have the same amount of mass and weight as that of 1 gram of carbon-12 = the mass and weight of 1 gram of atomic mass units (ie., protons)

If two substance, and regardless of their size or volume, have the same total mass, the weight of each substance is the same, and vice-versa.

1g of mass (matter, substance) placed on a common "weight scale" which is actually a "corresponding mass of that weight scale" will be displayed as 1 gram.

1 gram of mass = 1 gram of amu = mass of 1 mol of amu = mass of 1 mol-amu

The actual weight or force of a gram or other mass value can be found from:
F = weight = (m)(a) = (m)(g) newtons : with units of kg m/s^2. Note, 1g = 0001kg , and g = 9.8m/s^2

Ex. How many particles, objects, cells, atoms, protons, molecules, items or things is 5 mol?

Since: 1 mol = (6.022)(10^23) things if we multiply both sides by N, we have:
N mol = N (6.022)(10^23) things using substitution of the actual value in question, here 5:

5 mol = 5 (6.022)(10^23) things
5 mol = 30.11 (10^23) things = 3.011 (10^1)(10^23) things = 3.011 (10^24) things or items

Total Items = (N mol) (items per mol unit) :Total Items or Total Quantity Of Items In N mol Units

If Given: 3.011 (10^24) things, how many mol units of things is this?

Since: N mol = N ((6.022)(10^23)) things using substitution of the actual value:
N mol = N ((6.022)(10^23)) things = 3.011(10^24) things

We can solve for N by dividing both sides by the number of items in each mol unit:

N mol = 3.011 (10^24) / (6.022(10^23)) = 0.5 (10^(24 -23)) = 0.5(10^1) = 5 , Hence a formula is:

N mol = (number of items) / (number of items in 1 mol unit) : N mol Units Of A Given Quantity Of Items

If the number of particles (atomic mass units = amu, protons, neutrons) in an atom of a particular element is greater than that of another atom of a different element, the mass of that atom is greater, and the number of atoms per 1 gram (ie., 1 gram of mass) will then be less because it will take less atoms to make that 1 gram total amount of mass or matter, but still, the number of particles in 1 mol unit of particles (such as atoms) is always the same value of (6.022)(10^23) regardless of the specific element atom and its specific amount of atomic mass units (amu) and density. mol is a unit-less unit of measurement and is a count, quantity or number only, and is not a unit of mass. A unit of mass is the atomic mass unit = amu which is defined as the mass of 1 proton or 1 neutron. The question now is, how many amu of matter are in 1 gram of matter? The answer is **1 mol of amu of matter = 1 gram of matter.** 1 mol of hydrogen atoms, with each atom having just 1 proton for its mass, it will have a total mass of 1 gram and is said to weigh (on an equivalent or corresponding mass scale, "weight-grams" or "weight to corresponding grams" scale) 1 gram.

For any substances or elements having 1 gram of mass or matter, they will have the same total number of atomic mass units (amu) since these units are what actually determines a mass value and-or its corresponding weight.

Carbon12 (C12) is a common element with an atom containing 6 proton and 6 neutron mass particles (ie., atomic mass units or particles, amu) with each particle considered as having about the same mass, size (volume) and weight. The 6 electrons of C12 are not considered in the particle count for mass because their mass is negligible, practically 0. Therefore, a carbon12 atom has a total of 12 atomic mass units (amu), and is said to have an (summed total) atomic mass of 12amu. Each 1 particle in a carbon12 atom has a mass of (1 / total number of particles in that atom) = (1/12) the total mass of that atom. Note that the atomic mass of hydrogen is only 1amu since it is composed of just 1 proton, and does not have a neutron. A Carbon12 atom therefore has 12 times more mass (real material, matter) than the atom or element of hydrogen. For the same given number of mol of hydrogen and carbon12 atoms, carbon12 will always have 12 times more mass and correspondingly 12 times more weight than that of the hydrogen. 1 gram of hydrogen and 1 gram of carbon12 both have the same mass, and will therefore weigh the same value since they both have the same number of amu in that 1 gram of mass. Since 1 gram of matter has 1 mol of amu, 1g of hydrogen and 1g of carbon12 will both consist of 1 mol of atomic mass units, but not 1 mol of atoms. Since an atom of carbon12 has 12 times more mass than a hydrogen atom, a mol of carbon12 atoms will weigh 12 times more than a mol of hydrogen atoms. Any number or mol of carbon12 atoms will always have 12 times more weight than the same number or mol of hydrogen atoms.

In terms of mass per atom, or "mass density per atom", or "density or amount of mass per atom":

carbon12 has: 12 amu per atom = 12 amu / atom : mass per carbon12 atom
hydrogen has: 1 amu per atom = 1 amu / atom : mass per hydrogen atom

Since the mass of a carbon12 atom is greater than that of a hydrogen atom, It could be said that the "atomic weight" of a carbon12 atom is also greater than that of a hydrogen atom.

Because larger atoms have more volume (ie., physical space), there is fewer of them in a certain mass value and-or volume value, and-or or per unit volume. The atoms / volume density is lower for larger sized atoms with a greater number of amu or mass. Therefore, the (mol of atoms) / volume of those elements is also lower.

A mol of a "heavier element" (ie., atoms have more mass and or weight / atom = amu / atom) will have more mass, and therefore will weigh more than that of a mol of a "lighter element". A mol of carbon12 atoms will weigh 12 times more than a mol of hydrogen atoms since mass is directly related and proportional to mass.

hydrogen has 1g / mol of atoms , and since carbon12 atoms have 12 times more amu or mass:
carbon12 has a mass of 12g / mol of atoms = 1g / (1/12) mol of atoms = 1g / 0.083333 mol of atoms.
The reciprocal of this is: 0.083333 mol of carbon 12 atoms / gram of mass.
In short, **more massive, larger or "heavier" elements, have less atoms / gram, or less mol-atoms / gram , but also have more grams of mass / mol of atoms.**

The "atomic weight" listed on a table of elements, such as the common Periodic Table Of Elements, is actually the atomic mass units (amu) of each atom. 1 fundamental particle of matter has is 1 unit of mass = 1 atomic mass unit = 1amu. 1amu has a corresponding fundamental unit of weight (whose value depends on the locations gravity in the universe) which could be called an (fundamental) atomic weight unit. Therefore, in any location in a universe, the "atomic weight units" = "atomic mass units", or stated as: "atomic weight" = " atomic mass units".
The volume of 1cc = 1 cubic centimeter = (1/1000)Liter = 1mL = 1cm^3 of water at 4°, (ie., at the max. density of water, having the most mass of water per volume), is defined as having a mass of 1 gram. If an amount of material weighs the same as the weight of 1cc of water, and having any volume, it is said that it also contains the same amount of mass as that of 1 cc of water, and that amount of mass is 1 gram. In short, **if substances have the same weight, they have the same total amount of mass** since these two values always directly correspond to each other, and it is said that they are linear or proportional to each other. A 1cc volume of a denser substance and-or element will have more mass / volume and therefore have more weight / volume. For example, 1cc of iron has more mass than 1cc of water, and will weigh more by the same ratio or factor of two masses.

1 mol of atoms (ie., "mol-atoms" sized particle units) of carbon12 atoms will have (6.022)(10^23) atoms of carbon12. It actually takes 12 grams (mass) of carbon12 so as to have that many, 1 mol, of atoms. Since each gram of carbon12 element is composed of atoms with 12 amu particles each, the number of atoms in that gram is 12 times less than the number of its atomic particles (protons and neutrons) in its total mass such as 1 gram. This is why it was necessary to have 12 grams of the carbon12 element - so as to have 1 mol of complete carbon12 atoms. The **molar mass** (or mol-mass) of an element is the number of grams of it needed to have 1 mol of atom particles. The molar mass of carbon12 is 12 grams per mol = 12g / mol, or expressed as: 1 mol per 12 grams = 1mol / 12g. For other elements, their molar mass value will be a different amount of grams, yet the mol of atoms is always the same value.

1 atomic mass unit = 1amu, is the mass of a proton or neutron which are the two fundamental parts of the nucleus of an atom, and which has most of the mass of the atom. 1 mol of atomic mass particles is defined as having a mass of 1 gram. Since carbon-12 = C12 has 12 amu per atom, 1 amu can be defined as (1/12) the mass of a C12 atom. If 1 gram of C12 has 1 mol of amu, and to have 1 mol of entire or complete C12 atoms, it will take 12 times the amount of that mass. It will take 12 grams of C12 so as to have 1 mol of C12 atoms.

For C12, there is 12g / 1mole of atoms , dividing numerator and denominator by 12: we have:
1g / ((1/12)mol) atoms = 1g / ((6.022)(10^23) / 12) atoms = 1g / (0.502 x 10^23) atoms , and therefore, there is (5.02 x 10^22) C12 atoms in 1 gram of C12. We can multiply this value by so as 6 to find the total number of either protons, neutrons, or electrons in 1 gram of C12.

Ex. If 12g of C12 atoms is equal to 1 mol of C12 atoms, what is the mass of one-thousandth (0.001) of a mol of C12 atoms? [As a reminder, most modern scales are calibrated to display the equivalent mass value of a given weight].

Setting up a proportion type of equation:

(1mol-atoms of C12) / (12g of C12) = (0.001mol-atoms of C12) / (Xg of C12) , after solving for Xg of C12:
X = (0.001) 12g = 12g / 1000 = 0.012g = 12 (10^-3)g or= 12(0.001)g = 12 mg of C12 material

Ex. If 3g of C12 is added into a mixture, how many mol of C12 atoms did you add into that mixture?

First note that given 12g/mol, it can be also said there is: 1mol/12g. = 0.0833mol / 1g or 1g / 0.08333mol.
1g of C12 = 0.08333mol , and multiplying both sides by 3, we get: 3g = 0.25mol. This is also the result after multiplying both the numerator and denominator by 3 in the last previously expressed fraction above.

Or by setting up a proportion type of equation:

(1mol of C12) / (12g of C12) = (Xmol of C12) / (3g of C12) after solving for X:
X = 0.25mol of atoms of C12

Since 1 mol atoms of C12 is (6.022)(10^23) atoms, and that there is 6 protons in each atom, if we multiply a given mol-atoms value by 6, we can find the number of protons (or neutrons, or electrons) in 1 mol-atoms of C12:

(X mol-atoms)(Y particles per atom) = (X mol-atom)(Y) particles = X 6.022 (10^23) Y particles = XY 6.022 (10^23)
(1 mol-atoms)(6 particles / atom) = (1)(6.022)(10^23)(6 protons) = 36.132 (10^23) protons in a mol of c12 atoms

As the number of atomic mass particles in the atom structure of different elements is increased, the total mass of a 1 mole-atoms quantity of that element will also increase by the same factor, and therefore, the weight will also increase proportionately (ie., by the same factor) to this mass increase. Since the mass of an electron is negligible, the mass of an atom is considered due to its protons and neutrons only.

Extra: The neutrino

Although beyond the scope of this practical book, but still worth mentioning here just for the awareness of it, is that the smallest particle of matter found (as of of the year 2025) is called a **neutrino.** Its mass is considered a million times less than that of an electron, and it is then difficult to measure. A neutrino has a great ability to travel through all other matter without colliding into larger particles of matter, and it is sometimes called the "ghost particle". Occasionally, a neutrino will collide with a nucleus of an atom, and the more neutrinos there are, it will greatly increase that chance. Scientist **Juan Collar** from the University of Chicago, USA, has even proposed a radio-like communication system using neutrinos. This could send the particle signals though a mountain range, deep into the ocean or through the Earth to the other side. Neutrinos are thought to be composed of just 1 whole particle with no sub-particles or composition particles, and have no electric charge, and have no magnetic property, charge or (force) field, hence it is considered as a "neutral particle", and its name reflects this.

There are three neutrino types, and with one of these types being associated with one other atomic particle such as an electron, and that this specific neutrino is sometimes called an "electron neutrino". The subatomic particles were usually declared as real after many years of experiments, observations and producing similar results with the aid of particle accelerators and-or particle colliders (ie., "atom smashers"). It was also found that most particles have an anti-particle, even a neutrino, and which will cause both particles to go out of existence or disappear when they are joined together, and this process will emit some photons (ie., light, RF energy, radiation) during this process. Note that a neutrino does not orbit the electron or any other atomic particle, and that neutrinos are rather decay products of atomic interactions (ie., fission or fusion) and-or the nucleus decay of an unstable atom such as after emitting an neutron. Besides the electron neutrino, the two other types of neutrinos are the muon neutrino, and the tau neutrino. It is said that the universe if then always filled with an huge, uncountable number of neutrinos, and of which even pass through our bodies and Earth without much issue. Our nearby Sun, a star, emits the most percentage of neutrinos that encounter Earth. A neutrino can be affected by the (short range) weak nuclear force, and gravity just like any other mass.

In 1930, **Wolfgang Pauli** was first to propose a particles that would later be called a neutrino particles in 1932 by **Enrico Fermi**. The first neutrino was visually noticed in 1970 by using a "bubble chamber", of which is used to help observe particles paths, collisions, and other particles created. As of the year 2025, neutrinos are still being heavily studied. If interested further, please research atomic particle physics and the current, standard model of particles.

The **Periodic Table Of Elements** has much numerical data (information, knowledge, (periodic, repeating) trends or physical similarities, patterns and groupings) about each element, and a value called the **atomic number** is used to help identify a particular element and is equal to the number of protons in the atom of that element. If the atom is neutral or balanced in electric charge, the atomic number or proton number is equal to the number of electrons in that atom. The **atomic mass** (or atomic mass units, amu) of a specific element is the number of protons and neutrons in one atom of it. The total mass of the electrons in an atom is considered as negligible or so small as to be of no practical consideration for the total mass and weight of an atom. The **atomic mass number** of a specific element, if considered as a number of grams of that element that will then be equal to the required (mol, molar) mass of that element necessary to have 1 mol of atoms of that element. For example, carbon, or more specifically carbon12, has an atomic mass number of 12 since it has 12 amu per atom. It will take 12g of carbon (ie., carbon atoms) so as to have 1 mol of particles of carbon atoms, or 1 mol-atoms of carbon. In 1869, the first formal and modern periodic table or chart was made in Russia by a chemist named **Dmitri Mendeleev** and it included the 56 known elements at that time, and with the probable properties of some unknown elements yet to be found being proposed (ie., extrapolated, deduced) by the data from the known elements. The periodic table also organized the elements into similar (electron) electro-chemical properties. Modern chemists and other scientists often study and know the periodic table fairly well so as to be more knowledgeable and proficient in their field of science (ie., exploration and study).

When the number of grams in a grams per mol-atoms measurement increases, such as having an element with a higher atomic mass, we find that the number of mol-atoms is actually less per gram for the "heavier" (more massive in mass, and therefore more weight) elements. The result is that the total volume (such as the number of cc of volume) of that material or element will be less per gram of mass, and-or that 1 cubic volume full of that material weighs more than that of an element with a lower atomic mass number for each atom. Consider atoms as having a sphere shape, and that atoms with more amu per atom have a larger diameter and volume for each atom, and therefore fewer of them will actually fill a set volume such as a cubic centimeter.

Ex. The atomic mass of iron is about 55.85. Iron atoms have more mass than C12 atoms because iron atoms have many more atomic mass units (amu's) of protons and neutrons in each atom than that of C12. If there is about 55.85 grams of iron / 1 mol of iron atoms, and dividing both numerator and denominator by 55.85, we have 1 gram of iron per (1/55.85) mol. of atoms. Since (1/55.85) is less than (1/12), we see that the number of particles (here, atoms) is less per gram for "heavier" (more particles or amu per atom), more mass(ive), and therefore more weight elements. One result of all this is that the volume of that material or element needed per gram of a more massive element is less, and-or that the weight per 1 cc volume is more than that of another "lighter", less massive element such as C12 with only 12g/1mol = 1g/(1/12) mol. The g/cc, or grams per unit volume of iron is greater than that for carbon12.

Ex. How many grams is 100 billion atoms of C12. 100 billion atoms = 100(1)(10^9) = (1)(10^2)(10^9) = = (1)(10^11) atoms. Using the known data for C12, it has 12 amu per atom, and its atomic mass number is 12, and will therefore require 12 grams of it so as to have 1 mol of C12 atoms:

$$\frac{\text{12g}}{\text{1mol}} = \frac{\text{1g}}{\text{0.083333333 mol}} \quad \text{or} = \frac{\text{1g}}{\text{(6.022)(10^23) / 12) atoms}} = \frac{\text{1g}}{\text{(5.018)(10^22) atoms}} \quad \text{: for C12 only}$$

Expressing a proportion equivalence or equation:

$$\frac{\text{Xgrams}}{\text{(1)(10^11) atoms}} = \frac{\text{1g}}{\text{(5.018)(10^22) atoms}}$$, after solving for X: Xgrams = 1g / (5.018)(10^11) and

X grams =~ (0.1993)(10^-11) grams =~ 0.2(10^-11) grams = 2 (10^-1)(10^-11)g = 2 (10^-12)g = 0.000,000,000,002g
= 2 picograms

From this we can also find that 1pg corresponds to 50 billion atoms of C12.

Ex. It was found previously that 1 gram of carbon12 element had about (5.02)(10^22) atoms. We can solve for the mass of just 1 carbon12 atom if we divide 1 gram of mass by (5.02)(10^22).

___1 gram of carbon12 element___ or: _ (5.02)(10^22) atoms of carbon12__
is to: (5.02)(10^22) atoms of carbon12 is to: 1 gram of carbon12 element

Dividing the numeric values in the numerator and denominator, we find:
1 atom of carbon12 element has a mass of about (1.993)(10^-23)g =~ (2)(10^-23)g ~= 2(10^-26)Kg

Since C12 has 12amu, the mass of one C12 atom can also be found by multiplying the mass of 1 amu by 12. **The mass of 1 amu or proton = 1.6726219 (10^-27) kilograms = 1.6726219 (10^-24)g** , and this will be derived here:

Since a carbon12 atom has 12 atomic mass units (6 protons and 6 neutrons), we can divide the mass of 1 carbon atom by 12 so as to find the mass of 1atomic mass unit or particle:

2 (10^-23)g / 12 =~ 1.672621898 (10^-24)g :Mass of 1 atomic mass unit or particle such as a proton or neutron. (mass of 1 electron) < (proton mass / 1000). MASS OF A PROTON. The diameter of a proton is about 0.833 femtometers = 0.833fm = 0.833 (10^-15) meters. The reciprocal of this value is how many protons could be set or lined up side by side in 1 meter. If you divide that value by 100, you can find the number of protons lined up in a centimeter. If you then cube (take the 3rd power) of that value, you can find the number of protons in a cubic centimeter.

Since 1 gram unit is one-thousandth of a kilogram unit, 1g = 0.001kilogram, we can express this result in units of kilograms:

1.673 (10^-24)g =~ 1.673 (10^-24) (0.001)kg = 1.673 (10^-24) (1)(10^-3)kg = (1.673)(10^-27)kg

Ex. An estimated number of cells in the average 150 lb adult male human body is 30 trillion human cells = (30)(10^12) cells. That is about 200 billion cells per pound of weight. Some scientists have calculated the number of bacteria and fungi cells in the human body to be about the same number value as that of human cells, however a human cell is much bigger, and therefore it has much more mass than most bacteria and fungi cells. On average, a bacteria mass is only 0.02 or 2% of the mass of a human cell, hence about 2% of the mass and-or weight of a human is due to bacteria. The average diameter of a red blood cell is 7.2 um. The average length of a bacteria is 5 um.

If each cell was to be given 1 atom of carbon12 element, the total mass of that amount of carbon12 element needed is:
(mass of 1 atom of carbon12 element) (30 trillion) = (2)(10^-23)g (30)(10^12) = 60 (10^-11)g =
6 (10^-10)g = six-hundred trillionths of a gram = 0.6 billionths of a gram = 0.000,000,000,6g =
= 600 pico-grams = 0.6nano-grams . **Extra:** (150 lb / 30 trillion cells) = (5 lb / trillion cells) =
(1 lb / 0.2 trillion cells) = (1 lb / 200 billion cells)

Ex. How many mol of atoms is 30 trillion atoms? Expressing this as an equivalent proportions type of equation:

1 mol is to (6.022)(10^23) atoms as is = x mol is to 3 (10^13) atoms
1mol / ((6.022)(10^23)) = x mol / ((3)(10^13) after solving for x:
x = 0.4982 (10^-10) mol = 4.982 (10^-11) mol =~ 50 (10^-12) mol = 50 pmol : 50 pico-mol

The atomic number (ie., protons per atom) of element carbon12 is 6, and the atomic number of element iron is 26. Carbon12 has an atomic mass (ie., amu per atom) of about twice (due to an equal number of neutrons) its atomic number = (2)(6amu) = 12amu.

Iron has an atomic number (ie., amu) of 26, and has an atomic mass of about (2)(26amu) = 52amu per atom. The ratio of the atomic mass of iron to carbon is about: 52amu/12amu = 4.3333... An iron atom has about 4.33 times more mass than a carbon12 atom, and for a given mass or volume, iron will weight about 4.33 times more per unit volume than that of carbon12.

> 1 mol of iron, and 1 mole of carbon12 both have the same number of particles, such as atoms, but the total mass of each atom and-or 1 mol-atom count of the elements is different. 1 mol of carbon12 atoms has a mass of 12grams. Since the number of atomic particles in an iron atom is 4.333 times more than that of carbon12, 1 mol of iron atoms has 4.333 times the mass:
>
> 1 mol of carbon12 atoms = 12g of mass and 1 mol of iron atoms = 4.333(12g) = 52 grams of mass
>
> This example above verifies that when the numeric part of the atomic mass of an element is considered as having units of grams, it is equal to the mass of 1 mol count of atoms of that element.

Pure water is a compound (ie., a mixture or combination) containing molecules (ie., bonded, joined or combined atoms) made of hydrogen and oxygen atoms. The molar mass of water is 18.01528 g/mol and is often noted as simply 18g/mol. Drinking or nutritional water, such as spring water, contains vital and-or healthy amounts of some trace (small amounts) elements. Pure water is often used and-or required for chemical reactions so as to avoid contamination and chemical interactions by other elements. The common chemical formula and (symbolic) equation for pure water is:

2 hydrogen atoms bonded to 1 oxygen atom --> 1 water molecule : --> means "results to" or "equals", and in symbolic form:
$H_2 + O_1$ or= H2 + O and is often simply expressed as: H2O : chemical formula for water

A water molecule can be considered as the smallest particle of the substance or compound known as water, and so as to still be considered as being water. In 1 water molecule, often expressed as H2O1 or= H_2O with the 1 understood, there are 2 hydrogen atoms, and 1 oxygen atom joined (ie., a compounded) together at their electrons so as to make 1 water molecule. The ratio of the number of 2 hydrogen to 1 oxygen atoms in a water molecule is therefore 2. To make any amount or mass of water molecules, such as 1 mol of water molecules, it will therefore take twice as many hydrogen atoms than the number of oxygen atoms. 1 water molecule contains 2 hydogen atoms and 1 oxygen atom. 1 mol of hydrogen atoms is 1 grams of mass or matter. 1 mole of oxygen atoms is 16 grams of matter. .A mol count of water molecules or H2O = H2O1 will contain 2 mol of hydrogen atoms and 1 mol of oxygen atoms. It could be said that 2 parts of 1 mol atoms of water will be hydrogen atoms, and 1 part of that same 1 mol of water will be oxygen atoms. It could also be said that 2 mols of hydrogen atoms and 1 mol of oxygen atoms are needed to make 1 mol of water molecules. Also, 1 mol of water molecules contains 3 mol of atoms since each molecule contains 3 atoms. The volume size of 2 mol of hydrogen gas at standard temperature and pressure (STP) will be: 2 mol (volume of gas/ mol) = 2(22.4L) = 44.8L

Since the atomic mass of a hydrogen atom is 1, since it has 1 amu, then 1 gram of hydrogen is 1 mol of hydrogen atoms. 2 mols of hydrogen atoms is therefore 2 grams of it. Since the atomic mass (amu(s)) of an oxygen atom is 16, it has 16 times the atomic mass as that of a hydrogen atom, and therefore, there is 16 grams of oxygen atoms in 1 mol of oxygen atoms. Therefore, in 1 mol count of water or H20 atoms, there is 2 grams of hydrogen atoms + 16 grams of oxygen atoms. Therefore, **1 mol of water molecules has a mass of about 2 grams + 16 grams = 18 grams**. This can be measured and-or weighed out on a (weight to corresponding mass) scale. In terms of volume, 18g of water has a volume of 18cc = 18mL of water. This is slightly more than a 15mL tablespoon of water - about 1 tablespoon and 1 teaspooon. The mol/mass or "molar mass" of water molecules is 18 grams/1mol. It could also be said that a gram (or any other mass, or weight) of water has 2/18 = 0.1111... = about 11% of it being hydrogen atom mass, and 16/18 = 0.8888... about 89% of it being oxygen atom mass - practically 90%. This is so, even though the number of hydrogen atoms in a water molecule is greater at twice as much than the number of oxygen atoms, but the (atomic particle(s), amu) mass of a hydrogen atom is much less than that of an oxygen atom.

Note that the ratio of the atomic mass (ie., amu) of oxygen to the atomic mass of hydrogen is 16/1, and so if there are twice as many hydrogen atoms in a water molecule, the ratio of the atomic mass of oxygen to the atomic mass of hydrogen in water or a water molecule is: (atoms)(oxygen amu) / (atoms)(hydrogen amu) = (1 x 16) amu / (2 x 1) amu = 16/2 = 8. It could be said that the mass of water or a water molecule unit or particle is due to that there is 16 atomic mass units or particles of oxygen and 2 atomic mass units or particles hydrogen for each molecule of water. Therefore, any mass or amount of water has (16/2) = 8 times more of its mass (and-or weight) due to oxygen than its mass due to hydrogen.

Technically, a gram or any other specific amount of any matter such as atoms and-or molecules of an element or elements will have the same number of atomic mass units (amu) and will also weigh the same on a scale. A mol or mol count of different atoms and-or molecules will generally not have the same total mass (ie., grams) due to the different and total amounts of atomic mass units within those atoms or molecules. For example 1 atom of hydrogen has, contains or is composed of just 1 amu, and 1 atom of oxygen has, contains or is composed of 16 amu. 1 mol of hydrogen atoms will have (1 amu / atom)(1 mol atoms) = 1 mol amu. 1 mol of oxygen will have (16 amu / atom)(1 mol atoms) = 16 mol amu. Since 1 mol amu of hydrogen is defined as having a mass of 1g, 16 mols amu, here from oxygen, will have 16 times more mass, hence a mass of 16 grams.

A water molecule has a mass of 18 atomic mass particles or units. 16 are from oxygen, and 2 are from hydrogen.

Water molecule = H2 O1 = (2 hydrogen atoms) + (1oxygen atom)
= (1amu/atom + 1 amu/atom) + (16 amu/atom) combining the amu's:
= 18amu / water-molecule = mass of a water molecule and:

$$\frac{\text{waters atomic mass due to atomic particles or mass units from oxygen}}{\text{waters atomic mass due to atomic particles or mass units from hydrogen}} = \frac{\text{16 amu (1 atoms)}}{\text{1 amu (2 atoms)}} = \frac{\text{16 amu}}{\text{2 amu}} = 8$$

Therefore, mathematically:

waters atomic mass due to oxygen = 8 (waters atomic mass due to hydrogen) : 8 times more mass particles
waters atomic mass due to hydrogen = (waters atomic mass due to oxygen) / 8 : 8 times less mass particles

16 amu oxygen / 18 amu total = 0.8888... oxygen, or 2 amu hydrogen / 18 amu total = 0.1111... hydrogen

Since 0.1111.. of waters mass is due to hydrogen , (1 - 0.1111...) = 0.8888... of the mass of water is due to the other substance(s) in that water molecule, and here it is just oxygen. It could be said that about 88% of the mass or weight of water is due to the mass or weight of the (condensed, liquefied) oxygen (gas) in it, and that about 11% of the mass or weight of water is due to the (condensed, liquefied) hydrogen (gas) in it.

0.8888.. oxygen / 0.1111 hydrogen... = 8
or= 16amu O / 2 amu H = 8

: a water molecules internal amu particle ratio, and **not** the ratio of the number of atoms (here 3) or their ratios in a water molecule. In short, the mass of an atom from different elements is not the same value, and that an equivalent mass of different elements will have a different number of atoms. Both of these facts are due to the different number of atomic mass units (amu) or particles (protons, neutrons) in atoms of different elements.

Mathematically:

(0.1111...)(8) = 0.8888... or~ =: (11.1%)(8) = 88.8%

When a recipe or formula states to use a certain amount of a substance2 that is a certain percentage of another substance1's weight, rather than its volume, it helps ensure that the mass (the true quantity of material or matter) of substance2 is also the same percentage. Stating and using a certain volumes of a material is problematic for others since a volume (physical size) of material can change due to the physical structure of the material used and-or if it had moisture (water) in it, and-or if it was compacted (compressed) or not. A compressed substance (such as wheat flour) will weight more in a certain volume, than when not compressed. Using the weight in a recipe ensures the same mass or amount of substance. Mass and weight are directly proportional to each other. For various studies and measurements of weight and mass, it is beneficial to obtain an inexpensive and accurate digital weight scale that can measure small objects, say from a fraction of a gram and up to100g or 500g, and possibly another scale for heavier weight objects.

Some formulas to have available for chemistry studies, and of which variables can be mathematically derived from:

(total mass of an amt. of an element) = (molar mass of the element)(mols of that element) = (g/mol)(mol) = grams

(total number of particles) = (mols)(Avogadro's Number) : Avogadro's Number = Na = NA ~= 6.02214$\underline{1}$(10^23)

Using substitution for mols into the above equation:

(total number of particles) $= \left(\dfrac{\text{total mass}}{\text{molar mass of an element}}\right)$ **(Avogaddro's Number) :here, the total number of atom particles since molar mass is defined for atom particles**

$= \left(\dfrac{\text{g}}{\text{g/mol}}\right)$ **(NA) = (mol) (NA) as shown above (grams/mol-atoms)**

For electricity studies:

1 mol of electrons has, and is 1 mol of (negative) electric charges, and this amount of charge is called a (Michael) Faraday unit of electric charge, and this is somewhat of an outdated unit for an amount of electric charge, and rather the Coulomb unit for electric charges is now used instead. The Faraday (F) unit was mostly used in electro-chemistry science such as for electrolysis. Note also that the units of capacitance are called Farads and is still widely used today.

F = charge per mol of electrons ~= 96500 coulombs per mol of electrons = 96500C / mol : Faraday's constant
F = 96500C per 6.022 (10^23) electrons , mathematically:

$\dfrac{\text{Coulombs}}{\text{mol of electrons}} = \dfrac{96500\text{C}}{6.022\ (10\text{^}23)\ \text{electrons}}$ * = 1.602457655 (10^-19) C : charge per electron

1 electron charge = 1e = 1.602457655 (10^-19) C , also mathematically:

(1 mol of electrons)(charge of each electron) = Coulombs (C) of charge of a mol of electrons = Faraday constant

* This fraction, when num. and den. are divided by 96500, can be reduced to about: 1C / (6.24(10^18)) electrons. There are that many electrons per Coulomb (C) of charge, and-or that many electrons flow past a point in a circuit when the current is 1A = 1C / s = 1 Coulomb of electric charge (Q) per second = 1 Coulomb of electrons per second

A current of 1A = 1 coulomb of charge / 1s = 1c / s. If a current of 1A flows for 1 hour of time = 3600s, how many coulombs of charged have flowed past a point? 1c / 1s = Xc / 3600s. After solving for x,we find x=3600c

How long will a current or charge flow of 1A of electrons take to total 96500C = 1Faraday = 1 mol past a point? From 1A = 1C / 1s, we can write a proportion or equivalent fraction equation of: 1C / 1s = 96500C / Xs, after solving for Xs we find it equal to 96500s. If we divide this value by 1h=3600s, we have 96500s / (3600s/1h) = 26.81 hours. If the amount of

coulombs of charge was 5 times less, or the amount of current was five times more at 5A = 5Qc/1s , that time of 26.81 hours would be 5 times less at: 26.81h / 5 = 5.36h . 1 minute = 60s and 1 minute as a fraction of an hour of is:
1min / 1h = 60s / (3600s/1h) = 0.0166$\underline{7}$h , or simply: 60s / 3600s = 0.0166$\underline{7}$ =~ 1.67% and:
1 min / 0.01667h = x min / 0.36h , after solving for xmin , we find xmin = 21.6min , hence 5.36h = 5h and 21.7 min

To split a mole of water molecules = 18g of water into hydrogen gas and oxygen gas, will require at least a total current of 2 mol of electrons since each water molecule requires 2 electrons to be removed or unbonded and pass through the external battery circuit. 1 mol is to 96500C as= 2 mol is to Xc: 1mol / 96500C = 2mol / Xc , solving for Xc we find: Xc = (2)(96500C) = 193000C of charge. Note that if the water gets hot, some its volume be lost as steam, and in practice, more than 18g of water would actually be used - perhaps 500 to 1000 grams would be used, but only a maximum of 18g of that total volume of water would be converted to hydrogen and oxygen if only 2 mol of electrons flowed in this electrolysis circuit, and regardless of the time taken.

According to Einstein's famous equation: E=mc^2, the nucleus of atoms contains a very high amount of stored potential energy, and likewise it took at least that much energy to create that nucleus. The more protons a nucleus has, the greater the nuclear energy required to make that nucleus, and the greater the stored potential energy in that nucleus. In terms of molecules of two or more atoms, they take a much smaller amount of energy to create since the atoms of the molecules share electrons that are relatively at a large distance from the nucleus, and are bound by the electric force rather than the strong nuclear force such as found at the nucleus and its particles. To split a mol (6.022 x 10^23) of water molecules into its hydrogen and oxygen parts will require about 237000 Joules = 237kJ, plus about 20% more lost, wasted or transferred as heat energy during the process. Water molecules can be split apart by using electrolysis, and where a voltage is applied to it. This will create an electric circuit and current through that water, and which will replace electrons when they combine with positively charged ions (atoms that are unbalanced or non-neutral in terms of electric charges).

A mole of water has a mass of about 18g. To start removing electrons from this molecule so as to split it apart will require a minimum voltage of about 1.23v potential difference across the water if it is warm, and slightly more voltage if the water is cool. Since the atoms of each water molecule share 2 electrons, also called its (molecular, atom) bonding electrons, it will take 2 times the total energy to free them all from their molecular bonds than it does just to free one electron from its molecular bond. When a single electron is influenced by the energy of a 1V (ie., 1J / 1C of electrons) potential difference, it is said to have gained 1 electron-volt of 1eV of energy. For water to split into hydrogen and oxygen atoms, it will require at least 1.23v potential difference because it will take about 1.23ev of energy to break an electron from its water molecular bond, and 2 electrons will then require twice as much or about 2.46ev of energy.

1V = (1J / 1C) = (1J / (6.24)(10^18) electrons) , and after dividing the numerator by the denominator, we have:

1.602 (10^-19) Joules / 1 electron = **1ev** **,** To split each water molecule of water will require:

2.46 ev / water molecule = (2.46 ev / water molecule) (1.602 (10^-19)J / 1 ev) = 3.94$\underline{1}$ (10^-19) J / water molecule

(3.941 (10^-19)J / water molecule) (1 mol of water molecules) =
(3.941 (10^-19)J / water molecule) (6.022 (10^23) water molecules) =

237327 J =~ 237 kJ to split 1 mol of water molecules = 18g of water molecules : 1 tablespoon = 15mL = 15cc = 15g of water. 1 teaspoon= 5cc = 5g

From **V = J / C** , we have: **J = VC** , and from : **1A = 1C / 1s** , we have: **C = As** , and using substitution:
J = VAs = **(Pw)(Ts)** , and if J=237000 , V = 1.23 , and A = 5 how long will it take, hence solve for s = seconds of time:

s = J / VA = 237000J / (1.23v)(5A) = 237000J / 6.15 watts = 3853$\underline{7}$s = 10.7h

The ratio of hydrogen atoms to oxygen atoms in a water molecule is: 2 hydrogen atoms / 1 oxygen atom = 2. The corresponding amu's of the numerator and denominator is: 2 amu / 16 amu = 8 . The amu due to oxygen is 8 times more than that of hydrogen. When a water molecule splits into its component hydrogen and oxygen gas atoms, there will be twice as much hydrogen atoms produced than oxygen atoms, but the mass and corresponding weight of those oxygen atoms is 8 times more than that of the hydrogen atoms. In water molecules: hydrogen mass / oxygen mass = 1 / 8 , or oxygen mass / hydrogen mass = 8 / 1 or 8 to 1 = 8:1. 88.8..% of 18g or 1 mole of water = 16g of oxygen , and 11.1..% of 18g or 1 mole of water = 2g hydrogen.

Of an interesting note is that when the oxygen and hydrogen gas atoms having kinetic energy then combine to form (denser) liquid water, they will loose some of that kinetic energy. Likewise when liquid water turns into (cooler and denser) ice, it must loose some of its thermal and-or kinetic energy to do so.

During the **electrolysis of water**, it is generally considered as being the result of electrostatic forces at the two metal or graphite (ie., a form of carbon) electrodes or terminals in the water, and of which an external voltage is applied. Warm water will also supply some thermal energy to help the process of splitting water molecules apart, and possibly the electrostatic forces from a nearby electron passing through the water will also help the process of splitting water molecules apart. At the positive electrode, also called the anode, nearby water molecules are electrostatically split into positive charged hydrogen ions (ie., protons) and oxygen (a gas) atoms. The 2 electrons, 1 from each hydrogen atom, will be attracted to the positive electrode and travel through the circuit and through the battery and be repelled to the negative or cathode electrode. These electrons will then be attracted to the positive charged hydrogen ions and will create a complete hydrogen atom which is a gas. Since pure water does not easily conduct electrons, an electrolyte such as salt and-or an acid is usually added to the water to help conduct the electrons through it so as to complete the electric circuit. When table-salt dissolves in water, the salt molecules are split apart by the water molecules into both positive sodium ions and negative chlorine ions. These ions will help move electrons through the water, and so as to conduct electricity. The acid can also put many positive charged hydrogen ions (ie., protons) into the water, and which will aid the electron conduction through it. It is also possible to rather add a base into the water. Note that a table-salt (a sodium and chlorine molecule) electrolyte will release some dangerous chlorine (ie., like "bleach") gas when it undergoes electrolysis in the water, and you may wish to do this outside a dwelling (home, building, etc). Electrolysis is sometimes used to remove rust off of a metal.

In a galvanic cell, chemical reactions create and-or release energy and create free electrons and an electric potential (ie., voltage = J/C), hence creating a cell or battery. In electrolysis, the electric potential or energy of a battery is used as the energy to cause and power an electro-chemical reaction.

In electrolysis, oxidation, loss or removal of an electron(s) from the electrolyte happens at the anode electrode. These electrons are attracted to the positive (+) side of the battery and will be sent to the cathode terminal after being given some energy and repelled by the battery. Near the anode, reduction or gaining of an electron takes place.

Electroplating a metal can be done by a form of electrolysis. Electroplating is where one metal is coated with a thin layer of atoms (or ions) of another type of elementary metal. The metal where the plating metal or metal coating is deposited is said as being plated and-or electroplated. Here, the cathode or negative electrode is the metal to be coated or plated by the other (anode, positive electrode or terminal) metal and-or metal particles (fine and-or dissolved) suspended in the electrolyte solution. At the anode and-or electrolyte solution near it, positively charged ions of it will be created and they will travel via electrostatic forces through the electrolyte and will combine with the electrons on the cathode metal surface, hence placing an entire atom of the anode metal onto its surface. Electrons from the anode metal will attracted to the positive side of the applied battery (ie., electric potential, electric force) and will pass through it to the cathode, and so as to have a complete electrical circuit for the flowing or moving free electrons. The metal to be coated or plated on its surface must be very clean so as to be completely plated and firmly, and hence, it should have no oils, wax, paint, rust or other debris on it. Some metals do not plate well onto others, and a third or intermediate plating of a metal may sometimes be used so as to help facilitate the desired or final metal plating. Chromium (chrome) or gold plated metals makes them very resistance to rusting (ie., oxidation). To help facilitate electroplating, the metal to be plated can generally be placed into the electrolyte as dissolved (ie., atomized) particles. **Proper plating equipment and safety equipment needs to be considered: tanks, electrolyte, voltage, time, gloves, ventilation, eye protection, clothing protection, etc.**

The science of chemistry and electricity often coincide, especially for the general topic of **electro-chemistry**, and it is good to know at least some of both, but they are also different in their fundamental goals. Both of those sciences are beyond the scope of this basic mathematics book. however the topic of electricity has been given a larger discussion in this book due to its widespread use and interest by the average person. A recommendation is that a chemist should take a basic electricity course, and an electrician should take a basic chemistry course. The sciences of biology, agriculture, materials and many other fields of science will sometimes include and-or require at least some basic chemistry knowledge. An educational course for a field of science and-or work will often include the necessary and-or minimal and most useful knowledge needed, and without the need for a full chemistry course. Batteries, both primary (non-rechargeable) and secondary (rechargeable) batteries are results of electro-chemistry. Electroplating is one result of electro-chemistry.

More About Electricity And Electric Charges

Below are brief articles which contain selected key points of common knowledge, and consists of common brief facts, standards, some history and noted people, and so as to also not be excessive in detail and beyond the scope of this book and its practicality. The reader of this book may skip over these until another time needed and-or casually glance at the highlighted topics. They were included in this book so as the reader may have at least some practical familiarization and knowledge of these topics so as to be able to have a more robust, scientific understanding and use of how math can be applied in a practical manner, and to understand and-or possibly have some discussions with others. The science articles below are mostly about electricity, energy, flight, space, and measurement conversions**.** Each topic could fill a book by itself, and it is often not practical for all the knowledge, thoughts, examples and ideas to be presented in any one book, and you are therefore encouraged to seek more about any specific topic that you need to know more about. The way knowledge is presented, expressed or written, such as a derivation of a formula, also plays a role in how it is perceived as interesting, necessary, and-or easily remembered, such as being an important step for further knowledge.

Amber is a hard, petrified form of ancient tree sap, and was used to deliberately create some noticeable and interesting effects; usually showing the attraction and-or repulsion of small (electrically charged) objects after friction rubbing it with other objects. The words "electricity" and "electron" as we know of today is from the Roman word "electrum" that was used for the Greek word "amber". Today, we, now know that the friction (surface contact rubbing, or "drag" force) of the amber and-or other material(s) essentially applied enough energy to free some electrons, creating (highly mobile) electric charges, and charged objects (objects containing a net charge of either positive or negative).

William Gilbert (1544 - 1603), from England, made a study of many materials such as minerals that can be electrically charged and-or be affected by it, including a thin, lite-weight metal pointer in the year of 1600 which can turn its direction in the presence of electricity rather than magnetism. In particular, he studied electrical attraction, and his device was the first **electroscope**. He thought that the electric charge was a form of energy due to friction and the resulting heat increase of the object. He was the first to understand that the Earth had two magnetic poles, one called North, and the other called South due to their opposite directions on Earth. In the 1740's, **Benjamin Franklin**, from America, discovered that there are two distinct types of electric charges or "fluids": positive and negative. Current flow was then later conceived by Franklin to be from the positive side to the negative side of a battery, and this is modernly called **conventional current flow**, and this actually helps theoretically and mathematically such as that a voltage or energy potential greater should have a mathematical positive sign, meaning greater than 0 and-or nothing, and is a reality and of value. It was unknown during Franklin's time that electron particles usually carry (electrical, charges, with kinetic) energy and electric charge, and that they actually flow (id., repelled from other electrons of the same charge) from the negative side of a battery to the positive side of which they are attracted to. This is called as "electron and-or charge flow" of current. Since electrons have a negative charge, they are often simply called as being negative charges and-or carriers. In most circuit analysis situations, this strict technical or scientific truth of which terminal the charge or current flows out form does not need to be considered in most practical cases. Today we know that in a wire, it is electrons that are flowing or moving, and positive charges (protons) do not.

Once a practical way was found to make and-or store electricity or charges, such as with Volta's battery in about the year 1700 AD which made the study and use of electricity very practical, the revolution in electronic discoveries, understanding and applications grew exponentially where newer technology grew rapidly by using existing discoveries and technology so as to make further discoveries.

At about 400 B**.**C**.**, an ancient Greek known as Democritus called the smallest bit of matter of any particular substance an atomos (the indivisible or "uncut" part left after repeatedly cutting something into smaller and smaller pieces, and yet each piece is "unaltered" and still has the same (ie., one) physical properties). In the 1600's, the similar word of: **atom** was used for this smallest individual bit of a substance. The word "atomic" is in reference to atoms. Not long after **Volta** invented the battery in about 1800 so as to generate electricity, in about 1803, **John Dalton** (1766-1844)**,** a chemist from England, and in the first modern and scientific use of the word, called this smallest bit of a particular element as an "atom" of that element, and that each one is identical for a particular element. Some elements had atoms which behaved differently (such as observed in different gases) and must be somehow constructed differently and have a different mass because the same volumes of different elements weighed differently. Dalton was the first to consider that **compounds** (several elements that compose or create a unique substance) are composed of two or more elements bonded together so as to create the smallest fundamental particle of a compound which is called a **molecule** (since the word "mole" is an old word for mass, "molecule" means "mass part", "a part of a mass", "a small particle of mass") of that compound substance. For example, a water molecule ("H2O") is the smallest piece or particle of the substance called water, and each molecule of water is composed of hydrogen and oxygen atoms bonded or joined together - technically via electric forces and the "sharing of electrons" in a molecule. A molecule is significant particle in the field of chemistry science. Dalton started his atomic quest after theorizing that gases must be made of tiny moving particles that have mass and kinetic energy so as to put pressure upon the inner surfaces of its container, much like that of an inflated, expanded and (internally) pressurized balloon that is filled with some type of gas. Dalton is usually credited to starting the theory of atoms and their atomic structure, or simply: "atomic theory". Dalton is a contemporary to Avogadro.

The **electron** particle was discovered by **John Joseph Thomson** ("J.J." Thomson , 1856-1940) in the year 1897 when experimenting with a **William Crookes** (1832-1919) cathode ray tube (CRT). **Crookes Tubes**, invented in England in about 1869, were hollow glass shapes containing a vacuum, a metal cathode terminal at one end [used as a source of the mysterious cathode (energy) rays, later to be found as being electrons] and a metal anode electrical terminal at the other end. A high voltage (created using a Ruhmkorff induction coil, somewhat like a transformer) potential difference at each end of the tube is required for the mysterious "rays" to be produced and flow, and with the cathode name being assigned the negative (-) terminal, and the anode being assigned as the positive (+) terminal. A small amount of gas ions in the (near) vacuum assisted the flow of current from the cathode to the anode. The electrons will gain kinetic energy as they are attracted and travel to the positive electric force at the anode, and the stronger the vacuum, the less collisions within the tube as it travels. When the electrons collide with the gas or tube anode (+) end of the glass tube, a glow of light will be produced, and this is due to a "fluorescence" (ie., a visible radiation of light) which is due to the ray energy induced upon or applied to a weak gas, surface and-or element, and then being re-radiated as light from energized ("excited") atoms of that certain element(s). This glow of light indicated that invisible and mysterious (electromagnetic) rays from the electrified cathode to the anode were involved and causing it. A metal plate between the cathode and anode of a Crookes-Tube will block the "ray" beam (electrons) and cast a shadow of that metal plate onto the glass tube at the anode side, and this also verified that the rays were in fact emitted from the cathode end, and a Crookes tube is often called a **cathode ray tube**. A magnetic (magnetic field) could bend and-or direct the electron ray's or "beam" and this showed that ray or beam had some type of magnetic property like a metal. Crookes tubes would eventually lead to the discovery of the vacuum tube electronic amplifier. Years later, an enhanced version of a cathode ray tube would be used as the (output, viewer, image) display, reproduction, simulation ,"picture" or "image" screen of a television (TV) (radio signal) receiver.

In 1897, **Karl Ferdinand Braun** (1850-1918) from Germany, made a version of a Crookes tube and it had a phosphor coated screen which improved the visible effect to more of a (longer in time duration) after-glow or "glow in the dark" effect. Braun is also credited with the fundamental basics of the electronic **oscilloscope** ("oscillation" or wave, electronic signal, "scope" (viewable) or imaging) device where an electron beam could be moved about with a magnet (magnetic field) and-or high voltage (electric field) deflector plates. The movement of the bean across the screen was effectively done by using a (mechanical) moving mirror to reflect the vertical screen image (a glowing dot representing the value or amplitude of the input voltage or signal), and gives the appearance of a horizontal (left to right) movement with respect to time. This device visually displays a fluctuating (changing) voltage waveform shape and its (relative) amplitude (strength, as indicated by the size or height of the displayed wave) with respect to time of the input electronic signal. Later, **Jonathan Zenneck** (1871-1959), from Germany, made significant improvements to the oscilloscope in 1899 so as it be completely electronic (non-mechanical), and therefore having no slow moving parts to severely limit its maximum input and frequency, and it had a corresponding higher (ie., "faster") display (viewing screen) frequency, and it was practical. Zenneck's oscilloscope used more electrostatic focusing of the electron beam, and electro-magnetic control or deflection ("sweep", movement and direction) of it periodically onto, across (ie., horizontally rightward), and up and down (ie., vertically) the CRT viewing screen. Besides having access to a volt, amp, and-or ohm meter, an oscilloscope is one of the most useful instruments for the practice of electronics. An oscilloscope is often used for calibration, optimization, measuring and testing of AC signals and-or circuits. Today, there are several free low frequency (ie., audio range, < 20000 hertz) oscilloscope programs for computers, and of which a soundcard input overload safety probe may also need to be made or acquired, and there is also relatively inexpensive and portable digital oscilloscopes available from many electronics stores and-or websites.

The concepts of Crookes tubes would later play a (scientific knowledge) significant role in the concepts of (thermionic, where a heated cathode is used to release the electrons more easily and at lower necessary supply voltages) vacuum tube diodes (1904) or "(electronic, 2 total (1 input, 1 output) "lead" wires) one-way current flow valves", and 3 lead triode amplifiers, phototube light sensors and photo-multipliers [such as needed for TV cameras], oscilloscopes (first invented in 1897 by **Karl Braun** and who also discovered the **point contact**, "solid state", (galena) crystal **diode**, such as that used for radio use years later so as to hear the audio part of the radio wave received.). It is of note that this was not a lab grown crystal or diode, but more raw and natural, and not as reliable or easy to use. Television (**"TV", CRT - cathode ray tube**) tubes or "(image viewing) screens" are fundamentally based on an oscilloscope's type of beam control and of as mentioned, the oscilloscope is based on a Crookes Tube device. Most ("digital")TV's and computers today as of about the year 2010 have low cost, low power LED diode arrays as their viewing screens, however, the analog oscilloscope is still available and also used for very high frequency signals. Inexpensive oscilloscopes and-or kits are available for lower frequencies such as audio and AM radio signals.

Crookes tubes were also used during the discovery of X-ray [essentially, high frequency and energy, rf (radio frequency), penetrating particles] production as discovered in 1895 by the German professor **Wilhelm Rontgen** (1845 - 1923) after noticing that some of the mysterious, yet unknown (= X) rays (called Rontgen rays) from a Crookes tube were also passing through a thin layer of paper and-or metal near the outside wall of the tube. Today these rays are usually called **X-rays** and are often used in hospitals and dentistry so as to help have a reasonable internal (photographic, light and X-ray sensitive) image of internal things such as bone and metals which are not normally seen. X-ray radiation is created when an electron having a high velocity and kinetic energy, such as created in a Crookes tube, collides with certain materials. To create this high velocity, high kinetic energy electron(s), a high voltage is used. At about the same time, **Nicola Tesla** and others were also investigating X-rays and X-ray imaging (ie., photography). Rontgen noticed that these rays would easily pass through some materials, and also affect a photographic or light sensitive plate material as if it was a type of visible light . In 1895 Rontgen took the first medical X-Ray of his wife's hand, and too this day (year, 2022), X-rays's and-or X-ray imaging are widely used in the practice (ie., use of) and research done in the medical and scientific fields.

In 1953, a special type of X-ray image to study crystals helped discover the helical (twisting) of two main parallel rails and inner connecting rungs (like ladder steps) of the DNA structure that is often described as the "code" or "blueprint" or "instructions" of all life. The field associated with the structure of crystals is called crystallography. The structure is similar to a ladder that has been twisted or spiraled along its lengthwise or long direction. **DNA (DeoxyriboNucleic Acid)**, a special and very long type of molecule tightly packed into every cell, particularly its nucleus or governing part, of the body and is responsible for all the chemical (chemistry) structures and processes in the body, and heredity from both of a persons biological parents. In 1882, the structures called **chromosomes** were discovered by **Walther Flemming** from Germany, and later found by others to be responsible for "traits" or inheritance, and the next question was how is this actually done. The word chromosome means "colorful bodies", as seen through powerful microscopes. When a baby receives the chromosome structures from each parent, these mostly contain a copy of the DNA from each parent. The baby will then actually have a unique or combined DNA that is composed of both of its parents DNA. Each new cell of the growing baby will then need a replica (ie., a copy) of this unique DNA of the baby, and this is accomplished by a process called cell division. The DNA structure or code is composed of using 4 possible (chemical) molecules joined together as one rung or step of the long (many steps) DNA sequence, "chain" or ladder". Because of the preceding facts, certain sequences or lengths of DNA are said to contain the specific genetic data of a particular part or process of an organism or person, and these unique sequences or segments of DNA are therefore called genes. The main researchers to first see the previously proposed fundamental structure of life, now called DNA, were **James Watson**, **Francis Crick** and **Maurice Wilkins**, while in London, England. **Rosalind Franklin,** a chemist with some biologic studies and an expert in X-Ray crystallography study, is credited to actually taking the difficult to obtain, x-ray photograph(s) of DNA (deoxyribonucleic acid, aka "the [fundamental] building block of all life") in 1952 which showed its (atomic) molecular and (double) helical (twisting or spiral) structure. An image of the small object(s) being viewed is accumulated or "built up" by the diffraction of the electrons from the object and then onto a photographic sensitive plate. In more recent times, electrons with a reduced velocity are rather used than x-rays. Nonetheless, as of the year 2024, imaging improvements still need to be made in this field, and of which will yield many new discoveries. What we call DNA today was first noticed as a mysterious substance in the nucleus of a cell in about 1870 by **Johann Friedrich Miescher**, from Switzerland, and he naturally then called it "nuclein". **Albrecht Kossel**, from Germany, found that nuclein is actually an acid and called it **d**eoxyribo**n**ucleic **a**cid (**DNA**), and he identified the five nucleotide basses: Adenine, Cytosine, Guanine, Thymine and Uracil in 1881.

In 1888, **Philipp Lenard** in Germany, previously noticed some of the effects seen by Rontgen. Later, Hertz and Lenard are credited to discovering the photo-electric effect where surfaces, such as a cathode, would emit ("photo-induced") electrons or ions when struck by electro-magnetic radiation such as light and-or a radio waves. This effect can also be verified such as when shining UV light onto initially charged, similar electric force repelled and-or separated plates of an electroscope, and then the plates will get closer together as the charge and-or (similar polarity) electrostatic force gets less and can eventually be depleted. He also notice that the speed or (kinetic) energy of the electrons emitted depended on the wavelength (ie. frequency) of the incident light striking the surface, and not necessarily the intensity of the energy of the light. **Albert Einstein** would later suggest that this is due to that light or photons are composed of individual, discrete "packets" (ie., pulses) of energy, and this lead to the concept called quantum (energy) theory which is basically the study of individual, discrete, packets or steps (levels) associated to energy and matter such as electrons. Photons (ie., light particles) are essentially a form of a mass-less, electromagnetic (ie. "RF" - radio frequency) radio wave energy and vice-versa, that is, radio waves are a form of light, but having a frequency so high or so low that we cannot see it with our natural vision, much like how we cannot hear high frequency audio waves called "ultrasonic" audio frequencies. **Solarcells** function and create energy due to the photo-electric effect. The reverse of the photo-electric effect is the **(Arthur Holly) Compton Effect** (in 1923) where electricity can give energy to and free electrons in a conductor, and the electrons will release that energy as a photon of light. The Compton effect also applies to traveling electrons (rather than photons) that strike a metal and its electrons will release some of their kinetic energy as photons or RF radiation, including x-rays. Charged particles from mostly our nearby Sun cause the colorful (usually green) **aurora** lights near the poles of the Earth as these particles collide with gas atoms and-or molecules high up in the atmosphere, especially above the Earths magnetic pole region, and they become **ionized**, and the energy gained from each is eventually released as a photon of light (much like how Geissler tubes function) when the electron falls back into its steady natural orbit. The realization of this surly came after the discovery of the gas discharge tubes and the resulting electrical discoveries. The aurora lights are also called the ”northern lights” and ”southern lights” and they are a glowing, light green color usually.

Max Planck (1858-1847), from Germany, is credited (for his scientific contributions from 1900 to 1918) to creating the concept of quantum (discrete bits of energy, quanta or particles of a total quantity) theory which is proven by the fact that the energy of a photon (a light "particle") is directly related to the frequency of the light and which also determines the color of the light seen. When an electron gains kinetic energy, it will eventually release that gained energy as a photon (ie., photo, light, radio-frequency (rf), radiation, energy particle). Considering the rainbow or spectrum of colors, a particle or photon of red light has less energy than a photon of violet light. The color of a heated object such as a piece of metal can therefore be used to determine its temperature. When the mass conducts or radiates this energy away, it will reduce in temperature. Since wavelength is equal to the reciprocal of frequency, light or photon energy is therefore inversely related to the wavelength of the light. **Planck's constant (h)**, discovered in 1900 while studying a black-body's emitted radiation, is **h=6.62607015 (10^-34) Joule-seconds.** **j-s** is a unit for the total energy created and-or used during 1 second of time. h = (energy of the photon or light) / (frequency of the photon). Mathematically: (energy of a photon) = (h)(frequency of the photons) with units of Joules. The higher the frequency (pulses or cycles per second) of light or photons having energy, the higher the total amount of energy transmitted per second. This is similar to the concept of **duty cycle** or total percent of "on time" for a pulsed signal with respect to the "off time" of it during a unit of time, say 1 second. Note that just like there can be no real negative distance, there is also no real negative value for photons. Planck's constant is considered as the smallest, discrete ("quantized", "quanta") unit of energy. 1 quanta = h, and it is essentially the energy of 1 photon at the speed of light. The amount of energy of 3 quanta is: E = 3 h = (h)(3) joules. The unis of h are both: j-s and joules per cycle = joules per hertz. The Planck length is considered as like a boundary between known practical science, mechanics and energy, and quantum science where many things are yet unknown.

$d = v\,t\ ,\quad W = c\,t = c / f\ ,\quad f = c / W$: d=distance, v=velocity, c=velocity of light, W=wavelength, f=frequency

$$\text{Planck's constant} = h = \frac{\text{(energy of the photon of light)}}{\text{(frequency of the photon)}} = \frac{Ej}{Fhz} = Ej\left(\frac{1}{(Fhz)}\right) = Ej\,c / W \qquad : W = \text{wavelength},\ c = \text{speed of light}$$

$E = h\,F$ with units of Joules , and $E = h\,c / W$, and $E = mc^2 = h\,f = h\,c / W$: with units of joules

Since (h) is a constant, if the frequency of the light doubles, the energy from that light will double. $P = E/t = J/t$

From distance = (speed)(time) = (speed)$\left(\frac{1}{\text{frequency}}\right)$, and for electromagnetic radiation, speed = speed of light =c and distance traveled = the wavelength = W , we have:

$$W = c\,t = \frac{c}{F} \text{ meters} \quad \text{and} \quad F = \frac{c}{W} \text{ hz} \quad , \quad \text{therefore,} \quad E = h\,F = \frac{h\,c}{W} \text{ Joules}$$

Photo-sensitive conductors are certain elements (such as selenium) or materials that have a change in electric conduction or resistance when light hits their surface. These are also called light-sensors and-or photo-resistors, and the effect is called the photo-conductive or photo-resistive (a resistor that is photo or light sensitive) effect. **Solar cells** produce or create (ie., "generate") a voltage (ie., energy, and the induced or resulting electric current or flow is composed of free, unbound and moving electrons) from light energy striking and transferring some of its energy to the surface of the solar cell. This effect is called the photo-voltaic effect. A solar cell is more sensitive (generates more current and power) to a certain frequency range of light rather than being a pure linear (ie., equally sensitive) light sensor or and ideal electricity generator for any frequency of light.

One famous experiment with light is known as the "double-slit" experiment where a strong light was directed through two close horizontal slits (long thin openings) in a thin piece of material, and then it was shown onto a surface at a short distance away. Two vertical stripes or bands of the light were then seen on the surface as expected, but there was also other bands and gaps (spaces) between them which indicated both constructive (additive, strengthening) and destructive (negating, reducing) type of wave energy strength interference (affecting each other, and resulting in a net total) action going on. This interference pattern is similar to what happens with water or sound waves being in phase (ie., at the same time, and combining their intensity or amplitudes) or out of phase (ie., 180 degrees, completely opposite, out of phase or timing, and resulting in 0 intensity) with each other. This implies electro-magnetic waves such as light have a wave-like property during creation, transmission and reception. This was first noticed in 1801 by **Thomas Young** (1773-1829) from England**.** The results of this experiment and the nature of light are still somewhat controversial and are still debated during this writing in this book at the year 2022. A wave implies a frequency and an amplitude of something that is varying, either an amount of particles and-or energy. Another idea is if the main wave is rather composed of many (discrete) pulses or square waves of energy. Considering all this, a photon of light and-or radio frequency (RF) energy can perhaps be describes as an infinitesimal particle, bit, or quanta, of a RF wave.

In 1927 Clinton Davisson, Lester Germer, and George Paget Thomson (independently) showed that a beam of electrons that was directed to and scattered away (ie., diffraction, reflecting) from a crystal surface would produce a similar intensity pattern as X-rays and other electromagnetic waves, hence the new thought that light could also have some type of similarity to (atomic and discrete, quantized, integer, countable steps) particles such as electrons. This concept is called the **wave-particle duality of light.** A particle of light (technically a radio [rf- radio frequency] or electromagnetic-wave of energy) is called a photon, and is said to be mass-less and a packet of energy. Strong gravity can bend light slightly which indicates that light may have some type of mass, even if just temporary during part of the wave, and-or there is some type of "rf energy diffraction (bending)", much like light diffraction, due to an electromagnetic field about a star, etc. The electron diffraction pattern also gives a magnified view of the crystal structure of the object so as it can be photographed and studied. **Clinton Davisson** (1881-1958), from America, is therefore given some of the credit to the development of the **electron microscope** which can effectively magnify many times (ie., a multiple of) more than even the highest power optical microscopes available, and the resolution is therefore much smaller so as to see (ie. "resolve") smaller objects and details. The electron microscope discovery and creation is rooted in a (1926) theory by the German physicist **Hans Busch** that a magnetic field(s) could be used as an electromagnetic focusing lens for a beam of electrons. Some of the already known concepts of how the oscilloscope worked surely helped this effort. The first basic electron microscope was then created in 1931 by physicist **Ernst Ruska** and **Max Knoll** who was an electrical engineer who helped build it. Electron microscopes are more complicated than optical microscopes, and therefore, they are more expensive, and they usually require special preparation of the object being viewed, but it is still worth it, and even outdated and-or replaced electron microscopes are sill sought after. An electron microscopes does not use penetrating x-rays that pass through the subject and onto an x-ray image sensor, but rather uses electrons to be directed to and then reflect off from the subject and onto an electron image sensor. Electron microscopes use high voltages to create a high static electric field to repel electrons and give them kinetic energy and direct them. So that the electrons do not collide with air and loose their kinetic energy, they are made to through a vacuum that the subject to be magnified and viewed is also in. The resulting images of the subject are also displayed in gray-scale (various shades or intensities of gray [a mix ratio of black and white] color, and which is commonly called black and white images). Because electrons are so small, they can reflect off of the smallest of pieces of matter that optical microscopes can not even "see" or resolve due to their lower magnification, hence electron microscopes are capable of very high resolution. Because electrons are relatively much larger than photon (light and-or e-rays) particles and-or waves, they do not sense and return any color information, and that is why the images produced form an electron microscope are gray-scale images. These images can later be subjectively colorized so as highlight the main points of interest and-or similar items in the image. A complete electron microscope system is expensive, but a business and its personnel specializing in electron microscope imaging can be accessed and "rented" if needed and at a much lower price than buying an electron microscope system and employing its personnel just to have a few images needed. Electron microscopes have constantly been improved since the first one was made, and especially for having better image clarity. It is possible to image atoms with some modern electron microscopes.

Attempts at creating **television** (tele is a word prefix for "remote" or "at a distance", ex. telephone, TV = television = "remote vision", a "transmitted vision or image", electronically sending or transmitting images so as to be viewed at another location) has a long, varied and incredible history of electro-mechanical devices and people such as **Paul Nipkow** (1860-1940), from Germany, who created the Nipkow disk in 1884 that had a spiral array of holes to "scan" (horizontally, and vertically) during a bathing of a subject with bright light, and of which its reflection was then sensed with an electronic photo (ie., light) sensor.

The first electronic imaging (ie., camera) tube for television was called an **iconoscope** (ie., **an image viewer**, electrical device, an electronic camera) and was created by **Vladimir Zworykin** (1888-1982), from Russia, while working with **RCA** (**R**adio **C**orporation of **A**merica) in America. Some of its initial concepts were conceived in about 1923, but it took until about 1931 for it to be demonstrated as fast and practical. In 1929, **Philo Farnsworth** (1906-1971), from the United States of America, is credited to the first completely electronic, demonstrated, fast, non-mechanical television system. He created both an electronic camera or image sensor called an "image dissector (tube)" in 1927, and also the image viewing screen, for a complete and functional electronic TV system. It could be considered that Crookes (ray, electron, "cathode ray", CRT) tubes is where TV (television) and many other modern scientific discoveries such as the electron atomic particle, were initially rooted in, discovered with, and-or based upon. When a thin beam of electrons strike the phosphor coating on the viewing screen, a visible dot will glow due to the energy it absorbed and some is re-radiated as light. The intensity of the electron beam will determine the intensity or brightness of the visible light seen on the viewing screen, and this is the method used to display an (picture) image with a "black and white" (ie., shades of gray, gray scale, not mono-tone single color) television (TV) receiver and-or screen. Scheduled television (TV) broadcasts generally begin in 1928 to the relatively few people and-or business who could afford a (relatively rare) TV receiver, and until the production of TV receivers became relatively affordable for many after WW2 and-or 1945. Color television cameras and receivers began to be manufactured by RCA (Radio Corporation of America) in 1953, and it took until after 1965 for the large and popular TV transmitting stations to mainly transmit color TV signals, however, the less expensive "black and white" TV's could still view these signals as "black and white" (ie., greyscale) images.

It could be said that both Farnsworth and Zworykin independently share the majority of credits to the initial invention of the first practical electronic television system. The people and companies involved in the development of the first practical electronic TV system occasionally filed suit against each other. The **iconoscope** was eventually favored as being more practical than the dissector tube. The dissector tube was (independently) proposed as early as 1925 in Germany. Farnsworth also invented the "**electron multiplier**" during his TV research. With this vacuum tube device, each incoming electron can strike a charged plate that had a high voltage potential applied to it, and therefore having a high electrostatic force upon the incoming electron(s) and causing them to accelerate with more kinetic energy, and this will cause a few other (hence multiple) electrons to be emitted from that plate when it collides with it. These plates are usually placed at angles and in a series arrangement so as each electron, perhaps nearly undetectable or impractical to, can be easily sensed when there is many (ie., a multiple, "amplified") of them for each single and initial instance. Some devices which use an electron multiplier are some spectrometers which can determine what element(s) a substance is by the light and-or wavelengths emitted form it, and the electron multiplier has found use in some night-vision (low light ,sensitive) cameras.

A **movie** (ie., moving or motion pictures) is a recorded series of consecutive ("still") images or pictures of a subject with either the subject and-or camera in motion (ie., moving about). A good quality movie recording process will record enough needed images, pictures, "stills" or "frames" per second so as to have a seemingly continuous viewed subject having natural motion, and without any apparent "missing image gaps" or chronological distortion. A movie recording when viewed or "played back" should also appear as consecutive images having a nearly or seemingly smooth, unbroken, natural looking motion or sequence of the subject that was recorded or "filmed" (ie., onto photographic or light sensiteve recording film media, often formed into "reels" ie., a roll of recording film media, containing many consecutive individual photos or "stills"], but modernly as digital or electronically recorded, stored and viewed images). The movie concept most likely got inspired from what is known as a "**flip book**" which is a consecutive series of stacked drawings or photographs so as to effectively show objects having a reasonable, natural motion and time used, and it was only a matter of time until the technology allowed movies to be made and played back for viewing in a practical and pleasing manner, and for wide distribution for many uses. Before practical television (TV) was invented and-or (TV) video recorders, many of the first TV transmissions were that of per-recorded movies shown on a screen for the TV camera and radio transmitter to view and then broadcast to many, and often repeatedly as needed, such as once a day, or once a month, etc., and relatively inexpensively much like radio broadcasting with per-recorded audio.

Like "motion pictures" or movie technology that was made practical by Thomas Edison, TV technology also uses a minimum (ex., often 15, 30 or 60 frames) number of images, "pictures", "stills", or "frames" to be recorded and viewed so as to appear as being continuous and real. Movies are recorded onto a (photographic, light sensitive) film and are (re-) viewed on a viewing screen by projecting the images onto it with a light passing through the film images and onto the viewing screen. This frame rate was first done in order to reduce the amount or length of costly photographic film, but still be fast (frames per second) enough to record and view moving image as continuous, unbroken movement due to a concept called "persistence of vision" where we essentially can not perceive the slight "gap" (omission of any images) between each frame and-or perceived motion. Having a relatively low number of frames per second also effectively reduces the (fast, high-speed) electronic frequencies (cps, hertz) needed for a television system with electronic image camera, image recording, image transmission and image viewer (TV, screen). Each frame or image displayed on the TV viewing screen is essentially quickly built and-or displayed using many vertical rows from the top of the screen to the bottom that are each composed of many horizontal dots or picture elements ("pixels") side by side. This all happens very fast so as to produce 60 complete images or frames shown on the viewing screen each second. 15 frames per second = 15 fps is acceptable for when the subject is not moving much, after all, consider a picture on a wall that is not moving, and this would be like a TV system having just 1 frame per second to viewed subjects that are not moving much.

How long does a reel of 35mm (in width) movie film have to be for a movie that is 1 hour = 3600 seconds in time length or duration? If each movie frame or still was 24mm high, and its dividing border space or gap was 2mm from one frame to the next, the total frame height or length is 26mm, and if there were 30 frames per second, the answer is:

movie film reel length = (total number of frames) (total length of each frame) =
movie film reel length = ((frames / second)(seconds)) (each frame length) =
movie film reel length = (30 frames / second) (3600 seconds) (26mm / frame) = 2808000mm = 2808 meters = 2.808 km

Long movies were usually divided into several film reels to be practical, and with each real being perhaps 20 minutes in duration.

(movie frame and-or viewing) Aspect Ratio = (frame width) / (frame length) , Ex. 35 mm / 24 mm =~ 1.4

People tend to see things more horizontally than vertically, mainly due to their eyes being horizontally side by side, and that is why each frame is wider in the horizontal direction. Television displays also have an aspect ratio > 1.

Popular film width sizes: 8mm : The film and the camera were relatively inexpensive for "home quality" movies, and relatively inexpensive to process into the positive image from the negative image. These reels of film could allow a few minutes of image recording, and of which could be done in various and short time segments of interest. The cameras for 8mm film were relatively small, lightweight and inexpensive. The projector machine, that projects the film image onto a distant viewing screen were also relatively inexpensive, but still costing several times more than the camera. There is also inexpensive hand operated mechanical viewers that project the film onto a small nearby viewing screen of several square inches. 8mm movies were usually silent, but if someone had a tape recorder available, then some movie sound was possible, and if it could be synced (synchronized, meaning at the same time) or timed correctly with the movie.

16mm : For reasonable quality movies , somewhat inexpensive, but lesser quality than 35mm.

35mm : A common size for most film movies made to be of high quality. The professional movie studios often used 35mm film, and made color movies at a time even when TV was still black and white. Even when color video tape was available to record, such as for television, many movies for the movie viewing theaters were still made using 35mm film. These movies could then be rerecorded or converted for television.

> 35mm : Before electronic or digital photography, 35mm film, still image cameras were the most popular type of camera. "Studio, professional quality", "portrait film" and-or older "plate or large format" photographs used negatives that were large, perhaps 4" =~ 10cm for each dimension. Compare this to a modern (2022) "smart phone's" digital camera with an image sensor that is perhaps 2mm x 2mm and produces good quality, inexpensive images consisting of many pixels - actually several mega-pixels or millions of pixels for high image resolution, detail or precision.

Television signals can be stored on magnetic ("reel") tape recorders and were developed in the early 1950's by the **Ampex Co,**, and this made it possible to store (record, save) electronic images from an electronic ("TV") camera, and later broadcast (transmit to a wide area and-or population) and-or rebroadcast the recorded images as a common TV radio-wave or electro-magnetic signal. Metal wire, initially for crude and-or voice recordings only, and then magnetic tape for high-quality audio recording were already available by then since the 1930's. TV signals can be transmitted through the air like a radio-signal, and-or through direct wire connections such as for "cable TV". This direct connection usually results in a received TV signal with much less electronic and atmospheric noise in it, therefore producing a more pleasant viewing image and-or experience for the audience. For business use, thinner (1 in or 2 in) width tapes were available since about 1960, and for home use, even thinner width tapes were available in protective cartridges by about 1970 and these were essentially two reels, side by side in an easy to handle and use flat-like plastic box. Today many of us take these technologies for granted as part of everyday life.

With all the new technology becoming available in the 1950's and 1960's after the invention of various transistor devices, it was only a matter of time until first portable, consumer **digital camera** was created. A digital camera does not store picture data (ie., elements, pixels) onto light sensitive film which changes its shade or color depending on the amount and-or frequency of light striking it, but rather uses an array of many very small individual light (photon, "pixel") sensors and "color filters" (here, [Brice] Bayer filters), and then stores that light information or data from the sensors as binary numbers in electronic memory - perhaps 8 memory bits or 1 byte (0d to 255d) for each RGB color. This invention then lead to the digital movie camera. By 1972, some satellites, such as the (NASA) Landsat 1 launched in 1972, which could sense multi-frequency [infra-red (ie., heat, temperature), green, red] bands, so as to create decent resolution (~ 75 feet / pixel, on average) images such as of Earth's natural and agricultural resources on the surface. To sense and record the images, a scanning mirror and light sensor system, rather than a high count image sensor array that were available later. This imaging system was managed and developed by **Virginia Norwood** and some others - many working for the Hughes Aircraft Co. in the USA which researched and manufactured much technology. The small number of light sensors used and their data could then be used to build, transmit and eventually print a much larger image at a radio communication receiving stations on the Earth. Norwood also worked on the 1966, Surveyor 1, Moon lander's communication system. Her knowledge of both math and science surely helped her and others later so as to make many discoveries and products.

With modern digital and computer technology, analog audio, movies and video (ie., visual ,TV) tapes can and should be converted to a digital form for extended storage, safety backups, and-or for proper distribution. They can also be digitally edited and-or enhanced if needed. There are people and-or services who specialize in these types of conversion and-or enhancement processes, and it is well worth the cost for preserving precious and-or valuable memories and-or data.

To view digital images, they can be printed and-or viewed on an electronic digital image viewing screen (ie., a monitor and-or TV screen). It is possible to view digital images on a analog TV screen or monitor if the digital data or images is first converted to the input signal needed for those devices, such as a TV radio signal. Many pre-1990 computers, such as the VIC-20, **Commodore 64**, Amiga, and video-game systems, such as the Atari and Sega products, and with their internal digital (ie., binary data) electronics, often used a commonly available, standard TV receiver as the output display. It is an interesting note that some Sega products could connect to the relatively new internet, often freely. Before low cost digital storage or memory, relatively low cost magnetic (tape, disk) storage was rather used to store digital data, and you can research the KCS Standard which was one of the digital to analog conversion schemes or methods to do so, and which is also similar the SSTV (**S**low **S**can **TV**, picture, image) method that some hobbyists, amateur radio communicators, and some older weather satellites still transmit and can then be received by a radio tuned to the proper frequency, and then processed by a computer so as to create an image on a computer screen.

By 1975, reasonable images sensor arrays began to be available to the general public and utilized for image creation and recording (storage of information, data). The most common images sensor arrays are the **CCD** (charged-coupled device, invented in 1969 by Bell Labs with **Willard Boyle** and **George Smith** while creating electronic memory for storing binary [ie., "digital"] data) image sensor which essentially uses the capacitance of each tiny metal-oxide semiconductor (MOS) capacitors placed in an array configuration so as to sense (ie., a photo-sensor) and store the amount of light striking each one as an accumulated amount of created electric charge, and due to the photo-electric effect where the kinetic energy of a photon of light can create a free electron - hence more electric charge. The coupled concept is a description of transferring charge from one capacitor to the next. The amount of light in each capacitor is a true analog value, and this value will be converted to a representative and approximated binary value, say from 0 (ex., for black) to 255 (ex., for white) such as for 1 byte of data per pixel of the image sensor. Values between 0 and 255 would represent a gray tone or shades of the image, essentially the light intensity of. For creating the first color sensing camera, color filters would be used later. Various other image sensors have been developed since then: NMOS in 1985, and CMOS in 1993. CMOS is similar to CCD, however **CMOS** (Complementary-MOS) in an array (ie., a horizontal and vertical "grid" arrangement or placement), and uses more active electronics such as better amplification of each photo-sensor or pixel's signal. The first (semi-practical, crude) portable digital camera for potential public use was demonstrated in 1975 by **Steven Sasson** while working for the Eastman Kodak Co. which is well known in the film and camera industry, and making the camera relatively inexpensive and very practical with its Kodak Film and-or cameras. This camera stored digital images as binary (ie., digital) data on a magnetic, floppy disk. Since the CCD concept was realized, several companies have made significant contributions to digital imaging, and by 1983 video (ie., electronically stored movie, no film) recorders using CCD image sensors were becoming relatively affordable and were made by the Sony Co. in Japan. The data from these video cameras was stored onto magnetic tape rather than onto expensive movie film which stores an actual image. Magnetic tapes are relatively inexpensive and can be reused by directly recording over the previous information.

The **first completely digital camera** for commercial sales was made in 1988 by the **Fujifilm Co.** in Japan, and which stored the digital data of each image on a digital (ie., non mechanical, electronic only) memory device. By about 2010, many mobile telephones were low cost and included a decent quality and resolution digital camera, and these phones could also access the internet system ("WEB") so as the user could transfer the images and-or a movie to another phone and user. Modern phones also offer text-messaging which is very handy for deaf people and-or for people who can not immediately answer a ringing phone, and would rather read any text messages when they are more able to do so. As of about 2020, short duration audio recordings can also be easily included in some of the more advanced text messaging systems, and this also helps those who would rather not type much and-or have the time needed so as to enter a typed in text message.

Before arrays of tiny photo-sensors were created for imaging, the most basic image (such as a photo, or page of printed text) scanners rather used a single photo-diode for the image sensor and moved it horizontally across the page and gathered (ie., "sampled", "took", "scanned") and stored a single line of image data. The higher the number of samples taken, the higher the number of data values, and the higher the resolution of the image. The sensor or paper was then slightly adjusted to be a short distance away so as the next horizontal line of data could then be taken. When these lines of data were printed one after the other onto paper, the result was a created or representative image of the source image.

High Voltage And Gas Filled Glass Tubes

The first light to be deliberately or artificially produced by man, besides light from a fire, was probably produced from the friction of two fast moving dry sticks (wood from trees, having a high carbon element and low moisture content) producing red glowing embers and-or (yellow colored) fire (hot gas particles), and sometimes as visible bright sparks created by two rocks colliding. Later, candles were created that used oils and waxes as the fuel, and they produced a soft yellow-white light. A few thousand years later, man began tinkering with the mysteries of electricity - first with various methods of friction induced static electricity and charges, and sometimes producing both visible "sparks" (quick pulses of light) and-or felt as (electric) shocks. With the invention of the electric battery which can accumulate (slowly increased its stored amount) electric charge, particularly electrons, it was noticed that a bright spark of light could be produced that was very similar to that of lightning from the sky, and then realizing that lightning must also be due to the same cause, that is, lighting must be electric in nature, and contains electric charges. Lightning can be considered as a big, long and powerful electric spark. People noticed that with a higher battery voltage (ie., electromotive force or energy, emf) applied, a longer spark could be created across a greater distance, and surely lightning between the ground and clouds must be due to a very high voltage. But what was producing the actual spark of light? If the air was taken away, would a spark still be seen? It was found out later that no spark would be produced or seen when air is not present such as in a glass vacuum tube, but still, the electricity or current would still flow unseen through a vacuum if the voltage or electric field strength was high enough for it to happen. With air or some other gas, and applying a voltage that was high enough to overcome the internal resistance of the gas between the two electrodes or terminals, a glowing (faint light) gas could be created, and such as seen in the Geissler Tubes which are discussed next. Surely, electricity was doing something to the air or other gas so as to cause it to give off or radiate some light. It was discovered later that when an electron gains kinetic (ie., motion, speed) energy, such as due to a nearby electromotive (electricity causing motion) or electric force (ie,, in a nearby region or "field" of influence) caused by other charges (charged particles with their electric force), it can then release that gained energy as electromagnetic energy (such as light) when it collides with another particle and-or settles (ie., "grounds") into an orbit about an atom and electrically neutralizes that atoms net electric charge from being positive. The electron releases its gained or excess kinetic energy as light or radio frequency (rf) energy, but it could also include heat or thermal energy. For an analogy, consider how when a weight is dropped and it eventually looses its kinetic energy when it lands or "grounds" itself, but its gained energy (potential energy, or potential ability energy, from working and lifting it to a certain height and storing that energy in its location, and this is somewhat similar to how an expanded spring stores potential energy due to its configuration]) is transferred elsewhere such as radiated sound energy, and friction and heat, etc. during the impact.

Crookes tubes are based upon the glowing novelty (curiosity, fascination and amusement), neon-like gas tubes previously invented in 1857 by **Heinrich Geissler** (1814-1879) from Germany. These tubes (see [FIG 234] for some very basic drawings of some electronic devices), and its operating principle are sometimes called "gas discharge" tubes or lamps, which basically means an electrically charged gas lamp that emits light. Geissler tubes could also be used to detect a high voltage nearby and-or connected to one or two of its protruding leads (leading into and-or out of the device), electrodes or terminal wires. At both ends of the sealed glass tube, a high voltage was externally applied (ie., connected) to the internal metal electrodes placed within a low pressure gas that could be **ionized** (produce free electrons that broke away from their atomic (force) bond with the atom) by the applied voltage electric field and create many movable charges (electrons from the negative cathode moving towrd the positive anode, and the created positive ions moving tord the cathode) so as to help the conduction of current and-or through it. The excited (energized, higher energy) electrons created would eventually recombine with positive ions and produce a glowing fluorescent (ie., an absorbed and readmitted or secondary light radiation, but has less energy, hence a lower frequency in terms of color and-or intensity) light of a specific color that was determined by the specific type of gas, such as neon, used in the tube. As a side note to these man-made things, some creatures, such as some bugs and some fish, in nature can also produce light such as in what is called as bio-luminescence, such as (flying) lightning-bugs that can radiate some intermittent light and can be seen from a distance of up to about 100 feet away during the night.

To create a high voltages, such as for Crooks tubes, the previously invented (mostly for novelty and curiosity) friction (or "triboelectric") machines for creating (ie., separating) and-or storing a large amount of electric charges were used such as a **Wimshurst machine.** This is a hand powered rotating disk with several radial positioned conductors, and was a (kinetic) friction device to give (ie., transfer) energy to and create free electrons.. This machine, was actually invented about 80 years after Volta made his Voltaic or galvanic pile, and is based on the concepts of making electricity or charge with things like amber, etc. via hand powered rubbing or friction, and generally without any electricity or charge storage being considered. This machine was created in about 1880 by **James Wimshurst** (1832-1903) from England, and is a high voltage static electricity generator that accumulated (positive and negative) charges on two metal surfaces (usually metal balls) separated a short distance away from each other so as to observe a visible spark when the voltage created was high enough to overcome the resistance of the air between the positive and negative terminals, and therefore achieve the "breakdown voltage" needed to pass the charge through that air. A visible spark (like a miniature lightning bolt) is usually a temporary (short time duration) electrically produced light due to high voltage excited air ions or particles. As indicated previously, when an electron "lands", or "grounds" itself after falling into orbit about an ionized (missing an electron) atom, the electron releases its gained excess kinetic energy as [electromagnetic] light energy. For air to conduct electricity, the air and its natural resistance needs to "breaks down" by applying a very high voltage (or voltage potential difference) to it and it then becomes more conductive with ions and electrons, and particularly so when the charges are flowing though an effective low resistance region of air. Note that for a spark to occur, a high voltage is necessary, and by Ohm's law, a high voltage or potential difference will cause a high current and power, but here, the discharge of current and the resulting light created is very brief in time, and essentially a brief, high power (E/s = J/s) light pulse was created.

Before the Wimshurst machine was invented, there were several previous studies and inventions by others on the topic of generating static electricity or "charges". First, the fascination and study with amber and its attraction and repulsion (now known as due to the two types of electric charges - positive and negative) effects are about two to three thousand years old. Later, things such as a hand ball of (hand powered) rotating sulfur could be used to obtain a more consistent and practical electric charge. In 1831, and knowing that a wire and magnet moving perpendicular to each other could induce or create a voltage and current in a wire, **Michael Faraday** invented a hand powered electrical charge generator called a Faraday Disk or Faraday Wheel that used a fixed in position, rotating disk of metal such as copper that rotates in the magnetic field of a nearby permanent magnet, and it produced a relatively low voltage, but substantial DC current of electrical charge (ie., electrons) could be created due to the low resistance of the disk. This device would later inspire other devices that created (ie., generated) either static electricity, electric current, and motors. In 1865 **Wilhelm Holtz,** from Germany, invented an electrostatic machine that he called the Holtz electrostatic induction generator, and this also used a rotating disk. Rather than using a magnet like Faraday did, the Holtz machine used friction upon a non-metalic disk. Many other people soon made improvements to this device and its electrical working concepts, including James Wimshurst. for his electrostatic generator, and later, the **Van de Graff generator** created in 1929 by **Robert Van de Graff** from America, and which used an electric motor to move a friction belt, rather than using a hand turned ("cranked") disk machine. The Van de Graff generator could create a very low current, but very high voltages in the millions of volts of which could then be used for atomic particle research such as for experiments with electric charges and-or electrons. The spark seen and heat of the air created is very brief in time, and its energy and-or power does not exceed that which created it.

It is of note that a spark can not be created in a vacuum (ie., lack of air or other gas), and this indicates that the electricity is somehow affecting the medium (ex. a gas, such as air) in the vacuum. Today, we know that when an energized free (from the nucleus attractive, positive force) electron which has gained (kinetic) energy will eventually fall back into an orbit about the nucleus, it will release that gained energy as electro-magnetic energy, and for this example it will be light and other (invisible) RF energy.

The construction of the **barometer** ("weight meter") to measure air pressure is somewhat similar to, and has a construction much like the temperature gauge created by **Galileo** that used a glass tube placed vertically in a pool of water, and the height of the water in the tube would rise or fall in a direct relationship to the temperature. The modern form of a barometer was developed by **Evangelista Torrricelli** in 1643 and used (dense, heavy) the height of a thin column of mercury instead of water as the air pressure indicator, and this also allows a barometer device to be much smaller and more practical. There is a device to dispense drinking water into a container for animals, such as for cats and dogs, that uses the same principles as these types of barometers, and its amazing to see how an amount of water can be suspended higher in the sealed container than that of the lower water level in an open container or pool at the ground level, and without falling downward or flowing out due to its significant weight. During a storm of rain, the local (ie., nearby location) air pressure can also drop (ie., decline, reduce, decrease) in value due to an increase in the air temperature creating less dense, higher pressure air, and more dense, cooler air will try to move toward and into. Today, we know that mercury is considered as a toxic substance and should be avoided, and therefore, it has become difficult to purchase without good cause and legal permission.

Not too long after the invention of the barometer to measure air pressure was invented, **Jean-Felix Picard**, (1620-1682), from France, noticed in 1675 that there would sometimes be a visible "glow" (ie., like a fog [fine water mist, drops] illuminated by a candle) of light in the (near, almost) vacuum region in the top of the glass tube of the barometer when the mercury in it was agitated (ie., shook, stirred), and then by touching the glass with some static electricity which has a relatively high voltage value of a few hundred volts. This was the first publicly known instance of what would later be called a **gas discharge tube, bulb or lamp**. A modern example of a gas discharge tube or bulb is a neon ("indicator" and-or "night-light") lamp which is usually a dim, orange colored light. Electric charges were exciting the trace of mercury vapor ions in the top of that tube, and electrons settling into an orbit around atoms would release their excess, gained energy as some visible light This simple and accidental discovery, curiosity and novelty would eventually inspire and lead all the way to the inventions of arc-lamp, Geissler Tubes, Crookes Tubes, and later, vacuum tube amplifiers several hundred years later and which inspired modern electronics, This discovery was therefore a very significant and important discovery, much like how Edison discovered the (electronic) diode action in a light bulb experiment and didn't have much use of it at that time, but it did lead to the vacuum tube amplifier years later. Picard also created many more advanced devices so as to obtain more precise (ie., precision, more accurate, "finer", greater resolution) measurements for astronomy and various geometries (or "geodesy") of the Earth, land features, and map making (cartography), and these were also the forerunners of the more modern devices which have slightly better accuracy. He worked with other scientists and astronomers who made several important geological and astronomical measurements. Picard is credited to a calculating a newer and more precise value of Earth's radius.

Otto Von Guericke (1602-1686) from Germany invent the first practical **vacuum pump** in 1650, and this allowed experiments and devices that needed a substance-less volume or space, which is called a vacuum (vacated, evacuated, empty) region, and so as to produce a high quality experiment results, and to be practical. This pump consisted of a piston (much like a rod and-or "plunger") inside a cylinder (here, a rigid or solid tube shape) and having one-way directional openings or "valves" controlling the flow (input and-or output) of air so that it is removed from the vacuum region being created when the plunger is pulled outward, and then discarded into the air when the plunger is pushed inward. This pump could make high quality vacuums in rigid (ie., strong, non-flexible) containers. He then discovered that when the air (a gas) is removed from a container, that its internal pressure is also removed, and then the outside air pressure will still exert a great force (14.7psi) everywhere upon the surface of that container, and directing it to the much lower pressure region inside, and it therefore tries to compress (ie., "squash") it and may collapse it. This fact also makes it more difficult to separate the parts of some containers of which a vacuum is within. Guericke also made an electric charge generator out of an iron rod which held a rotating sulfur sphere of which friction was applied, and so as to give that sphere some charge which could then attract or repel nearby small objects like amber would.

In 1705, **Francis Hauksbee** (1660-1713) from England, and who was Isaac Newton's assistant, would use a vacuum pump to do some electric experiments. He made a hand powered rotating glass sphere like Guericke, but one that had a vacuum and with a trace (very small amount of mass) of mercury gas vapor or atoms in it. Guericke would see a visible **glow** when it was agitated, and particularly, when the surface of the rotating sphere was touched, creating some static electricity charge and forces, and-or touched by another (statically) charged object, and this is very similar to that of the historical, barometer glow effect discovered in 1675 by **Jean-Felix Picard**, and which was mentioned previously in this book. These discoveries and technologies would later lead to **Geissler tubes** in 1857 that also created a gas discharge or glow when a high voltage and low current is passed through a trace of gas in a vacuum, rather than using (high voltage) static electricity to excite or energize the gas. Hauksbee's glowing sphere would later lead to the invention of electric **fluorescent tube lamps** ("lights"), where much of the invisible radiated (UV light) energy from the glowing mercury gas is converted to a visible (or "fluoresced") white light by using a thin, phosphorous (a natural element), paint-like coating on the inside of the glass tube. The phosphor powder essentially absorbs the UV light energy and converts it to re-radiated visible light which is also lower in frequency and longer in wavelength than UV light.

In 1729, **Steven Gray** (1866-1733), from England, found and demonstrated that static electricity (ie., static = non-moving, stored charge) can essentially move or "flow" from point to point along a (static) electricity (ie., electric) conductor such as various types of materials including cloth, rope, and metals and to then attract or repel other lite-weight objects near the end of a length it. Gray's work is also based on some of the work of his friend **John Desaguilers** (1683-1744), from England, study of electricity, and who made the words "insulator" and conductor". What Gray also discovered is the first form of distant or remote communication using electricity, and before the much longer distance, (non-static, but current flow operation) single-wire, electric telegraph communication system developed over 100 years later in **1837** by **Samuel Morse**, and of which was just a few years after the invention of the electronic buzzer in 1831. Volta's electric battery (1799/1800) and Morse's code system made this form and method of (long distance) communication both possible and practical enough to be placed in many cities, and for fast and inexpensive communication, and therefore having much social value. In 1816, **Francis Ronalds** (1788-1873), from England, made an early form of a (static electricity) telegraph, and being 8 miles long, and proposed it could be used for long distance communication. In 1845 Ronalds invented the first instance of time delayed photography for recording the data and-or measurements from scientific instruments, and this was essentially an early and crude form of a movie, although not so continuous as a real movie such as by Edison, having a continuous appearance of motion. **Carl Gauss** and **Wilhelm Weber**, both from Germany, tested a simple telegraph system for nearly a distance of two miles, and in 1833 - just a few years before the more practical Morse telegraph system. Their system used a galvanometer as the receiver and-or indicator. It could be said now that having a battery and a wire, that it was only a matter of time since Volta's battery until electricity was used for practical communication.

In 1831, **Joseph Henry**, (1797-1878), from the United States of America, while experimenting with electro-magnets (essentially a coil of wire with electric current flowing through it - often called a solenoid, while wrapped around a piece of iron). he invented the **electronic relay** (ie., an electrically controlled switch where a low current can switch on a higher current, and-or isolate current in two independent circuits from interfering with each other). In a relay, the magnetic field from the activated solenoid will attract a (springed) moveable conductor to make contact with another fixed metal conductor, and thereby completing an external electrical circuit. A technologically similar related device he created was the **electronic buzzer** or sounder, and is modernly known as an "(electric) doorbell", signal and-or sound alerter or sounder. This device is an electro-mechanical oscillator. In 1850, the telegraph sounder for the telegraph system was one of the first practical uses for an electro-magnet.

The relay was later was used by others, such as for a version called a Telephone Sounder (ie., a electro-mechanical device to make a sound) that was invented by **Alfred Vail** in 1850 for the electric telegraph system created by **Samuel Morse**. Essentially, this device is a telegraph receiver, and is much like the opposite of a telegraph sender that has a user operated (input or signal) switch called a "(telegraph) key" to send a pulse of current (and-or information) to the distant receiver. The current in the telegraph wire would pass through an electromagnet in the receiver and temporarily cause a piece of metal on a pivot to be attracted to the electromagnet, and then that metal will gain energy and move and produce a sound when it struck another piece of nearby (fixed in position) metal. A buzzer or bell also includes this principle, but the moving piece of metal also opens the electric circuit and stops the current, and so as to essentially reset itself (sometimes with the assistance of a spring or gravity) so as to make another possible pulse of sound. An electro-mechanical buzzer is essentially the first electro-mechanical oscillator. If the moving piece of metal would strike a tuning fork or bell, it can produce a pleasing tone, such as used for a doorbell. **Joseph Henry** also invented the concept of self inductance when two coils are in series and being near each other, so as to magnetically affect and induce each other. Some electronic oscillators (with triode-tube or transistor amplifiers) use a self inductance or "tapped" coil so as to obtain and reuse a small amount of the output power by sending it back into the input of the oscillator so as to keep it functioning without any other input or starting signal needed.

Another device, besides the Wimshurst machine, that can create high voltages is a **Ruhmkorff Coil** which is basically a pulsed operated (input, first, primary) coil of wire that will apply its current created high magnetic field through the many more turns (of wire) of a nearby secondary (output) coil. Since the secondary coil has many more turns of wire, and therefore, a higher voltage is induced or generated in it. The ratio of the ("magnetically [energy] coupled") number of turns in each coil will determine the increase or gain factor of the input voltage. Since the output energy or power (energy/time) cannot be greater than the input energy or power, the maximum current available will decrease (ie., demagnified, be divided) by the same factor as that of the voltage gain or increase. This decrease in current occurs naturally due to that thinner wires have a higher resistance and therefore do not pass as much current. Power = (voltage)(current). It is also possible to use many low voltage single voltaic cells connected in series so as to have a high total available voltage being equal to the sum of their individual voltages. A Ruhmkorff coil can produce a high voltage to power a (glowing) Crookes tube. After the necessary initial "breakdown" or "arcing" voltage is applied to a Crookes tube, it will begin to conduct current, and thereafter, the applied voltage can actually be reduced so as to reduce the current flowing through it and so as to prevent damage to it and to reduce wasted power. The Ruhmkorff coil was invented in 1857 by **Heinrich Ruhmkorff** (1803-1877), initially from Germany, and later, England. This device is essentially the first practical or useful low input voltage, DC (steady or direct current) to high voltage pulsed DC transformer and-or oscillator. The output is actually a form of "half-wave" or one-direction AC, that is, the voltages rises and falls like AC does, but is much faster at reaching the peak or maximum value. With this device or **transformer**, a few thousands volts can easily be produced and this is very similar to how an automobile's (car's) high voltage spark is created so as to ignite the compressed gas mist inside the engine cylinders (ie., compression and combustion cylinder tubes or containers made of metal) which causes it to **combust** and release its stored energy in a brief, but powerful (joules/second) high energy pulse, and this eventually applies mechanical rotating power to the wheel(s) of that automobile so that it can move forward.   Though a one-cylinder, one-piston engine is possible, such as for a small remote controlled airplane, most automobile engines have 4 to 8 pistons so as to reduce mechanical vibrations by firing each piston one after the other in a repeated succession. This also effectively applies more (ie., a multiple of) power to the wheels over an instance of time, and improves cooling and system efficiency. Multiple cylinders will also reduce the frequency of combustion in each cylinder, and by the number of cylinders used, and this will provide a greater longevity of use for each cylinder. Larger cylinders and pistons are used in the combustion engines for very high power devices such as large truck vehicles and ships.

Ruhmkorff based his high voltage transformer on the first known induction coil or transformer created which was made by **Nicholas Callan**, a priest in Ireland in 1836. and which also produced a very high voltage from a low input DC voltage battery. Callan was influenced by Michael Faraday's discoveries. These coils produced a high voltage and spark across a short distance called a "spark-gap", and would later be used by others to study and transmit radio waves, and even be used to produce the high voltages necessary to produce X-rays for hospitals and dentists. Callan's interest in electricity was inspired by **William Sturgeon** (1783-1850), from England, who invented the first electromagnet in 1824 which was made from an insulated coil of wire wrapped around a piece of iron, and then connecting the ends of the coil to a battery so as to have electric current flow through the windings ("turns" or "loops") of the coil so as to produce an electromagnetic field about it. The more turns of wire or loops in the coil, the greater the accumulated magnetic field. The accumulated sum of the magnetic field of the complete coil is due to the (smaller) magnetic field of each length segment of 1 turn of wire in that coil. The turns essentially concentrates the magnetic field of the entire length of a long wire into a smaller and practical volume. The intensity or strength of the magnetic field produced is directly related to the number of turns of the coil and the current through it. A longer length of total wire to make a coil, the greater its resistance, and the less current through it given a certain voltage.   Increasing the diameter of wire can reduce the total resistance of that coil given the same number of turns, however the volume or size of that coil is now larger.   Thicker wire is also more costly. Due to all these parameters of a coil, and a desired magnetic field strength, a practical trade-off or compromise needs to be found and-or calculated.

The Electric Motor

Sturgeon also made the first practical electric motor. This motor did not rely on electrostatic forces of attraction as previous electric motors did, but rather relies on the magnetic forces of attraction, and could therefore produce much more movement and-or torque so as to do and-or move things. In general for a give amount of power (P = VI) input to a motor, a higher torque or rotational force motor requires a higher current so as to create a stronger magnetic field and its resulting force to create (rotational) motion of the rotor (ie., rotational axis and-or body structure) in that motor.

Note that an electromagnet does not actually need an iron core, but the iron or steel core improves its performance since the magnetism does not have to travel through the air which does not pass magnetic fields as easy as the metallic iron. Air is then like a resistance to magnetism, and iron is a conductor of magnetism. Some common examples that use an electromagnet is in an electro-mechanical buzzer or sounder, audio speakers, a crane to pick up scrap iron metal pieces, and a relay that is essentially an electro-mechanical switch. Note that although a DC electric current can cause and keep a steady valued magnetic field about an electromagnet, a DC electric current cannot be used with transformers when there is a need to transfer an AC signal from the input coil to the output coil, and this is because the input current must also be AC or changing in value and not DC which has a steady, unchanging value of current and this will not induce any voltage and current in the output coil. In short, besides for a brief, temporary or quick magnetic pulse during current "inrush" or application creating the magnetic field pulse or rise, a steady magnetic field strength of any value does not induce a voltage or electric current, but it is rather a changing magnetic field strength that does.

To help understand how a common electric motor (ie., electrically powered) works, consider two magnets on a flat surface with the same magnetic poles or magnetic polarity facing each other. If magnet (1) is pushed closer to the other magnet (2), magnet (2) will be repelled by the magnetic force from magnet (1), and then it will move away from that magnet (1). This is an example of a linear or non-rotating motor (such as a solenoid) and its motion. In a rotating motor, magnet (2) would be affixed to a rotating shaft called the rotor which rotates. Magnet (2) would then move in a circular direction or motion rather than in a linear (line-like, straight) motion. Here, one or both magnets may be electro-magnets rather than "permanent magnets" (non-electric, no current needed) made of iron metal and-or ceramic material.
Michael Faraday (1791-1867), from England, and who first discovered in 1831 that even a single wire with electricity (ie., electrons, current flow) going through it would produce a magnetic field around it, and after noticing that it would make a compass pointer (as a magnetic field and direction sensor) change direction. The more current, the greater the magnetic field produced and the greater the compass pointer deflection - hence the compass become a current sensor and meter. When pulsing current through this wire, Faraday noticed that another nearby wire circuit would then also have a pulse (temporary) of current flowing through it.. Faraday called this phenomenon of creating or inducing a (changing in value) voltage and current due to a (changing in value) magnetic field, particularly its strength, as **electro-magnetic induction**.

Faraday also invented the first simple (but not yet practical) electric motor in 1821 and which produced some mechanical motion from the applied electricity. **Moritz Jacoby** would improved upon all the previous motors and made the first useful electro-magnetic motor in 1834. Before the electro-magnetic motor, there were the scientifically interesting, but not of much practical use at the time, electro-static motors created by people such as Andrew Gordon (Scotland), and Benjamin Franklin (United States of America, U.S.A.). These electric motors used the acceleration and velocity caused by accumulated electric charge which has an accumulation of electric or coulomb forces which can affect and-or apply energy to other nearby electrically charged objects.

Anyos Jedlik, (1800-1895), from Hungary, invented an electrical connection called a **commutator** of an electric motor in 1827, and it was significant for improving the direct current **(DC) electric motor**, and of which needs to rotate in only one direction. His invention allowed motors to be powered by DC (direct current, single direction, steady voltage, such as from a battery) power. He also made a small "toy car" with his motor which surely inspired cars of the future.

The first high power motors for machinery were invented by **William Sturgeon** in about 1832 and **Thomas and Emily Davenport,** from the Americas, in 1837. Experiments with primitive electric vehicles began at about this time at about 1834 such as one developed by **Robert Anderson** from Scotland, who made the first electric carriage (ie. "car"). The Davenport's are also given some credit to the first electric car at about the same time as Anderson. **Antonio Pacinotti** is credited in 1864 to the next significant advancement in the DC electric motor, and this is the **ring armature** for the coils of wire, and which improved the efficiency and performance of the motor. Some other people who made further and significant improvements to the electric motor will now be mentioned. In 1856, **Werner Siemens** [siemens is now a unit of electrical conductance = G = 1/(resistance in ohms)], who invented the needle-letter telegraph system in 1843] made some improvements to the electric motor. Siemens and Halske in 1872, Jonas Wenstrom in 1880, and Frank Sprague in 1886 would later invent some further and significant improvements to the efficiency of the electric motor. As of the year 2022, an electric motor having a maximum efficiency of 70% to 80% is common if the output load (ie. resistance) and-or power used is about the same value, otherwise the motors efficiency = (output rotating power) / (input electrical power) is reduced due to the wasted power from not optimizing the load and designed performance or capabilities of the motor.

The **AC electric motor** took longer to develop and to became a reality after the DC motors became practical. AC motor design also took longer to improve since it required AC generated electricity to power it, rather than DC power from a commonly available battery. An AC powered motor does not need a commutator (ie., a mechanical, electrical connection via a piece of thin flexible bent metal, or spring pressure upon carbon (electrical contact) "brushes") so as to keep the flow of electricity and magnetic field in the same desired polarities so the motor will rotate in the same (CW or CCW) direction. There were many developments to the AC motor, and by many people and-or companies, but **Nicola Tesla** and the **Westinghouse Company** are generally given credit to the basic modern design of an AC powered motor in 1882. Rather than a commutator as in a DC motor causing the flipping or changing of the polarity of the magnetic field so as to cause more movement of the rotor, the fluctuating polarity of the AC power supply voltage will automatically perform the changing of the magnetic field polarity so as to cause more movement of the rotor in the same direction. Since a changing magnetic field strength induces current in a wire or coil, an AC motor is also called an induction motor, and it is sometimes said that the stator has a (apparent, or simulated) rotating magnetic field to cause the rotor to spin.

Zenobe Gramme discovered the **AC electric generator** in 1871 after noticing that a DC electric motor, and in a reverse type of use, can also produce electricity without modification]. If a rotating force is applied to the rotor of the DC motor, and causing it to rotate, it will produce electricity at its two terminals and through a circuit connected to it. The faster it is rotated, the higher the voltage and current produce, hence the higher the input and output power. An AC electric generator, perhaps at a distant electrical power station, can be used to power an AC electric motor. Though an electric motor can be used to produce electricity, such as for some small, homemade electric power stations, a generator is usually designed so as to have more efficiency at making electricity than an electric motor. In particular, it is the high current in a motor with relatively few windings or turns on its coil that creates a high magnetic field and resulting torque needed for many (mechanical power or force needed) power applications. an electric motor will generally produce a lower output voltage than a real electricity generator. For a electric generator at a power station, a high voltage is rather created by using many more turns of wire in its coils so as to transmit high voltage electric power efficiently via long distance electric power transmission wires.

It took until 1854 for a **lead-acid based and rechargeable battery** to be created by **Wilhelm Sinsteden** (1803-1891), from Germany, and it was later improved in 1859 by **Gatson Plante** (1834-1889), from France, and this then facilitated many advances in various electronic devices and energy storage to come later, such as with electric motors in many types of devices and for many uses, and for example, an electric water pump, electric transportation vehicle, and various electronic and-or radio communication. This type of battery has relatively large surface, electrode plates made of lead metal immersed in sulfuric acid that is a compound made from hydrogen and sulfur. The acid with its hydrogen ions (ie., protons) and lead will chemically form lead sulfate, hydrogen ions (ie., protons), and two free (unbounded to an atom) electrons which can then be used to travel through an external circuit as electrical power. This chemical reaction is reversible by charging the battery.

In 1887, **William Morrison** (1855-1927), from Iowa State in United States, is credited to the first usable (for transportation for relatively short distances [a maximum total of about 45 miles] over unpaved roads) modern electric car that used a (lead-acid) rechargeable battery. Rubber covered tires (ie., wheels) were not invented until 1896, and this vehicle was truly a horseless carriage, and and having a similar wooden type of spoked wheels as used for covered wagons that were drawn (ie., pulled) by horses. This transportation vehicle that did not require a horse, boat or a steam-powered train soon began to create much interest in it and of the future improvements to it in the minds of many people. In about 1890, Morrison also made significant internal construction improvements to the electric rechargeable battery by using a fiberglass layer, and where the total amount of energy storage and-or power output available (ie., its energy storage density) per weight of the battery was significantly improved. This made electric power storage, and usage very practical. This also increased the number of total charging and discharging cycles possible with a rechargeable battery, hence improving the battery and-or power stability, and "battery life". Battery power stability, is essentially how long it can maintain at least its rated voltage and current ability, and before it drops below its ratings. Morrison greatly improved the rechargeable battery's stabililty and reliablility with a relatively low cost improvement to it.

While on this subject of transportation, the **Studebaker Co**. in U.S.A. made the first practical electric car (automobile) for the American general public in 1902. This was at a time when gasoline was a limited produced item, relatively expensive, and not yet available in many locations, and most public transportation roads were still dirt covered and unpaved with a hard surface. The batteries in these cars was a lead design and was therefore heavy and reduced the efficiency of the car. A few years afterwards, in 1904, Henry Ford began making the Model-A automobile. In 1913, the (Henry) Ford Motor Co. became a factory for mass producing relatively inexpensive gasoline powered automobiles, and this greatly diminished the public's desire for an electric car or horse-and-carriage for personal transportation. The "Model T" car was a very popular and relatively affordable design, and it was the initial basis to many future designs in the entire automobile industry. Many dirt roads soon became paved roads for better travel and efficiency. Trucks could now transport many and heavy items to many miles away and with greater speed than a horse (an animal engine) powered vehicle. As of about the year 2000, with advances in lite-weight electric batteries to power all types of devices, the electric car is once again on the wish-list of many people. During the same year as Ford's Model-A car was available, the Wright brothers created and flew the first practical plane in 1904, and which would revolutionized long distance transportation and made it practical.

Generation of electricity without using a battery:

Heinrich Emil Lenz, from Estonia-Russia, in 1834, created **Lenz's Law** which describes the voltage polarity and direction of magnetically induced currents of which happen due to the relative and perpendicular (90°, right angle) motion of a magnet and wire. The "Right-Hand Rule" considers conventional positive (+) to negative (-) current flow, and with your right hand thumb going in the direction of the wire and current, and with your other fingers of your right hand then wrapped around the wire is the (clockwise) direction of the magnetic field about around that wire. The symbol L, in honor of Lenz, was first used as the unit of measure of inductance, and others may use H (Henry's), instead of L, as the unit. Still, many inductors are still noted using an L symbol, but measured in henry units.

In 1841, **Michael Faraday** discovered (Faraday's Law of) **electromagnetic induction** by applying a voltage (and resulting current) to two coils placed closely together; essentially a transformer, and which are said to have "mutual inductance" in that they actually affect each other with their magnetic fields. As mentioned, Faraday also discovered that a moving magnetic field (and-or wire, relative to each other) such as from a magnet moving near a wire or coil of wire, will produce (ie., induce or generate) a voltage across that coil's terminals (end points, connections or leads) and create a proportional amount of resulting current through that coil and circuit connected to its ends. Electrons can move (ie., be given kinetic energy [ie. joules, and V=J/C]) by electrostatic forces or magnetic forces. Moving charges likewise produce both an electric field and magnetic field. Faraday's discoveries about magnetism and electricity (magneto-electricity or electromagnetism) are crucial for generating electricity and using electric motors, both solenoids [non rotating, but for linear (push and-or pull) motors providing non-rotating, but rather straight motion], and rotational or spinning motors. The unit of measurement of charge storage or capacitance is now called Farads (F), and was given that name in honor of Faraday.

In 1865, **James Clerk Maxwell** (1831-1879), from Scotland in the U.K (The United Kingdom of Britain) was greatly influenced by the work and discoveries of Michael Faraday, and he took electro-magnetic (electricity and magnetism) science to new heights and future possibilities with his four electromagnetic "Maxwell equations" of which were later simplified and credited to: **Maxwell**, **Faraday**, and **Oliver Heaviside**. These equations showed the mathematical relationships between electricity. magnetism and light, and even considered the transmission of electro-magnetic energy (ie., radiowaves) when they are considered as a type of light and-or vice-versa. Heaviside invented the coaxial cable in 1880 for short or long distance, efficient, and noiseless (low electromagnetic interference) transmission of signals through this special (outer "shielded", inner cable) "wire", "cable" or conductor. Maxwell's work influenced Albert Einstein with his discoveries. One equation by Maxwell relates the amount of created magnetic flux (ie., magnetic field strength) of a coil to the amount of input current (Amps) and the number of turns (windings, loops) of that coil. Maxwell also deduced that light is an electromagnetic (ie., a radio) wave (ie., has a frequency like a wave or oscillation). In 1861, Maxwell made the first, but crude, color photographic method, and where three color (green, blue, and red, or RGB) filtered images of the subject were made onto three separate, (transparent) glass plate, black and white photographs. The amount of greyscale (or sometimes spelled as grayscale) of the image on each photograph would effectively indicate and record the intensity and-or color of the light of the subject. If bright light was then passed through each photograph, and then that light being passed through the same color filter that was used to created it, the three separate color images can then be combined, by "overlaying" (to be at the same position or location) the project images to coincide, be combined with, or "on on top of the other", into one multi-colored image of the subject. Besides Heaviside's work on Maxwell's equations, he also invented the coaxial cable in 1880 for short or long distance, efficient, and noiseless (low electromagnetic interference) transmission of electric communication signals. This internal two wire "cable" is shielded from the natural elements such as rain, and often by using some type of plastic. Within that insulated outer surface coating is a two wire cable. There is an outer radius, metal "shielding" wire wrapped about or covering an insulated, inner [signal] "wire", or conductor. Both wires can be used as part of the circuit to conduct the signal, and the outer wire may sometimes be "grounded" so as to help reduce unwanted radio interference and-or noise such as from storm lightning in the area. More distance radio (ie., rf) noise will be weaker in amplitude and will be easier to reduce, tolerate, filter out and-or eliminate.

Crookes tubes are based upon previously invented Geissler (gas) tubes, but Crookes tubes do not contain any gas so as to glow, but use a pure or high vacuum with no internal gas desired. The glow at one end of a Crookes tube is rather due to electrons striking a thin phosphor (sensor) layer. Crookes tubes also demonstrated that electricity could flow through a vacuum that is essentially an insulator or very high resistance that does not conduct or allow current using practical, relatively low voltages. For very high or pure vacuums, the (vacuum) breakdown or conduction voltage is about 80kv per centimeter. Since there is no air or other substances in a vacuum, there will be no glowing gas or spark produced and seen as the electricity passes through a vacuum.

Once the electron particle was discovered, it was then fairly understood what electricity and-or electric current was actually composed of. Since electron particles are associated with negative charges, there must also be corresponding opposite or positive charged particles to attract them with their charges and forces. This opposite type of electric charge would later be indicated and found by observing Geissler ("discharge") tube experiments where holes were put in the cathode plate, and some new type of "anode rays" or particle went through those holes in the opposite direction than electrons did through the Geissler tube. This was first noted in 1886 by **Eugene Goldstein** (1850-1930) from Germany**,** and later understood to be positive charged ions (atoms missing an electron and its electric charge, hence having a net positive charge) composed of positive charged, fundamental particles called **protons** by **Ernest Rutherford** in 1911. These proton particles are in the nucleus of every atom and contribute to nearly all of an atoms physical matter which is measured and expressed numerically as its mass size in standardized units called grams or kilograms. The amount of mass of an electron is considered negligible as compared to the mass of all the other particles (protons and neutrons) of an atom. **The mass of a proton is 1836 times more than that of an electron**. Because of their very small size and low inertia, electrons can travel more freely between atoms, hence they can more easily travel through substances such as metals, especially in the presence of a (electromotive, emf) force attracting or repelling their low, easy to move mass:

The **mass of an electron** has been calculated to be about: **9.1093837 (10^-31) kg** =
9**.**1093837 (10^-31) (10^3 g) = 9**.**1093837(10^-28) g

The high voltage (ie., electric field of force or electric potential energy) in a Crookes tube actually repels and-or emits and repels electrons at the cathode, and the anode (ie., the positive terminal) at the other end of the tube will attract, via electric force, and accelerates the electrons to a very high speed and they will gain high kinetic (ie., motion, movement) energy and will produce light or (invisible, and higher in frequency) X-ray electomagnetic radiation when they collide with some (hard, dense) objects such as the metal anode in the tube. Geissler's, and Rontgen's (who discovered X-rays) research probably considered the previous discovery, in 1785 in London by **William Morgan,** a glow being created when a high voltage was applied in a glass tube that had a slight vacuum. Nicola Tesla is also known as a contemporary (ie., at about the same time, and studies) to Wilhelm Rontgen, particularly in the filed of X-rays production and recording onto light (or rf - radio frequency, radiation) sensitive film, such as for medical purposes.

Electrically charged protons and electrons attract each other with a force that is called an electric or electromotive force. It is much stronger than their gravitational force of attraction which is considered negligible for the very low mass particles. When the particles are close to each other, their electric forces are stronger than Earths gravitational force. The force from a magnet on a nearby iron object is also stronger than Earths magnetic field and force. Protons and electrons are two of the three fundamental particles (protons, neutrons and electrons) of an atom, and are the known as fundamental particles and-or units of electric charge and-or force. When these particles are not in motion, they are static (stationary, resting, as opposed to dynamic, kinetic or moving), and this charge or force may be called an electrostatic charge or force. If the particles are moving such as an electric current, the force that causes them to move is more correctly called an electromotive force (emf).

"Unlike charges" and-or charged particles, such as protons and electrons which have "unlike" (non-similar) or opposite charge, will attract each other like the two opposite poles of a magnet, and so as to naturally and eventually balance (settle, rest, equalize) the charges and have a net charge of 0, such as in a non-ionized or neutral atom with a balance of (ie., equal) electric charges in it when it has the same number of electrons and protons. Each element has a unique number of protons, neutrons and electrons. Generally for a given element, both the number of neutrons and both the number of electrons will equal the number of protons. An electrons attraction to a proton and-or the repulsion by other electrons, will cause (ie., induce, force) a "free" or unbound (from its atom) electron to move or flow towards a positive charge, such as when it is moving in an electric (electrically conductive path such as a metal wire) circuit to the positive voltage polarity and terminal side of a battery. This direction of current flow is for the true, physical and actual flow, but "conventional" or "common" flow of electricity, or electrical energy and-or power, is considered from positive terminal to the negative or "ground" (considered at 0 remaining potential) terminal of the voltage source, and this does aid with the math of it. For most common circuits, there is not problem using conventional flow and-or analysis. For things like Crookes and other vacuum tubes, the actual direction of electron flow matters more than having a (generalized) current flow and-or direction.

1911, Rutherford, who discovered the electron particle of an atom, theorized that the proton and electron composed a larger particle (called a nucleus of the atom) with a balanced or neutral charge state and called this unknown particle the **neutron** particle, and that an atom must have a large center or "**nucleus**" of mass. Rutherford and his team of scientists then experimented by sending fast moving alpha (protons, positive charged) particles at a very thin layer of gold foil, and because most of the alpha particles went through the foil and struck a fluorescent screen made of zinc-sulfide and could then be seen as re-radiated light energy, he theorized that the atoms of the foil had mostly empty (no matter) space between them. Since alpha particles have a positive charge, they should also be attracted to, and combine with the electrons in the gold foil, but it was noted that this alpha particle was sometimes changing or swerving away from its expected straight direction after leaving the foil, hence it must be colliding with and-or deflecting (changing) its direction due to a positive, electrically charged particle at the center of the atom. He theorized that electrons must be very small, and must compose some space or volume of an atom, and that they must then be attracted to, and orbit the nucleus.

Neutrons are very similar (but actually just slightly greater) in mass to that of protons, however, they don't have any electric charge like a proton or electron. They are not influenced by an electric field, and are only slightly influenced by a magnetic field, but are rather influenced only by kinetic force or collision. Later, in 1932 **James Chadwick** (1891-1974), from England, discovered a particle that did not have any electric charge, hence neutral in charge, and therefore called it the **neutron**. Neutrons do not attract or repel each other, and it is thought that they therefore do not have a "rotational spin" on its axis, and that they are attracted to the proton by a mysterious "strong atomic [nuclear] force". In the 1960's it was theorized and discovered that protons and neutrons are composed of even smaller particles called quarks. Each proton or neutron is composed of 3 quark particles. In 1979, even smaller particles called "gluons" were discovered and are thought to hold ("glue") the 3 quarks together. The concepts of quarks and gluons is generally not needed and-or used in the practice of electricity and electronics. If a nucleus has an unbalance (excess or lack) of neutrons, the atom is called an (unstable) **isotope** of the stable or balanced form of the element, and it can then split or decay into other lower mass atoms while releasing or radiating energy in the form of radioactivity, and then becoming (more) stable. Nearly all of the mass (real physical material, or substance) of an atom is due to the total mass of its protons and neutrons.

A proton is said to have and be the 1 fundamental unit or particle of positive (+) electric charge and force, and an electron particle is said to have and be the 1 fundamental unit of negative (-) electric charge and force. Neutrons have no charge. Protons will repel each other, and electrons will repel each other. Electrons and protons will attract each other due to their opposite electrical charge. Since the electric charge of a proton is equivalent to that of an electron (e), the electric charge of a proton may be expressed as ($+1e = e$), and the electric charge of an electron may be expressed as ($-1e = -e$). Note that the mass of an electron is much smaller than the mass of a proton, and yet an electron has an equal, but opposite, electric charge as that of a proton's electric charge.

Just like magnets having a magnetic (force) field (area of presence and influence), or field of force about them which can induce, attract or repel other magnets and (magnetic, iron) particles, charged particles also have an electric (force) field about them which can induce, attract or repel other charged particles. Because of an object just having a non-zero electric force, these electrostatic particles and their charges can also cause (induce, force) other particles and their charges (particularly electrons) to move or flow (attracted to, or be repulsed away) without any electrical (ie., electron) path or conductor between them such as a wire. The **electric field strength** value is much like that of a magnetic field strength value and a gravitational field strength value, in that its (force) **field strength or effect decreases in value by the square of the distance away from it**, hence this is a mathematical inverse-square law relationship of the field strength and distance squared in value. The force of gravity between two objects is relatively weak compared to the sizes of masses involved. The forces due to electricity (ie., charges) and-or magnetism are much greater between the same two masses.

In an uncharged, electrically balanced or neutral object, the net charge is 0e. It is as if it has not gained or lost any charged particles and the object is electrically neutral without any extra charges. If an object is said to be "negatively charged", it has a net negative charge because it has lost some of its positive charge. If an object is said to be "positively charged", it has a net positive charge because it has lost some of its negative charge. Charges are quanitized (ie., counted) as integer sized steps and values only, and that there is no fraction of a charge. Charges can be added together to produce a net total effective charge. If an object has 4 positive electric (e) charges and 7 negative electric (e) charges, the net effective charge of that object is: (+4e) + (-7e) = (+4 -7)e = -3e. Since the net charge is negative in sign, that charge is due to an excess of 3 negative charges, hence electrons.

An electroscope is a simple device to sense, observe (see), and possibly measure, the presence of a net electric charge of an object. The device is a glass jar with a very thin, lite-weight (low mass) metal foil sheet folded in half and held in position by a wire from the lid and external metal terminal or input connection. When the metal foil sensor is charged due to the presence of another charged object, it will expand due to the electric charge repulsion of the like charges on it. It is even possible to indicate and measure the type and basic amount of the net charge. The basic concepts of an electroscope were partially invented by **Charles DuFey** (1698-1739), from France, in 1721, and who also discovered that there is two types of (static) electricity, now known as two types of electric charges, and that the same type of electricity (on charged objects, including metals) cause a repelling, and the opposite type of electricity (on charged objects) causes an attraction. Charged objects can also induce or cause an opposite charge region in an uncharged object, and hence cause an attraction as if it were already oppositely charged. This effect can also be seen with an electroscope instrument when the two plates repel each other due to having the same type of charge on them.

Benjamin Franklin (1706-1790) from the United States of America (U.S.A) made several basic or fundamental discoveries about static electricity. Franklin noticed and proposed that a spark is similar to lightning, and vice-versa, and that it is due to electric charges. Franklin invented the concept of a metal "lightning rod" on the top of a high structures so as to divert (electric) a dangerous strike lightning away from that structure and down through a high conduction wire placed into the ground. The rod was made to have a pointed tip so as to help concentrate electric charge and force of attraction at the tip. Franklin made the first battery or array of connected and stored charges so as to have more of it for experiments and to possibly do useful things with it. The charges were stored in glass jars with two metal plates, and were called "condensers" (charge accumulators, hence "condensed" charge in a location) and are commonly called today as "**capacitors**" (ie., store a capacity, quantity or an amount of charge), and were first known as **Leyden** Jars since they were invented in that city, and in about the year 1745. Franklin discovered that many of these storage devices placed in parallel would store more charge, and called this capacitor arrangement as a "battery". In 1746, Franklin discovered that electricity would flow from a (having more, or "positive") charged object to that of a lesser (lacking, or "negative") charged object, and that the total charge of both objects would always have the same total, hence there is a "conservation" (ie., remains the same total amount, the amount is conserved and none is lost) of charge. Franklin had a theory that there is only one type of electricity or charge carrier, and today we know this a electron charges and flow.

A simple electric communication system (as conceived in the 1750's) can be made with electricity conductors (such as wires) and electroscopes used as the communication sensors or receivers, and a mechanical analogy to this could be a rope placed between two distant bells to be used for a communication system. A step above this system would be to use a battery, on-off switches, (transmission) wire, and electric buzzers or lights as the receivers. This system or circuit is similar to, and very useful as that of a modern electric doorbell (invented by **Joseph Henry** in 1831) and of which the unit of measurement called Henrys (H), for inductance (L) was named after, and it was also similar the **electric telegraph**, communication system that was made practical in 1837 by **Samuel Morse** (1791-1872), from the United States, by utilizing a single electric wire. Morse, who studies included communication for the deaf, also helped developed the **Morse Code** method of transmitting and receiving distant communication by using a series of short (a "dot" [**.**]) and long (a "dash" [_]) electrical pulses to construct and represent a specific letter of the alphabet and so as to effectively build each word, letter by letter. At the distant receiving station, perhaps hundreds of miles way, these pulses were received, (sometimes) recorded, collected and then decoded or reconstructed back into letters of words and written down by the telegraph operator so as to create a written "telegram message" (or simply a "telegram") to be delivered as mail to the receiver of it. This was a significant step in fast, low cost communication, and it helped society advance more efficiently and rapidly. The telegraph did not replace the mail system, for it was, and still is needed for the many and long messages and packages, whereas a telegram was often limited in the "length" of it in terms of the total number of characters and-or lines permitted by the station, and therefore, the messages were often short and "to the point" or issue, much like that on a postcard (mail). The Morse code is given an article in the "Late Entry's" section in this book.

Rubbing (friction) can "charge up" some objects. Rubbing two objects together can free some electrons from their atomic orbit or bond so as to produce ("free", movable) charges or "electricity". Larger, more massive atoms of elements have a weaker bond or force applied to their more distant outer electrons, and they are more easily freed using less force such as electric force. An object that has more negative charges (free electrons) than positive charges (positive ions, positive ionized or charged atoms) is said to be negatively charged.

In 1832, and not long after Michael Faraday discovered electro-magnetic induction, **Hippolyte Pixii** (1808-1835), from France, and inspired by Faraday's crude non-coil design of an electricity generator, created a hand cranked and powered by arm force, rotating machine which can be turned or rotated so as to generate (AC, Alternating [in two directions] Current) electricity. **This electricity generator machine converted or transformed input mechanical energy and-or power to electrical energy and-or power.** His machine rotated a magnet near a coil of wire. With this, he invented a practical A.C. **electric or electricity generator** machine or electricity generator. This simple concept and device was actually monumental in terms of the electricity advancements it would inspire and be used to power. **Andre Ampere** gave Pixii the idea of using a mechanical device (now called a [electric] commutator) so as the current would be caused to flow in just one direction, somewhat like DC does, but here, with AC involved and always changing in value, and the generated DC will also vary in value, magnitude or amplitude, but not in two direction like AC does.

A **dynamo** is an advanced type of **electricity generator** created by **Werner Seimens** (1816-1892), from Germany, in 1866, and which used electro-magnetics instead of permanent magnets. These electrified coils (electro-magnets) have a higher magnetic strength or power, and therefore, the output electric power was (theoretically) greater if the generator's rotor (ie., its rotating or rotational part) was spinning as fast as that without electrified coils. It should be of note that generators, for either mechanical or electrical output power, can contain mechanical input and-or output gears so as to alter the rotational speed and torque (force) needed for the rotor and a stable (ie., a constant value of voltage and current, or power), regulated electricity production or output. Seimens created many useful electrical inventions, and his name is used for the SI unit for conductance in his honor, and supersedes the mho unit created by George Ohm. Before the ohm unit of resistance, the Siemens reference unit of resistance was slightly less than 1 ohm as we know of today, and by about -0.05 ohms = five-hundredths of an ohm, and was determined by a specific length, diameter, and temperature of a tube filled with mercury liquid which can conduct electricity. Since mercury is now understood as being a toxic substance, this unit is no longer used after about the year 1890, but rather the ohm unit is now used for the resistance to the flow of current and-or electricity. Perhaps you will find an old book where the Seimens unit is mentioned, and the above reasoning will help you comprehend and-or convert its value to its modern equivalent having ohm units.

How Electric Current Is Generated In A Generator

A changing magnetic field, such as through the coils in a spinning electric (electricity) generator, can be used to cause ("induce" or generate) electrons to be free (from their atoms) in a wire (or coil of wire) so as to then have an electric (electron) current (flow, movement) in a circuit. The magnetic field force will give kinetic energy (ie., J/C, joules of energy per coulomb of electrons, and this is defined as Voltage) to the electrons in the wire of the spinning coil (or sometimes the magnets are rotated, rather than the coil), and an external electric circuit will allow those energized electrons to flow. The (alternating, and in a sinusoidal wave) voltages produced from a generator and-or output from a transformer can be very high and dangerous, and can easily force a relatively low current (due to high resistance) through long distance wires to the destinations of use. At the destination(s) for public use, the voltage available at the electric power transmission lines is reduced ("stepped down") by a device called a **transformer.** An electric (power = voltage and current) transformer is basically two electrically separated, but magnetically coupled (magnetically influenced) coils that will convert a high voltage, low current input, to a much safer and lower voltage (about 220v, 50hz in Europe which requires less current per same amount of power needed, or about 120v, 60hz in many American countries, and with 127v in Mexico) output and with a higher current ability than that normally found in the long transmission wires. Long transmission wires have a certain resistance per meter or mile and therefore have an additive or accumulative resistance and would waste (as heat) much of the power generated and available for use. When the resistance is higher, the current is reduced, and the power loss becomes more significant because power is related to the square of the available current value. The voltage on a long distance transmission wire may be about 10kv to 20kv and is extremely dangerous, lethal, and can easily cause electric arcing (ie., like lightning, electrical discharges), shocks, damage and-or fires.

Power = P = (voltage)(current) = V **I** = I^2R = V^2 / R. Power is directly related to voltage (V) and the square of the current (I), but is obviously, inversely related to resistance (R) which will limit the current and then limit the power available to do things such work, and of which was initially defined so as to be measurable as: work = (force)(distance); a force applied through or over a distance. The units of work are the same as the energy needed or used to that work, and that unit is called joules (J). The higher the resistance, the less the current, energy or power available for use because it was wasted as heat (ie., friction energy) through that resistance.

The first hydro-electric (or hydroelectric) power was created by **William Armstrong** in England in 1878. Flowing water has kinetic energy and can apply pressure to the rotating blades of a turbine, much like how wind-electric power is generated. The turbine is connected to the electric generator via a shaft, however gearing may also be used. By this time of 1878, using hydro-power, water wheel power, and wind power for industrial purposes was already commonly used in many industries. The first wind-electric generator was made by **James Blyth**, of Scotland, in 1887. **Charles Brush**, from the USA made a large and practical wind-electric generator in 1888.

Experimental Long Distance Power Transmission

Before Tesla and others, **Lucien Gaulard** (1850-1888), from France, and **John Gibbs** (1834 - 1912) as a financier, from England, conceived of a practical way to transmit power using electricity and long distance power wires or lines in 1881 and of which the Westinghouse Co. would later buy in 1885. Gaulard and Gibbs invented a different type of transformer and-or design that could handle large amounts of power, and of which William Stanley of Westinghouse Co. would later improve upon. This transformer was of course an AC electrical power transformer, and this was also made to reduce (or step if needed in a house, factory or business) the high transmission voltage down to a lower, practical and more safe level. Later, others would improve upon Gaulard's transformer and replace some metal parts with layers of laminate metal so as to reduce internal, eddy [side, edge of, opposite] current, power losses, and specifically as heat energy.

By using transformers as part of power distribution, this is a much more efficient version of using high voltage (AC) power lines for an electrical power distribution system that we still use in these modern times, and it is mostly credited to **Nicola Tesla**, and who also made many other significant advances such as in motor design, particularly, inventing the (AC induction) motor that can be powered by AC power. AC means alternating current that is created from an alternating (sinusoidal, reversing polarity ("back and forth") periodically) voltage and current source created, often in a spinning electricity or "electric power" generator. A generator is much like a motor, but a public electric utility generator is designed to produce output power (= voltage x current) that has a form of a high value of voltage and a low current such as for the transmission of it. An electric (powered) motor is rather designed to use that generated power in the form of a much lower voltage and a higher amount of current. When more current is available, an electric motor can develop a stronger magnetic (force) field in its windings or coils and so as to have more output torque ([mechanical] rotating force), rather than high speed, to rotate and do things such as work, perhaps for an electric drill or water pump.

At a distant city from the electric power generation plant, the high voltage output at and from the power station is "stepped-down" (ie., reduced) to a more manageable voltage by using a ("step-down") transformer. A common AC power supply for households is 110-120v single (1) phase AC wave with a frequency of 60hz, such as used in Canada, Mexico, U.S.A, and many other western countries, and with most of the other countries using 50hz, 220-230v single phase AC wave for their households. It should be noted that the higher the frequency of AC electricity or signal, also means more power or energy per second available, and so with the lower frequency 50hz AC electricity, the voltage generated must then be higher so as to deliver the high needed power, and that thinner, lower current ability, but lower cost wires can be used. As mentioned previously, electric motors and generators are nearly identical, and some homemade generators may be constructed by modifying an electric motor, particularly the coil(s).

Nicola Tesla, (1856-1943) was an immigrant from Serbia in eastern Europe, and then to the United States of America in 1884, and worked as an engineer for the popular and significant (inventor) Thomas Edison Company., and later with the Westinghouse Company. Tesla made many significant improvements in many electric devices and concepts, and made discoveries such as with ("2-phase" or 2 electric sine waves) alternating current (AC, 2-phase, 4 wire, and 3-phase, 6 wire system in 1888) powered electric motors, radio (electric radiation and transmission to a receiver) and remote control via radio, xrays, high-voltage coils and transformers, etc. Tesla was a master of the electrical-magnetic transformer so as to convert or transform the voltage and current of electrical power (Power = voltage x current). A "Tesla-coil" is essentially a very high voltage transformer than can easily produce many visible sparks of light, much like man-made lightning bolts. Due to Tesla's initial discovers and inventions, he is generally credited as the main creator of the modern AC long line and distance electric power distribution system to factories, businesses and households. The key to this system, as indicated previously, is using "step-down" transformers so as to convert a much higher generated voltage to a more practical and safer lower voltage. Voltage can be thought of as the potential or kinetic energy of the electrons in the current, and-or as a measure of the force applying energy or power to the electrons and pushing and-or pulling them through the conductor metal (ie., wire). The more electrons or current, the more energy or power being transferred.

A contemporary to Nicola Tesla, named **Mikhail Dobrovolsky** (1862-1919) of Prussia (Poland-Russian, once a German held region) soon took Tesla's 2-phase discoveries further, and is credited to inventing a differently constructed 3-phase AC generator, and a 3-phase, 3-wire AC transmission or distribution system in 1890. In these generators, there are three coils and where each coil produces one of the three phases or sine waves, and these coils are physically offset by (360°/3) = 120° This is what most of the modern world still uses as of the year 2024 for its electric ("grid", public serving utility) household (ie., home, residential, personal) AC power. The three coils used inside the transformers for this generation and-or distribution system used an internal "star" (or "Y" shaped), or "delta" ("D" shaped, triangle-like connection) connection. A three phase generator is more efficient at producing electric power than the two phase generator, and since the average amplitude or voltage of all three of the AC waves or "phases" at any one instant is greater, and the output power (P = VI) is therefore greater. Note that a typical household or home is still normally only supplied a single phase (usually 110V or 120V peak in the USA) of AC electricity from the local area, (voltage) step-down or reduction transformer. A circuit connection of 220V peak is sometime available for a high power machine such as a washing machine or dryer. Dobrovolsky is also credited to the "squirrel cage" AC motor design that uses segmented metal pieces instead of larger pieces, and so as to reduce the unwanted (magnetic field caused) "eddy" (ie., side or residual) energy storage and resulting wasteful (back-emf [ie, a reverse voltage] caused) current reduction, heat and other losses, and this improves the efficiency of the motor and power available. It is also of note that the frequency (ex., 50hz, 60hz, or some other and-or adjustable frequency) of the AC power to an AC motor will determine the fundamental speed (ie., RPS, RPM) of that motor. In general, a 3-phase, AC electric motor has three coils connected in such as way that a two pole (N and S) magnetic field is created and which will effectively rotates due to the applied AC power, and this will then rotate the rotor shaft of that motor.

A contemporary to Nicola Tesla, named Karl Steinmetz (aka., **Charles Steinmetz**, while in the USA), (1865-1923), from the Prussia area that is now located in Northern Germany and Poland, made many practical discoveries about AC electricity, and made some of the equations for it to be more practical and learnable. He gave us the understanding of the phenomenon of (magnetic) hysteresis in electro-magnetic motors which contained magnets. Hysteresis is when an electro-magnet briefly retains some of its same magnetic polarity after the current has switched to the opposite direction such as what commonly happens with AC (Alternating, changing direction, Current) electricity. If hysteresis can be reduced, it will improve the efficiency of motors. He is honored by the IEEE (**I**nstitute of **E**lectrical and **E**lectronics **E**ngineers). Charles was born with a form of dwarfism and a genetic [DNA]) physical handicap and-or (bone, osteo) disease. After his education and several initial discoveries, he went to the United States of America in 1889 and worked as an engineer for the (Rudolph) Eickemeyer Company that specialized making (AC) transformers, and then worked with the General Electric Company so as to further develop both the science and application of electricity.

Edith Clarke (1883 - 1959), from the USA, was one of the first women to be recognized and (formally) be certified as an electrical engineer by the IEEE, and is honored for her practical work, calculation charts, and significant educational writings about AC electricity, circuits, and AC power transmission so as to help make them more understandable and practical for many to study and comprehend.

There are many electricity generators available and are intended to be powered by certain forms of input energy such as wind, water, and hand cranked, and each type of generator has a certain maximum rated output power (Pw = V I) . There are small portable ones which hikers, campers and remote locations without grid power can use. Some of these can charge a capacitor and-or batteries so as to store energy for when it is needed, such as for an emergency radio and-or light. It is even quite possible to rotate a fairly large electric generator of a few thousand watts output by using an automotive (car) wheel that is being powered by the engine, and this powered wheel is not on the ground, but a few inches above it so as the car will to remain in place for safety and to stay connected to the generator. It is possible to use some electric motors as generators of electricity.

Many of the people mentioned in this book about electricity, and many others not mentioned, are mentioned in a new book called: **The Lightning Tamers , by Prof. Kathy Joseph** as its author**.** It is a book about their lives and times, and how it then interacted and contributed with their important discoveries about electricity. It is a rare type of book to create and publish, and she has made it available for us so as we may better understand the science of electricity from its origins. This book is available on some popular e-commerce store websites. She also has a Youtube.com video channel, and a website called KathyLovesPhysics.com

RADIO

Radio is a word derived from the radial-like (radius from the center) direction of the outward transmission or radiation of electromagnetic energy from a central source such as from a metal wire antenna with electric energy applied to it. Visible light is one form of electromagnetic radiation and is of the (radio or electromagnetic) frequencies that are visible to the human eye as colors. Most radio frequency (RF) waves are invisible radio waves such as used for the electronic transmission of audio (sound) such as for a radio receiver and its audio speaker, and-or for visual images as for a TV receiver and its viewing screen. The telegraph and-or phone system requires a direct electrical connection (with a metal wire) to the people communicating, but radio communication (ie., "wireless" communication) does not require a direct electrical connection, and is therefore available and cost effective for many more people, and-or for all at the same time such as with standard TV (television). This discussion is mainly an introduction to radio, and some of the technical or specifics of it are discussed further ahead in this book.

Ever since electric sparks were created, invisible and unknown radio wave energy was also automatically created and transmitted, and it was also not known at the time that these waves could pass though non-metallic things such as a wooden box or wall that is not too thick and-or made of metal. It was also not then known of how to sense or receive this invisible radiated (ie. radio) energy. A high voltage spark of light through the air is visible, but was there also some invisible (radio) waves also being transmitted at the same time? In 1888, **Heinrich Hertz** (1857-1894), from Germany, detected the first invisible (or radio) wave, by using a receiver (ie., antenna) that was composed of just a single loop of wire having a very small spark-gap and (initially) placed just a few feet of distance away from the electric spark-gap The transmission spark (which created the (invisible) radio wave energy) used was made using a high voltage induction coil, which is a type of transformer that can also raise the voltage of the input signal, and so as produce a high voltage output signal, but actually at a lower maximum amount of current since the energy output cannot be greater than the energy input. That is, (energy out) = (energy in), and-or (work out) = (work in) or (power out) = (power in) if there are no losses of power along the way. Modern radio transmitters and-or receivers do not use a spark-gap, but rather use much more modern and sensitive radio wave circuits. The electric spark and spark-gap in this type of application became known as the (electric) spark-gap (electricity, energy, radio-wave) transmitter.

Hertz probably got his idea while considering Faraday's discoveries and that an electric current pulsed wire and-or coil could transmit a magnetic field, of which each (transmitted) pulse can be detected, sensed or received by a (nearby) magnetically sensitive compass. Would a spark be an indication of some type of charge or energy being radiated? Hertz then made a receiving antenna to find out. The metal antenna received and collected just enough (a small fraction) of the transmitted energy so as a small spark was visible across its own spark-gap or end terminals. This discovery started a revolution in electric oscillators (ie., electric signal [voltage, current, frequency] oscillators that use or are powered by electricity) and wireless communication such as with radio, and eventually TV, and as of the year 2022, it has resulted in what are called "smart (tele-) phones".

One of the first practical radio wave detectors or sensors created and used was called a **coherer**. It was invented in 1890 by **Edouard Branly** (1844-1940), in France, and the scientific fact of fine metal dust particles being affected by a high voltage had been known for about 50 years previously, but it was of no practical use yet. To imagine this effect, consider how amber and static-electricity attracts small lite-weight bits of material. Branly made the first practical (ie., here, useful for something) coherer device, and used it to help sense or detect a received, relatively weak, radio signal collected by the nearby antenna attached to one of the coherers two end terminals. Branly's coherer used iron dust particles. It was basically loosely packed metal bits that would cohere (ie., combine, cling or stick together) together in the presence of (electro-magnetic) radio wave energy transmitted by a (on-off, radio pulses) high voltage, spark-gap radio wave transmitter. This then created a less resistive, more conductive path through it - presumable through an oxide layer after it electrically overcame its high resistance and conducted, and therefore behaving like a electrically activated, remote controlled switch that then allows electricity to conduct or flow through it to the rest of the electric circuit. The circuit may include an electric buzzer (sound) device, or the pulse heard in sensitive earphones, and-or be recorded with a Morse paper tape recorder which used a wound reel of paper to record the received (pulses or radiowave energy) Morse Code encoded signals and information. The coherer device then had to be physically tapped by the radio operator so as to reset it so as to be in the receiving mode again. Later, an automatic tapper circuit with a (electr0-magnetically shielded) relay or electromagnet that could force and move a small metal tapper (ie., a "decoherer") was used to automatically reset the coherer back into receive mode. After about this time, others made improvements to the coherer device, and they were notably made by **Oliver Lodge** who used it to study radio or "Hertzian waves", **Sir J.C. Bose** (iron and mercury, liquid coherer, and which did not need a decoherer, and was fast), **Nicola Tesla**,, and **Guglielmo Marconi** used a coherer for the first wireless (radio-wave) telegraphy system. Marconi's radio-telegraph system was made practical by using Bose's improved type of coherer.

Crystal detectors (ie., various forms of solid-state diodes) and the vacuum tube diode would eventually replaced nearly all of the mechanical-like coherer devices, and because they were much faster and sensitive to the weak (low energy) radio waves received, and could later demodulate (ie., retrieve) the information and-or audio that was transmitted by the aid of a radio wave. A coherer was susceptible to lightning and other radiowave noise (ie., [electromagnetic, electronic,"rf"] interference) that would cause unwanted radiowave detection and-or information losses along the way.

In 1903, **Reginald Fessenden** (1866-1932), from Canada and America, developed an electrolytic detector (basically, a bare or uninsulated thin platinum wire with its point or tip in a liquid acid) and called it a bare wire detector called a "barretter". This radio wave detector was more sensitive, fast, and could actually be used to demodulate voice-signal, amplitude modulated (AM) radio waves much like how a solid-state diode demodulates AM radio signals today. The technology of AM radio is given a brief discussion in this book. Besides the crude-like coherer that as discovered previously, Fessenden's solid-state-like discovery showed that various elements and their interaction with radio waves and-or electricity could detect radio waves, however it was still a mystery of what was exactly happening.

The technology of radio wave transmission and reception was improving rapidly after 1900, and rather than keep using pulsed radio waves without much frequency tuning and control, and then also receiving much interference of the radio signals, radio waves began to be tuned to be a specific frequency and were automatically and constantly made and transmitted due to fast electrical oscillation (repetition, here of making radio waves at a certain frequency) or oscillator circuits. Amplitude modulation (AM) of radio waves uses an input or control signal, such as an audio signal, to directly vary the output or broadcast signal's amplitude or power, and according to the amplitude of that input signal. AM began to be known as "continuous wave" radio and having one main, limited or narrow frequency bandwidth (ie., frequency range) associated with it. If a transmitted radio wave a has tuned, set, main, specific or fundamental ("carrier") radio frequency, then the radio receiver circuit must also be "tuned" or adjusted so as to receive that specific radio energy or wave frequency, and for the maximum or best energy transfer from the transmitter. Fessenden was greatly involved with the initial development of **radio telegraphy** (ie., Morse code via radio signals, such as for ships, and before voice via radio) communication and AM radio (communication) of which was first demonstrated in the year 1900 as being able to transmit human speech (audio).

Sound Recording

Thomas Edison (1847-1931), from the United States of America (USA), and his company made many significant advances in technology, such as for the first practical electric light in 1879. Since Edison used a filament within a vacuum, rather than regular air, it did not degrade or (slow) combust like the carbon electrodes in an arc-lamp. Edison also invented a completely mechanical, audio (ie., sound) recording and playback machine in 1877 called a **phonograph.** It was sometimes called a "talking machine". A phonograph could both record and mechanically play back sound vibrations and-or imprinted "bumps" on the surface of the recording media such as aluminum-foil, and later, wax was used which allowed a better quality of recording and later, reproduction of the recorded wax cylinders for mass production and distribution. These mechanical machines were hand-cranked powered, and nearby, loud sound was recorded and without strict timing and-or revolutions per minute. To hear the recorded audio at its proper frequency, the recording needed to be played back the same amount of revolutions per minute (rpm) as it was recorded with, and it was often about 120 rpm (ie., 120 rev / 1 min = 120 rev / 60 s = 2 rev / s). A recording standard was later recommended and used, and it was 160 rpm which improved the higher frequency recording range up to about 5000 hz., making it more suitable for accurately recording high frequency musical instruments. At those times, due to the lack of electronic amplification for both recording and playback, a sound needed to be relatively loud to record it, and sound collectors shaped like funnels were used to concentrate sound so to increase its intensity or pressure for the mechanical recordings. Years before Edison's sound recording and playback machine, there were some crude inventions and recordings of sound waves (ie., air or mechanical vibrations) and seismic waves (ie., earthquakes. seismograph recorder) onto paper using ink, and with no invention yet invented at that time to play (ie., convert to audio) and hear these recordings. The first sound recorder of this type was made in about 1857 by **Edouard-Leon Scott de Martinville** , from France, and the recording device is called a phonautograph. Paper recordings are still needed and used in the modern world so as to mechanically record many types of data and their values (ie., typically their signal amplitude) and the time they happened. Recordings of electronic and-or digital input signals to created a recording (ie., in electronic memory) composed of the data are also becoming widespread, and that a microprocessor or computer device is needed to display the data or results on a screen, and vast amounts of data can be easily analyzed by a fast computer so as to produce a result. Most likely, Martinville's recorder inspired Edison to make his sound recorder and playback machine. Before Edison made his version of a spring motor to power a phonograph and at the correct speed in 1898, there were several other previous researchers in this endeavor for the phonograph such as: Edward Amet in 1891, for a speed regulated spring motor, and Levi Montross in 1896.

In the times of Edison, the concept of "motion or moving pictures" to photographically record and display objects in motion was around for many years, but he made the first practical **motion picture camera,** and of which began to set the standards for motion pictures or "movies"**.** He also invented a greatly improved **microphone** (converts an input sound energy or signal into a corresponding or simulated electric energy signal) in 1876 which was then used to significantly improve the existing, but relatively crude telephone system created by Alexander Graham Bell. Edison is generally credited to the invention of the carbon microphone in 1877 which also allowed larger (ie., in amplitude, louder) audio signals to be used with the telephone and other devices. Noted credit to the invention of the carbon microphone at about the same time as Edison is also given to David Hughes from England, who also invented a telegraph system that printed telegraph messages onto paper tape, and to **Emile Berliner** (1851-1929), from Germany-USA, who worked with Edison in 1876 and created a better carbon microphone in 1878 that Alexander Graham Bell would use to significantly improve his electric telephone system. Berliner would later, in 1887, invent the ("Gramophone" phonograph) flat or disk phonograph recordings (commonly called as just "records"), and he also invented a significant record playback reproduction method for mass distribution of audio recordings or records. This technology was a vast improvement over the relatively soft and degrading wax recordings made previously by both Edison and Bell. Berliner created a process to record the audio into a thin wax coating on a metal disk, and then electroplated it, and this resulting metal disk would then last much longer than (flimsy) wax cylinder recordings and any possible (degraded) re-recordings of it. This metal disk was not actually played back, but was used as a type of mechanical die or imprint that could then be used as the source or mold to stamp (ie., press, imprint) exact (but reversed) copies of itself onto a heat-softened plastic that would soon harden firm when cooled. These recordings would last much longer than wax would when a vibration sensor called a "pickup needle" was physically dragged through its groove (ie., a long indentation) as the recording was played back so as to hear it. These disks were to be heard or played back using a rotational speed of 78 rpm (revolutions per minute), and have a recording that had a maximum of about 5 minutes of time duration or length. These disks originally were 7 inches in diameter, but later, and mostly, the 10 inch and 12 inch diameters were used. As of 1948, and created by the **Columbia Record company**, similar 12 inch diameter types of records having a longer recording and playback (ie., "listening") time and having improved sound or "audio fidelity" quality were called LP (Long Play) records. These records were to be played back at 33.3 rpm using a sensitive electromagnetic needle (physical-mechanical vibration "pickup", sensor and transducer to an electric signal) so as to then be heard louder by using an electronic sound (signal) amplifier. Each side of these records had a recording and-or playback time of about 30 minutes maximum, and therefore these records could contain a total of: (30 min / side)(2 sides) = 60 minutes of audio. If the rotational speed (ie., rpm) and-or listening or "playback speed" of a recording is changed by a factor of (n), all the frequencies of that recording will be changed by that same factor of (n). For example, frequency of (x) cycles per second will become (n)(x) cycles per second (ie., cps = hz).

In 1948 the **RCA Victor Co.** invented the 45 rmp, 7 inch diameter plastic record, and which was often used to sell "single" (ie., one song per side) recordings of which were often the most desired or popular songs found on the more expensive LP records. These relatively small disks were also used with coin-operated (ie, pay first) playback machines, often called a "Juke Box", that had many available songs on these small disk records inside it, and for a coin fee, it could play a desired song using its internal record player and audio amplification. As of the year 2022, a few of these original machines could still be found working, and usually inside a restaurant, bar or night-club. They are quite collectible, especially if they contain old recordings. A popular and-or song being promoted was usually placed on what is called the A-side of the record, and the B-side of the record was generally a song that still needed to be heard, but it often was not promoted and -or it did not have much of a chance of being a popular or "hit" record, but there are some exceptions to this.

The available magnetic type of audio recording technology, and available before the magnetic tape technology, was called "**wire recording**", and where a long and thin iron wire on a spool could stored a corresponding magnetic image or recording of the input sound. This wire was moved very close to and past a "recording head" (ie., an electric to magnetic transducer), and the wire became locally magnetized there, and having a magnetic representation of the input audio signal (amplitude [amount or level of power] and frequency) at that location on the wire. This technology surely inspired the magnetic tape, "(tape) reel-to-reel" recording technology later. Wire-Recording was invented in 1898 by **Valdemar Poulsen** (1869-1942), from Denmark. This technology improved greatly over the following years, and especially with advances in microphones, speakers and electronic recording and amplification. This was the first form of electro-magnetic recording technology and of which would later find much practical use for recording or storing audio and-or video (TV signals or recordings) onto magnetically sensitive tape, and for storing vast amounts of digital (ie., computer data) onto magnetically sensitive "floppy" (flimsy, soft) or hard metal disks before the modern (2022) times of very high capacity digital (ram) memory made from small (ex., 1 sq. cm of area) integrated (IC) circuits on pieces or "chips" of silicon.

The first practical magnetic **tape recordings** and technology were initially invented and created in about 1928 by **Fritz Pfleumer** (1881-1945) in Germany, and it became affordable and popular in the late 1940's due to its high quality recording and playback sound, and its long total time possible to record and-or and playback sound. The word tape used in this context is a thin real or roll up of media that is plastic with a coating of fine iron particles which can be magnetized and record magnetic signals. This also made it practical for the average recording studio and-or person to record and edit sound. If a mistake was made, the same exact tape could be erased and-or directly recorded over, again and again until it was satisfactory. These recordings could then be used as the audio source so as to then make a relatively inexpensive (plastic) record (ie., recording) for the public. Cassette tapes and the associated audio recording technology (ie., portable playback machines), having a narrow tape width were a very popular, very low cost recording format in the late 1960's to about 1990. (Magnetic) tape recording technology places the electronic audio image or representation onto a long paper and (usually) plastic tape that has been coated with a fine dust of iron particles. This recording tape was much wider than a thin wire, and therefore, it had a higher possible audio quality, especially with the advances in audio sensor-transducer or microphone technology and electronic amplification.

In about 1982, recordings began to be made onto **Compact Disks (CD's)**, and this technology which is a mixture of the older (rotating) disk-record technology and the newer digital technology, and here, the (audio and-or computer digital data) information and playback sensor is a small LED laser. The CD or "optical disk" recording medium is specially constructed, thin (1.2mm) plastic disk having a diameter of 4.75 inches = 120mm. **James Russel** (1931 -), from the United States, is credited to the initial invention of the CD concept and its technology, and the **Sony Co.** and **Philips Co.** jointly created the production standard called the "Red Book CD standard". This audio standard is 16 bits (ie., 2 bytes long or "wide", having an equivalent decimal steps or range of values from 0d to 65535d) of data for each audio sample and storage of it, and a total of 44100 (ie., 44.1kHz) samples per second. Each sample is essentially the voltage level of the audio signal and-or waveform at that brief instant it was sampled and-or measured. The sample value is about twice as high as the theoretical 20kHz maximum frequency of human hearing, but it is necessary so as to still be able to effectively detect and record those high frequencies with reasonable quality. Lower, and most, frequencies in common music sound would naturally be recorded with much higher accuracy, representation or quality than the very high frequencies. It is of note that recording studios will probably use a higher frequency for the digital or analog to digital sampling and then reduce it to 44.1kHz for the CD standard. The CD standard also allowed a maximum of 74 minutes for each separate track of stereo (L and R recordings, Left and Right, dual, two tracks) audio recording and-or playback time. 74 minutes = (74min) (60s/min) = 4400 seconds. These CD's are also capable of storing 640Mb, or slightly more, of (digital, computer) data such as images, documents, programs, etc. Using a laser, a CD's digital (ie. a logic and-or numeric 1 or 0) data is actually burned through the inner foil layer as either a tiny microscopic hole or absence of one onto a "track" (ie., the spiral and location of data) or memory address location within the disk of the CD medium. Although much of the finalized, usable invention of CD optical recording and playback technology is credited to **James Russel**, some ideas about optical digital recording were already being thought of by some others working for the **Philips Co.** as of the late 1950's, and also by **David Gregg** (1920-2001) while working for a **Western Electric** partner company called **Westrex**, and he even filed a patent for a videodisc concept in 1962. Russel began his optical recording research in about 1965 and by 1973, he developed a prototype version of it and offered it to companies to consider producing it. Many personal computers before about 2022 had CD readers and-or writers ("burners"), but their use is fading because of the newer, completely "solid-state" (having no moving parts to wear out), all digital medium, and having a very high density (many bytes) or amount of memory. This memory is RAM [rewriteable], Random Access Memory) data IC's (integrated circuits "chips") inside many electronic devices. A RAM chip is inside the relatively small USB (Universal Serial [data] Bus) memory sticks that are often called "thumb-drives" for digital data storage. **DVD** (Digital Video Disk) recordings are an advanced form of CD data storage, and a DVD could contain up to several times the data as a CD could.

As of about the year 2000, music and-or other (computer or digital) data can be recorded, stored or saved onto non-mechanical memory IC's (ie., integrated circuits, or "chips") devices, and one common method and-or portable device is called **USB** (Universal Serial Bus having a standardized (bit by bit) serial data connection so as to store data to or from a computer) memory card, a "thumb drive" or "memory stick". A particular modern USB memory stick can hold from 1 GigaBytes (GB, = 1 billion bytes) to perhaps 128 GigaBytes of binary and-or digital data. If this device gets lost or stolen, much valuable data, perhaps proprietary, company, employee, family, friends and personal data is then at a security risk, and you may wish to use your computers software (ie., perhaps a Windows program(s)) so as to secure folders of data on your device(s), and to also make and store "backup" copies of your data. If possible, include a readable, plain text file in the data on the device, and which includes your phone number so as the device may be returned to you, and-or write or engrave your number on the device.

A dynamic (or "magnet and coil", electro-magnetic) microphone was invented in 1877 by **Ernst von Siemens** in Germany and it is very similar to what we know of today as a small loudspeaker, both electrically, physically and mechanically with its suspended, movable coil of wire around a fixed in position permanent magnet. The first practical **loudspeaker** used a suspended or movable coil (about the magnet) and cone, and it was made in 1925 by **Edward Kellog** and **Chester Rice**. In general, it turns electrical current into a varying magnetic field which will interact (attract or repel) and moves in relation to the fixed magnet of the speaker. **Edward Wente** is also credited to inventing the loudspeaker at about the same time. To make speaker, inductor, generator and motor coils, a special wire called **magnet wire** is used, and it is made from copper or aluminum metal and coated with a material to prevent it from electrically shorting with other parts of the coil and-or wire. It is called magnet wire since it is used to develop a magnetic field in it and without it remaining so as it can be used in high frequency circuits. The dynamic loudspeaker and dynamic microphone have similar construction.

Today (as of the year 2021), **condenser microphones** with great audio input sensitivity (ie., able to detect small signals) have mostly replaced the use of the more rugged carbon and dynamic microphones. This microphone consists of a capacitor with two plates, and with one plate that has low mass and weight and is very sensitive to sound (audio) waves and could easily vibrate or move in unison to sound. Because a plate of this capacitor can move, its capacitance value will vary and which will then cause its output electric signal to vary at the same frequency and amplitude as the received audio. The condenser microphone was first invented by **Edward Wente**, from America, in 1916. As of about the year 1995, condenser microphones are in great use as for computers and phones. There are also other types of microphones available, such as the (thin, metallic) ribbon microphone, and which is sometimes used in the recording industry.

Before the invention of the first audio tube amplifier, some principles of the carbon microphone were sometimes used to make audio (low frequency) amplifiers before the invention of tube (or "audio" or "[electronic] valve") amplifiers. The concepts of the change in resistance and-or conductance of the microphone so as to amplify sound would also later be found as part of the understanding and functioning of the semiconductor in a transistor amplifier. Before the transistor, hearing aid sound amplifiers used a small **carbon amplifier**.

How Edison's Electric Lightbulb Made Electronic Signal Amplification Practical

In about 1875 while Edison was experimenting with his **electric light**, he notice an effect that the electricity (ie., current, later to be called as electrons or electron flow) from the hot filament would flow to a (voltage applied) charged metal plate inside the tube or light-bulb, and also having a much higher current when the plate had one voltage or charge polarity than the other. After applying a reverse polarity voltage connection, this resulted in no current flow, hence there was a very high resistance to the flow of current in one direction, and a low resistance to current in the other direction or polarity. Edison therefore essentially created the first man-made electronic "one-way" (ie., direction of flow) valve or diode for electric current, and he did patent it, but he had no immediate use for its application since he was more interested in perfecting the electric light. This "**Edison Effect**" (ie., technically a diode with the **diode effect**) would later be improved and used in a radio receiver as the first practical and reliable (vacuum tube, "tube") diode or **(**thermionic [thermal, hot filament, electron radiator], electronic, not mechanica**l**) "valve" that was practical and formally presented in 1904 by **John Ambrose Fleming** (1849-1945), from England, and while working for the Marconi Company, and which he had helped make the equipment for the first radio transmission across the Atlantic ocean in 1901**.** Before this time, Fleming once worked for the Edison Company in the United States of America and was well aware of the discovery and basic knowledge of the Edison Effect. The input signal to this diode device is applied to a hot filament wire, here as cathode (-) side, and which radiates electrons (here, by thermionic (heat) emission, kinetic energy and electrostatic repulsion by other electrons) as current to a positively charged anode (+) plate in the same vacuum. This diode allowed the practical rectification and-or detection of high frequency radio waves as needed for radio reception, and since this was before practical semiconductor (PN) diodes were understood well and manufactured for practical use,and without the need for properly setting a sensitive "cat-whisker" detector diode. This diode tube is essentially a descendant of the Geissler Tube and Crookes Tube. It is unclear if Fleming new about the invention of the mercury vapor lamp technology invented in 1901, and the mercury arc rectifier in 1902 by **Peter Hewitt** (1861-1921), from America. This was not a sensitive rectifier like the Fleming Valve (diode) is to weak radio signals, but was rather for a more practical (electronic, not mechanical) method of the rectification of high AC current from electricity generators into a high DC current. Again, even this is a descendant of the tubes made by Geissler and Crookes.

Before the electric diode or (electric) "valve" was invented and made practical so as to maintain and-or create a voltage polarity and-or current direction, mechanical (diode-like) methods were used such as the commutator which was a mechanical or physical electrical connection near the rotating shaft or axle of rotating motors and-or generators. Though these could safely handle large amounts of electrical current, they were slow and impractical in terms of being useful for the high (AC) frequencies used radio signals, and not then being able to rectify them to be a form of DC.

Before Edison's incandescent electric light, many already knew that electricity through a material or that a high voltage arc could produce light, but Edison's electric light filament (a hot, light radiator or emitter) was placed in a vacuum so as to not burn (slow combustion) quickly. His filaments of choice was a carbonized wood fiber made from bamboo, and a very thin platinum wire. In 1875, **Joseph Swan** (1828-1914), from England, independently created a practical incandescent light bulb at about the same time as Edison, and his filament was a piece of carbonized plant fiber thread, and then later a drawn cellulose thread. Edison and Swan actually created a company to manufacture electric incandescent lamps (ie., lightbulbs, light-bulbs, light bulbs, "electric lights") which consisted of the best research, manufacturing technology, cost, power required, and the lifespan (average time of use before failure) of the filament and lightbulb. Swan would also invent the use of nitrocellulose plates for creating photographic images, and this eventually lead to movie film reels made from a thin (ie., a film) layer of nitrocellulose. Edison's carbon filament construction was later greatly improved by one of his science and business associates who was an African-American named **Lewis Latimer**. Various types of tungsten metal filaments began to be invented, initially in Austria, Europe by **Alexander Just** and **Franjo Hanaman** in 1904, and in United States by **William Coolidge** in 1910 with his own tungsten filament study and construction, and where he then greatly improved the X-ray tube for medical use in 1913. Tungsten has a very high melting temperature, and is therefore ideal for bright, high current, electric lighting, and high voltage produced X-rays.

Soon after the invention of the vacuum tube diode in 1904 by Fleming, **Lee De Forest** (1873-1961) from the United States of America (USA) created what would become the first reliable and practical electronic signal amplifier called a **triode** in 1906. "Tri" is a word-prefix meaning 3, and the device is much like a 2 lead diode tube, and with another lead and plate (actually a "screen" or plate with holes in it) in the middle of it. The triode was sometimes called an "Audion" or "Audion tube" (ie., audio tube, an electronic audio amplifier tube) a few year later in about 1911 since is was thereafter often used to amplify weak electronic sound (audio) signals (AC voltages and current, electric signals representing the actual audio signals (V,A, frequency, and waveform) so they could be heard as louder in volume. The first triode amplifiers had low gain (perhaps < 10), however putting them in series (ie., "cascading" them), one directly after the other like a chain of amplifiers and-or repeated amplification or multiplication, they would effectively multiplicity the signal gain (amplification) together and act as like one powerful amplifier. If two of these gain of 10 triodes were placed in a cascade amplification mode, the total gain would be: (gain of first triode) x (gain of second triode) = 10 x 10 = 100 , and this is about the average gain of a modern (power, high current capable) transistor. The triode used an electric current heated (hot) cathode (ie., a "filament") so as to give the electrons on it more kinetic energy so as to be easier to be released and repelled by the polarity of the cathode having negative polarity, electromotive force (emf) from the battery supply. The electrons would then gain more kinetic energy while being attracted and traveling closer to the (positive charged, polarity) anode or "plate" terminal of the tube. A small input signal to be amplified was applied to the terminal connected to the triode tube's internal metallic "control screen" or "grid" that is located between the cathode, hot filament (-), and the anode plate (+). The grid is then used to (electronically, electrostatically [electric forces]) control (ie., set the amount of) a much larger current (of electron flow) through the entire device, and this process is what can be called: external electronic current control. With some ("bias" or working) current already flowing through the cathode to the anode, a small or weak AC signal can then be applied to the control grid of which the electric field there would greatly affect nearby electrons, and that input signal can then be used to create an amplified version of itself by modulating or controlling the amount of current flow from the cathode to the anode terminals. When no current is flowing from the cathode to the plate, the tube essentially has a high resistance like an open circuit, and the full supply voltage will be across its terminals. When current is flowing through the tube, it will have a lower internal resistance. For maximum amplification of an input AC or sine waveform, the voltage across the tube is set using an external resistor in series with it to half the supply voltage, and this is called (voltage) biasing (ie., settings) the device, and this is also done with transistor amplifiers which came years later starting in 1947.

The triode and other similar electronic amplification technologies have been a significant technological achievement for mankind till this day because of there prolific usefulness. The triode with both its diode and amplification ability was very useful for improving radio communication [receiving (reception), and-or transmitting (sending)], and for many other devices and products such as record players with loudspeakers, and the internal electronics of both radio and TV receivers (ie. a "TV set"). The triode tube amplifier made radio communication (transmission and reception) practical for the average household to obtain a practical radio receiver and listen to the (demodulated rf) audio (sound, entertainment and news) for extended lengths of time. See [Fig 234] for a basic drawing of a triode tube.

By about 1920 transmitting sound using radio waves was commonplace and radio receivers became less expensive due to price competition, wide-scale manufacturing and availability of triodes and radio-receivers. Vacuum tube amplifiers would later be superseded by the small, low power loss, inexpensive, more reliable transistor amplifiers that were first created 28 years later in 1948. Vacuum tubes (amplifiers, etc) were still in common use for many devices such as in some television (TV) receivers made the 1970's, and even then, most transistorized TV's still had a CRT (cathode ray tube) as the viewing screen up to about the year 2000. As from about the year 2010, most TV's use "digital screens" that use low power and consist of "(LCD) plasma" or LED arrays to reconstruct a decent electronic approximation of the television camera images on the ("pixelized", ie., dots) viewing screen.

After inventing the **triode tube amplifier**, **Lee DeForest** is also credited to inventing the first demonstrable and practical optical and electronic technology of recording an audio or sound signal directly onto movie film images, and in the year 1928. This method is commonly known as "sound on film". Before this time, movies did not have sound, and are sometimes called as "silent movies", or they had an external audio recording on a record which then had to be synced (properly calibrated, aligned, in step or timing with) carefully so as to have the correct and corresponding timing with the subject and-or actors. Sometimes a piano player would play some ambient music while the movie was playing, and-or there were visible, on-screen titles, captions and credits overlayed onto and then into the final movie film images, and-or appended to the start or end of a movie. Before De Forest's work and reality, there were some other (more crude, but inspiring) sound for movies ideas and patents such as by Charles Fritts (1880's), and Ries in 1923.

In 1912, **Edwin Armstrong** (1890-1954) from the USA, while experimenting with a radio receiver with a triode tube amplifier, he invented what is called positive (ie. enhancement, additive) feedback or "regeneration" (ie., reusing), and where a small amount of the (same wave phase) output signal of the RF tuner and amplifier circuit is electrically recombined or joined with the input signal at the control grid (or signal input grid) of the triode amplifier. With this feedback, the total gain of that amplifier was many times more than what the triode could otherwise produce without it. Now, instead of using earphones to hear the sound, large diameter, high power "sound reproducers" or "loud-speakers" could be used. Today these are simply called as "speakers". If the feedback was strong enough, a radio wave frequency, electronic **oscillator** or "signal generator" could then also be created which is often a self-starting oscillator and circuit without the need for any input signal to start the process of making a (tuned, specific frequency) waveform, and this is called an **Armstrong oscillator circuit and-or concept.** This greatly improved the field of radio communication, for before this time, continuous-wave (sine waves) were limited to a relatively low maximum frequency due to that they had to be mechanically made using high speed alternators, or by relatively crude, low frequency electro-mechanical oscillators which worked well for musical organs (electric piano's).

Armstrong was one of the contemporaries of engineers who invented the concepts of superheterodyne for radio receivers. Heterodyning (ie., to create a difference by force) was previously developed by Reginald Fessenden and is a type of advanced tuning concept that is more stable, efficient, but it requires more circuitry such as to combine (ie., "mix") the received AM carrier signal with a fixed high rf frequency sine wave so as to produce a fixed or constant "intermediate frequency (IF)" signal that is the difference (ie., the "beat frequency") of those two combined signals and which is then demodulated (ie., to remove) so as to have just the desired audio signal. **Heterodyning** allows the radio receiver to be more sensitive to the (weak) received radio waves, and more "selective" by offering a more precise (ie., a limited or narrow frequency bandwidth or range) tuned signal with little interference from other radio stations that might be using a transmission frequency just a little higher or a lower than the one desired or selected. Armstrong also found a way to stop the high frequency oscillations in a regeneration receiver, hence this allowed even more amplification, and therefore, he invented the super-regeneration concept and receiver.

In 1933, **Edwin Armstrong** made the first practical "wideband (bandwidth, frequency range)" **FM** (Frequency Modulated radio) transmitter and receiver which has nearly no audible noise, such as from "static electricity" interference caused by lightning which is commonly heard as noise during AM (Amplitude Modulated radio) reception which is based on the amplitude or strength of the received radio wave energy, and lighting will greatly affect that strength, both increasing and decreasing it. FM (Frequency [changing slightly] Modulated radio waves) is often used for "high fidelity" (low noise, "high quality") radio communication. Frequency modulation is when the input information or audio signal slightly can vary the carrier or main radio frequency to be slightly higher or lower in value, and which corresponds to the input signal's amplitude. In an FM receiver, the frequency changes in the tuned or desired ("channel") frequency are converted back into changes in audio amplitude. In general, most FM transmitters are designed to be of lower transmission power than **AM** transmitters, and therefore have a shorter range or distance of radio transmission. This also prevents possible reception interference from other distant (FM, wideband, frequency range for each channel) stations that may be assigned to and using the same frequencies. The standards set by the **FCC** (Federal Communications Commission of the USA) allow AM radio signals to have a maximum allocated frequency bandwidth (ie., total change in frequency) of 10khz and with 5khz below the main carrier, center or "channel" frequency, and 5khz above it. FM radio signals are allocated a 200khz frequency bandwidth and with 75khz below, and 75khz higher than the main assigned carrier frequency. Since FM broadcast stations and their signals and are allocated a wider frequency bandwidth than actually needed, the full audio spectrum of 0hz to 20000hz is easily included into its rf signal, but this also greatly limits the total number of (nearby) stations allocated to the complete, but limited, FM frequency bandwidth communication allocation.

Some "primitive, solid-state-like" or semiconductor discoveries and devices were made years before the first transistor amplifier was discovered, and some of these are discussed next.

In 1874, in Germany, Professor **Karl Braun** first noticed an electrical diode action in certain (semiconductor) crystal materials. A diode is the name given to any device that only allows current in one direction, and is the electric equivalent or analogy of a special (mechanical, force sensitive and operated) valve that is used to permit only one-direction of a gas or fluid flow in a pipe (conduit). This type of mechanical valve is often a "ball-valve" due to its internal construction with a ball that will essentially block the pipe and fluid flow if that fluid goes in the opposite direction for some reason, such as some pressure applied to it someplace. The first non-manufactured, natural and-or primitive, solid-state light emitting diode (LED) was discovered by the British scientist **Henry Joseph Round,** (1881-1966), from England, in 1907. Round worked for Guglielmo Marconi who made many advances in radio (ie., "wireless") communication. Round is also noted as independently discovering the triode amplifier tube, and then positive feedback independently at about the same time as Lee DeForest and Edwin Armstrong. In 1907, Round noticed what is called today as "electro-luminescence" (electrically caused) light being created when a voltage (and a resulting current) was sometimes applied to some locations on certain crystals of minerals such as silicon carbide. Round noticed it was possible to make various colors of light depending on the crystal used, and blue light was one of those colors of which would later prove difficult to manufacture, but it was also surely known to be very possible due to Round's work. Round's observation and discovery was significant, for today, we have LED's in nearly all electronic devices such as in electronic (TV, computer, phone) viewing screens composed of thousands of miniature LED's acting as picture elements (ie., a pixel, an image piece). Surly, a thought of those time must have then been if the yellow glow from a lightning bug was electro-chemical in nature.

Today (2025, and years previous) LED's can be purchased discretely or individually as what is called "LED strips" of multiple LEDs attached to a thin strip of material so as to easily place them on a wall, etc. These LED's are usually placed in parallel, and with each having a current limiting resistor in series to it, but depending on the design and applied voltage of the circuit, sometimes multiple LED's in series might compose each parallel branch. These will usually be powered by either a small, low voltage electric grid "wall transformer", or sometimes directly plugged into the electrical grid, or sometimes battery powered of which a voltage regulator is then usually used to ensure a constant voltage and current to the LED's. Since LED's are much more efficient (ie., light produced / input power in watts) than incandescent lamps, the cost of lighting a room or area will be much less, and more reliable. There are now electrical components called an "active resistor" that can regulate the voltage and therefore, the current to a LED(s), such as if the applied input voltage is changed. This device is essentially a small voltage and current regulator, and for example, it ensures that only 3.3V and about 20ma of current is applied to a white LED.

In the early days of public radio service, many ("solid state", metals of certain elements and-or compounds) minerals were often used for a radio wave detector device. A common detector device was called a point-contact-surface-diode and was informally known as a "cat-whisker" diode. This semi-man-made diode construction includes a thin, hair-like metal wire so as to make contact with the crystal at just a small specific point of which was determined by the radio-operator or listener as having good detection and-or diode action and audio reception. The concept of a special boundary or "junction" (depletion) layer between each element in the crystal and-or cat-whisker was mostly likely started here, and which lead to further understanding of the diode and the development of modern and practical solid state diodes, and then later, the BJT (Bipolar diode Junction Transistor) transistor that has its technology and understanding that is largely based on the concepts of the diode.

Since a diode can only conduct in one direction, it can effectively remove the entire reverse polarity and-or current direction part of an AC wave or signal. This is called AC to DC conversion or **rectification**. The (half ac-wave, half-wave, or half-rectified) output from the diode will still have a general form of the AC input signal in terms of the varying amplitude of that portion of the wave that was effectively passed through the diode and not blocked. Because half the AC signal is blocked 50% of it and its available power is blocked by the diode. To output a complete and-or steady DC voltage and-or signal is have a full-wave or complete AC rectification. This will allow most of the input AC available power to be available as DC power. To accomplish this will require the use of an energy storage device such as a **capacitor** that is charged up to the maximum voltage of that input AC signal, and then to release that power or charge when the diode is not conducting. The larger this storage capacitor is, the more charge it can hold and the longer it will take to be released through a circuit, and this effectively "smooths" or "levels" the DC output voltage to be a more consistent or constant value with a low value of AC "ripple" or voltage fluctuations.

An AC power source can be made using a DC power source such as a battery that has its current output being controlled and varied by several high power, "current pass through" transistors that are in series with that battery. The amount of current passing through these transistors is being controlled by the output signal from a small power, AC, sinusoidal oscillation circuit. There are premade DC to AC converters available for purchase at many and various types of stores, and these are often marketed as **(AC to DC) power inverters**, and some are capable of creating a few watts to over a thousand watts of AC power. For sensitive electronics and "just in case", a pure sine wave output inverter is better and more expensive to have than a modified sine output wave inverter. Many power inverters are for converting a common 12V automobile or car battery input power to be a 120Vac output power which is commonly used for and called as household or grid power in the USA and some other western countries. Since the output voltage peak is higher than the input voltage, a voltage "boost", "step-up" or increase is needed, and this is accomplished by using step-up transformers in the inverters circuitry. A common car battery has an amp-hour (aH = current x hours) rating of about 50aH, and this is usually not a "deep-cycle" or "deep-discharge" battery. For example(s), if the battery is still at least 12v, it can supply 50 amps of current for 1 hour of time, or 25 amps for 2 hours of time, or say 10 amps for 5 hours of time. Pmax = V max A max = (12v) (50A) = 600Wmax. rated output or load power. A typical **car alternator** (ie., electricity generator) can create about 600W of electric power at about 14V output to charge this 50 aH battery. Do not have a load of current that exceeds the maximum current of a batteries aH rating. In this example it was 50A max, otherwise higher values and heat can damage the battery. To overcome this problem, and so as to have safe, and larger power available, use a battery with a higher aH rating, and-or similar batteries in parallel. More current means thicker wire will be needed. These wires are usually very short from the battery terminals to the power inverter terminals. When the inverter is in use, it is recommended to also have the alternator charging the car battery at the same time. A 24v, 36v and 48v inverter system will require more batteries, but requires much less current, and therefore for a longer time of use at a given load current. This book has several articles and examples about electrical power inverters, and so you may do an electronic search for them when needed.

Before the transistor was developed, the solid state (non-vacuum tube, etc) diode made from germanium semiconductor metals was developed and manufactured to a high degree of quality and reliability, and was often used as a microwave frequency radio wave detector in **RADAR (Radio Detection And Ranging)** systems for airports and the military so as to detect and display on a screen, the directions and-or location of (metal) airplanes in the sky due to the reflection back of some of the transmitted microwave radio wave energy from a transmitting RADAR station. This process is kind of like shining a flashlight in the dark and seeing what direction and angle that a distant metal coated mirror is located when it reflects the light back to you. RADAR for both weather and plane location began being studied and developed in the 1930's.

Pre-transistor-like devices

Since the development of the two-lead diode tube rectifier, and the three-lead triode tube for amplification in 1906 with its third lead between the two end leads or terminals, it most likely made people consider if there was some way to place a third terminal between the two layers of a (point-contact, "cat whisker") semiconductor diode, typically used in radio receivers, so as to provide some radio signal and-or sound amplification. There have been several claims of such a semiconductor amplifier device(s) having been known about and-or made in about the year 1926 and later, and this was well before the formal creation of the first practical, man-made germanium diode for sale, and then the transistor in 1947, and of which also relied on the newly available and pure semiconductor metal of germanium. These (crude, unstable and-or impractical) (pre) transistor-like devices must of surely inspired the future refinement and development of the transistor. Germanium has largely been replaced by silicon being used for semiconductors since the 1960's. Any such (pre) transistor device must of been impractical to use for most experimenters, but it could of inspired some semiconductor research for creating pure and practical in size semiconductor metals for diodes, and the science of doping them with other metals to slightly enhance their ability to conduct and to create a (pn) diode junction..

The **transistor** is a solid state amplifier. Some people may say that the vacuum tube amplifier was the first solid state amplilfier. It is a word based on "transfer and resistance" whicih loosely means "changeable resistance". A transistor construction is somewhat based on the solid state diode. A **FET** transistor (**F**ield **E**ffect **T**ransistor) has a (first) semiconductor layer or (flow, current) channel with a terminal at each end, but it also has a (second) opposite polarity or type of semiconductor layer surrounding that channel. The overall consturction of a FET is then also somewhat like a common two terminal resistor who's resistance can be controlled and-or varied by the third or input "gate" terminal. The gate is not connected directly to the channel but is actually insulated from. The electronic control is rather done electrostatically. - either enhancing conduction (ie., less internal resistance), or reducting or depleting conduction (ie., more internal resistance) through the channel layer. The **BJT transistor (Bipolar Junction Transistor)** mentioned below, the current flow is not controlled by electrostatic forces, but rather by a small input current.

The **BJT transistor** electronic device was invented in 1947 at Bell Labs in the state of New Jersey, USA. The first working transistor amplifier is credited to **William Shockley, John Bardeen and Walter Brattain** in late 1947 while working for Bell Labs**.** A bipolar junction transistor (BJT) is a small, three layer (NPN type or three layered construction, or PNP type or three layered construction) metal semiconductor(s) material device that functions as an electronic signal controller (ie., an on-off switch), or an AC signal amplifier, and which has replaced most vacuum tube amplifier devices since it is much smaller, much cheaper, and much more efficient since it wastes far less power as heat or thermal energy.

The first BJT transistor used germanium PN junctions, and in 1954 silicon PN junction transistors were invented at Bell Labs. Most modern electronic devices after 1954 have used lower cost silicon transistors which offer several other advantages than that of germanium transistors, and particularly having much less reverse bias "leakage" current. The size of a common low power transistor is slightly less than (1/5 = 0.25) square inches - excluding the wire or "leg" leads. Power transistors can be say a square inch in size. The size of a single transistor on a large (count) scale integrated circuit (IC or "chip") can be very small, nearly microsopic in size as of the year 2025.

The two main types of transistors are the FET, (electric field, electrostatic) Field Effect Transistors, and the (BJT), Bipolar Junction Transistors which can be described as a two-layer (solid state) diode of identical semiconductor material and with a thin (control, or "base") layer made of opposite (electric charge, and carriers) polarity semiconductor material placed between them. A transistor can be tested as being good if the two diode sections are tested as two good diodes that will conduct in one direction and not in the other direction. Essentially, transistors control the flow of current through it with the control layer called the "gate" as for FET's, and the "base" as for BJT's. In general, FET's require higher load voltages to operate than BJT's, and this is due to the (Source to Drain) channel material and its resistance in the FET.

An FET is basically controlled by its input voltage, and a BJT is basically controlled by its input current. It is of note that a single FET generally does not come close to amplifying as much as a single BJT could, but the FET has the advantage of having a very high input resistance or impedance, and therefore it requires almost no input signal current to function, and therefore nearly electrically isolates that transistor's output circuit from that transistor's input circuit. An FET is usually functions faster than a BJT, and therefore a FET is often chosen to be used in very high frequency circuits such as for radio frequency (rf) amplification of the weak radio waves received by a radio antenna. Due to its high input impedance an FET is an ideal choice for the output signal from a tuning or oscillation circuit, whereas, if a lower impedance device was used it would actually reduce the performance of that tuner and or oscillator by effectively lowering its (tuned) impedance and the outputs signal's maximum voltage.

In 1948 **John Bardeen** is credited to inventing the **Insulated Gate Field Effect Transistor** (IG-FET or IGFET), and which its specific technology design lead to the more practical Metallic Oxide Semiconductor Field Effect transistor (**MOSFET , Metalic Oxide Semiconductors, FET**) invented by **Mohamed Atalla** (from Egypt) and **Dawon Kahng** (from Korea) working for the Bell Labs company in 1957. MOSFETS eventually became widely used in both low power, inexpensive (cost per transistor), "high density" or transistor count per unit area, integrated circuits, and for high power transistor-like device applications such as for high current switching and signal amplification due to their fast speed.   It is of note that the BJT was created in 1947, and before the theoretically "more simple" (yet more difficult to produce, and having more consistent device reliability) FET was created and made available between 1957 and 1959. The Junction Field Effect Transistor (**JFET** which is often called as the common FET) manufacture was being studied and developed by several people and companies between 1950 and 1953.

Compared to BJT's, JFET production and device standards have been much more of an problematic issue at first, and it took until many years later to gain a high device reliance from each JFET created, such as a consistent source (S) to drain (D) resistance of a specific (ie., manufactured, registered number, type) JFET of which some circuit initially utilized (and then required) in its design, and for replacement if needed.

Besides being a signal (ac wave) amplifier, the transistor is also used as a simple switch, a fast electronic on-off switch or (solid state, fast, no coil) relay (ie., an electronic equivalent of a water on-off valve), for logic and signal control via electronic ("digital") circuitry, and for data storage in computer or digital memory devices. When used as a switch, the control signal such as the base current in a BJT is at a high enough level so as the collector to emitter resistance becomes the lowest value it can be, much like the low resistance of a closed switch. The transistor is said to be "full on" or completely on and conducting as much as possible. When the control signal or current is 0A, the transistor is not conducting and is said to be "off" and its effective resistance is very high, much like that of an open circuit or switch. In terms of (on-off switching) speed, as of the year 2022, BJT's are still capable at operating at a higher frequencies than MOSFET's, and in both cases, the smaller the device, the more faster it can be due to less internal capacitance, and the smaller the distance that the charge carriers have to travel through the device during the full on (conduction) to full off (no conduction, high resistance) states of it. JFET's can operate at high frequencies and are becoming close the (switching and frequency handling) speeds of many BJT's as of the year 2022.

Before transistors were finally created, some of the initial patented concepts and-or theory of the (future) FET transistor, such as for a possible electrostatic control with semiconductor materials as the conductor were conceived in about 1925 by **Dr. Julius Edgar Lilienfeld** (1882-1963) who was an immigrant from Austria-Hungary to America. Because his conceptual device and-or idea required high purity semiconductor materials, he did not make any known example or public demonstration, and his idea was therefore remained as a theoretical one, an inspiration, and to become realized. Lilienfeld is also credited to inventing the **electrolytic (ie., liquid electrolyte) capacitor** in 1931. These capacitors are said to be "polarized" (have a positive (+) and negative (-) electric polarity plates and indicated terminals and-or current direction) due to the materials used for the plates and the liquid-paste electrolyte between them. These capacitors have a very thin (essentially, electrically or electrostatically polarized so as to store electrons) oxide layer for the dielectric material, and have a large capacitance (ie., charge and-or energy storage) for its volume and-or small size, and are therefore used in many electronic circuits where a high capacitance using a small sized capacitor is needed. Because of this very thin layer of construction, the maximum safe or "breakdown" voltage between the two plates of these types of capacitors is generally a low value. Like the FET's theory of operation, a capacitor relies on an electric field to function, and of which most likely got Lilienfeld thinking about a device (ie., the FET) to control the flow of current using static electricity or charges. Perhaps some of his reasoning is also based on some of the concepts of Crooks tubes, and the glass tube, triode amplifier. Generally, electrolytic or polarized capacitors are not recommended for AC circuits such as audio (electric) signal circuits which constantly change polarity - particularly if the applied voltage changes between above and below ground = 0v, and particularly so for the high power circuits and a ("plain") non-polarized ("ac") capacitor should then be used. **DANGER: Applying reverse bias voltage to a polarized capacitor can cause it to eventually**

explode. It is of note that the term electrolytic capacitor seems to have been used for (low power) liquid (diode) rectifiers since about 1913, such as for example having an aluminum plate that will develop an oxide layer, and an iron plate for the other terminal, and with an certain dissolved electrolyte substance to aid current conduction between them. To build a satisfactory oxide layer, it was done slowly using a low amount of current, and by first using a series load of say a lower power lightbulb(s). The oxide layer could also have been initially started using a chemical solution and process. These diodes have a relatively high reverse bias or leakage current, and several liquid diodes could be put in series so as to reduce that. Lilienfeld's capacitor could then be said as being a solid electrolytic capacitor. To prevent electric shocks and-or injury, do not touch a capacitor that was not discharged first. For a time reference of technology, the relatively high-tech (for those times) diode tubes were formally invented many years previously in 1904 by Flemming, and this goes to show that many new concepts and improvements are still possible in the realm of "lower-tech" or "previous-tech" devices.

A simple descriptive analogy of electronic amplifiers such as a triode - "tube amplifier", or transistor ("solid state amplifier") is to first consider a tiny easy to operate simple electrical switch (or possibly a mechanical pipe valve) that controls the (on or off) power to a machine that requires a high current. Now consider if that switch had the capability to be someplace between on and off, such as in a class A, transistor amplifier circuit, and can vary (increase or decrease) or limit the amount of power to that machine at some level between full off, to full on. In this center or "bias" (operational) position or state, and with no AC signal applied to the input or control pin or lead, half the total possible DC power of the battery or supply voltage is passing through the transistor, but there will be no AC output signal output until there is an AC input signal. Due to amplification of the input signals, even small changes in the input signal or switch position can control huge changes in the output power. This is very similar to what happens in a light dimmer switch which is basically a variable (adjustable) resistor controlling the amount of output power to the light. For a tube amplifier, the control is the center "grid" (a metal screen), and for a transistor, the control is the base (as for a BJT transistor), or gate (as for an FET transistor). The gate material of a FET is insulated from the main current or conductance channel that is constructed between the source and drain leads, and therefore the FET has very high input impedance [ie., AC effective resistance] with almost 0 current needed for it to operate like a switch or (low-gain) amplifier, and it is rather a (electric charge) voltage operated or controlled device. The FET device is ideal for amplifying weak radio signals, requires almost no current since it has a very high input impedance, and without reducing the efficiency of the radio's tuner circuitry. The main result of these electronic amplification devices is that a small input signal can control and-or vary (ie., modulate, affect) the transistors conduction or performance ability, and it creates a larger or amplified output AC signal that is essentially an exact and amplified (ie., multiplied, or a magnified image) copy of the smaller AC input or control signal.

The increase or multiplication factor that an input signal is amplified by an amplifier is called the gain (A), and which is simply the ratio of the output signal to the input signal, and which is numerically how many times more or greater that the (amplified) output signal is than the weaker input signal.

Voltage Gain = voltage amplification = Av = (output voltage) / (input voltage) mathematically:
(output voltage) = (Av) (input voltage) as for an FET , likewise: (output current) = Ai (input current) as for a BJT

It is sometimes necessary to amplify a signal that was already amplified, and the resulting gain is the product of the two gains of the series connected ("or cascaded") amplifiers: Total signal gain or amplification of this system can be shown to be simply the product of the gains within that system, hence a gain of another gain:

(Gain or Amplification 1)(Gain or Amplification 2) = (A1)(A2) = At. and

$$\text{Total Gain} = At = \frac{\text{(output signal)}}{\text{(input signal)}} \ , \quad \text{(output signal)} = At\ \text{(input signal)}. \quad : \text{use voltage, current, or power for signal)}$$

If designed properly, two transistors can be specially connected one after the other (ie., cascaded) and so as to effectively increase the resulting gain, and which is the product of the gain of each transistor. Special 3-terminal transistors have even been made that do this more easily and they are called **Darlington transistors**. This construction effectively functions as a single, very high gain transistor that is generally unavailable. Many Op-amp (or opamp) IC's with their characteristic high input impedance can also create high gains with their on-chip amplifier(s). One of the most common

Darlington transistors is the MPSA13 with an AC signal gain (ie., hfe) of about 10000. This amount of gain is very useful for small signals such as weak radio signals, however any noise is also amplified this much also unless it was filtered out first and-or later.

In digital ("1's and 0's") electronic circuits, transistors are usually used as very fast and simple electronic ("on and off", or "1 and 0") switches for logical (truth) decisions and results, performing mathematical operations using binary values, and-or for storing the bits (ie., digits) of data and-or binary numbers to be used for mathematical calculations and their results.

Semiconductors

As previously mentioned in this book, some preliminary solid-state or semiconductor electronics before the invention of the transistor actually goes back to the first effective discovery of effectively a **light emitting diode** (LED) by the British scientist **J.H. Round** in 1907. He noticed some "electro-luminescence" (electrically caused light) being created when a voltage (and a resulting current) was applied to certain minerals (such as silicon carbide) crystals composed of certain elements. Many of these (solid state, metals) minerals were often used for a "cat whisker" (a thin hair-like metal wire for point of [surface] contact, electrical connector) part of a radio wave "detector" (ie., technically a half-wave rectifier) device. A radio wave detector used in the first radio receivers was effective as an (ac) radio wave (audio signal) extractor or demodulator, and has a one-direction (dc) diode-like action, hence a basic (ac) to (dc) signal converter. A theory of a special boundary or "junction" (depletion) layer (such as an oxide layer) between each element in the crystal and-or the cat whisker wire, was mostly likely started here, and which eventually lead to further understanding and man-made production of the diode and further development of modern high speed and-or power diodes, the three-layer (NPN, or PNP) BJT transistor amplifier - diode-like. layered construction, and even the modern and efficient light emitting diodes.

In 1894, **Dr. Jagadish Chandra Bose** (1858-1937), from India, was the first to discover and use (what was to be eventually called a semiconductor) metals (here, naturally formed "metallic crystals") as a radio wave detector, particularly with (high frequency, generally direct line of sight) **microwaves** which have a very high radio wave frequency and therefore also have a very short wavelength. Unlike the first coherer, radio energy or wave detector, this device was very fast and with a with high frequency ability, and it did not need to be physically reset after each pulse of energy. In 1901 he patented the first crystal **(**modernly called a **"solid-state", semiconductor**, and here with **galena** [a natural lead and sulfide (sulfur) compound], (semiconductor) metal radio detector, and of which had a thin metal wire as the other metal necessary for the detector (ie., diode or rectification) action, and general electrical conductivity required for a circuit. Today, we understand more thoroughly that a (necessary) junction and-or a (electric field caused, and a current) barrier region between the two metals is created. Perhaps Bose was considering the mystery of the two different types of metals used in the construction of a single voltaic cell of a battery. Two years before Marconi's radio-telegraph communication system, in 1895 and inspired by Hertz's previous experiments with both creating radio waves and the detection of, Bose was the first pioneer in **microwave** (have a short wavelength) radio-wave creation, transmission and detection (via a solid-state metallic detector that he invented). Bose made microwaves using a specially designed electric spark-gap, transmission and detection system. He was the first to create what can be called as radio signaling, and which can be thought of as (electronic) remote-control or switching remotely at a distance without a wire. Like Hertz, he associated and studied invisible radio waves as being similar to that of visible light waves which can be directed, reflected, but microwaves can also pass through non-metalic materials like walls between the rooms of a house. Though his galena device (fundamentally called a radio-wave or microwave detector) worked, the physical properties and concepts of semiconductors and diodes were generally unknown at that time, very limited in use, and that it just happened to work so as to be useful. This mysterious, magical, and very useful device inspired others to research these types of devices (ie., diodes) and materials so as to improve upon radio wave detection, and then later to be used for voice demodulation or audio detection (particularly by isolating or filtering it from the received radio signal [electric wave energy, voltage, current, frequency] so as it could be properly heard and not effectively lost due to effective out of phase signal cancellation) such as for AM (Amplitude Modulated) radio wave communication and for many other electronic circuits. After many years of research and technology, high frequency signals such as microwaves are used in RADAR (to locate distant planes via radio energy reflection), communications, and to heat many food products in a microwave-oven.

Greenleaf Whittier (G.W.) Pickard (1877-1956) from the United States of America is credited to the first study of identifying and using many types of semiconductor metals, often in a natural crystal form, and which when deliberately joined together, they and their **junction** (surface area connection) have a diode action necessary for radio wave receivers that are often called "**crystal radios**" so as to distinguish them from the vacuum-tube (electronic amplifier) radios available. He also patented the first **silicon crystal** as a radio detector in 1906. This book contains a basic and common crystal radio circuit of which you can also research, experiment and improved upon. You may also research both long-wire and (portable) loop (directional, coiled) antennas and their circuits so as to improve the amount of radio energy collected so as to be able to hear weak and-or distant stations. The farther a radio signal travels, the weaker or lower its intensity and-or energy becomes per unit of area. This is due to the energy expanding like a cone shape outwards, and also encountering air molecules in the atmosphere. AM radio reception can often be improved simply by turning the radio and-or antenna to a direction having the best audio performance, hence often in the direction of the transmitting antenna or radio energy source.

Many types of solid state, "cat whisker" diodes were put into use at about this time, especially for the use of radio reception, and when considering the high cost of vacuum tube amplifiers and the relatively large amount of energy needed to make them function, and the ("warm-up") time to heat up the filament to its normal operating temperature so as to emit electrons. The commonly used semiconductor mineral used for "amateur" radio receivers ("crystal radios") was often lead-sulfide ("galena", a lead and sulfur compound, PbS, and found or minded as an ore). A thin wire was the other terminal or contact used to (audibly, via the carbon headphones [speakers]) locate and set "sweet spots" in the mineral that would provided the best or a reasonable diode rectification action and the best possible, loudest, highest power, audio quality output. The diode blocked either the negative side or positive side of the incoming (ac) radio wave so as the audio portion could be heard (with the sensitive earphones) when the (high frequency) AM radio wave with the sound information in it are not effectively canceled out in the (low frequency operated) earphones when not using the diode. The high frequency radio wave cannot be heard in the headphones since the headphones are too low in natural resonant frequency and effectively filter out or remove the high frequency radio wave, but the lower frequency audio (AM) wave or fluctuations will still be heard.

Pure lead will not create a diode action, but lead-sulfide (called galena metal) does, and this started much research of what was happening microscopically and-or at the atomic level so as to produce a lower conduction, and diode (one-way, direction) action to current movement or flow. Lead sulfide does not conduct electricity as good as pure lead, and hence it was called as one of the semiconductor materials now known. First of all, elements such as sulfur and phosphorous are non-conductive elements, so it is reasonable to expected that mixing a conductor and non-conductor together creates a semi-conductor. Because two different metals were always part of the construction of a diode and-or for the diode action it indicates that something is probably happening at their junction or contact region, often with an oxide and-or depletion layer. Today after much scientific research, we now know that the diode action of two metals has to do with the applied voltage across the diode or its junction region, and which then creates a static charge region, either causing an abundance or a lack of the two types of charge at the junction region, and which then affects conduction and-or resistance of the diode.

Galena is a lead crystal (atomic bonding with a geometric arrangement and structure) structure that has some trace (about 13.6% by weight) amount of sulfur atoms mixed (aka, "doped" = containing just small "trace" amounts of only, impurities, contaminants, additives and-or enhancements for a particular purpose) in it. The ratio of the mass (and corresponding weight) of lead atoms to that of the mass of sulfur atoms in a galena crystal is about 1 to 1. This does not mean that there is an equal number of atoms of lead and sulfur, but rather there are an equal number of atomic particles (protons and neutrons) from the atoms of each element. Since their mass are the same, the weight of each will also be the same. Galena is essentially a naturally made equivalent to a modern day N or P type doped germanium or silicon crystal used for semiconductors such as diodes and transistors. Note, the materials (ie., elements) used and the percentage of "doping" in modern semiconductors may not be so similar to that of natural or man-made galena, and is in fact much less of a percentage due to the nature of silicon and germanium crystal structures. Galena has a bandgap of about 0.4 electron-volts (eV). A (energy) **bandgap** of a specific material is the amount of energy (with units of Joules) needed to remove or free an electron (that is usually, relatively far from the nucleus of the atom) from an atom and promote the conduction of electricity (the flow (ie., current) of charges) in and-or through the material. This negatively charged electron moving about will essentially leave behind a hole in the atomic crystal structure, and that atom then has a net positive charge. When an electron fills the hole, its gained bandgap amount of kinetic energy is then released as emitted light energy such as seen in an **LED** (Light Emitting Diode, and of which a common Red LED has a relatively low bandgap of about 2 ev). Many man-made semiconductor materials are doped with phosphorous to create an N-type semiconductor with an excess of electrons in its crystal structure, or with boron so as to create a P-type semiconductor with a lack of electrons, and therefore having an excess of holes in its crystal structure. This doping greatly improves the conductivity of a semiconductor material, and it also gives it a main (N or P) polarity and sensitivity to an applied voltage polarity. Both N and P type semiconductor pieces are used to build diodes, transistors and other semiconductor devices. Electrons in the farthest orbit about an atom's nucleus are called valence electrons and the electric forces of attraction are weaker at this distance, and it is then more easier to free a valence electron than any other closer electron.

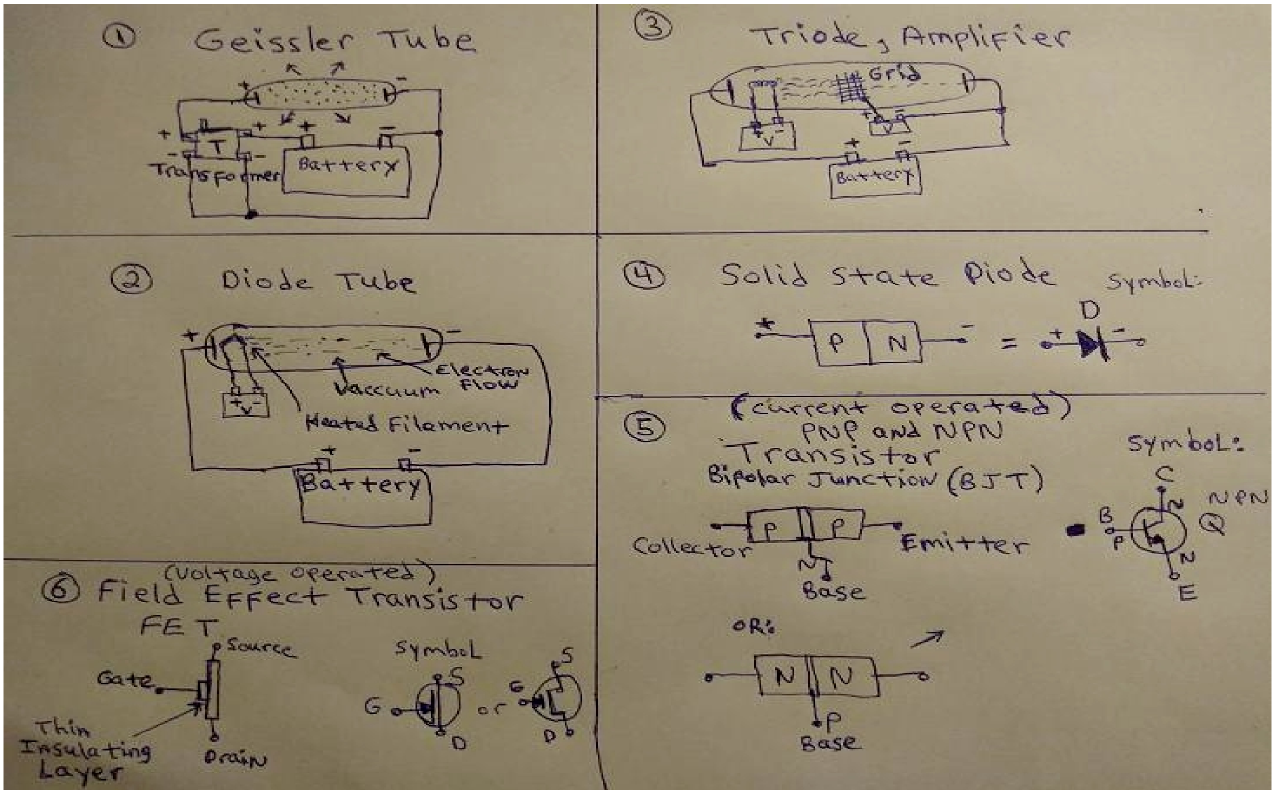
Solid-state diodes (non-tube, metallic, passive - no external (bias, setting, turn-on) power needed to make them function) began to be studied in the 1870's, and this was before the era of having pure, refined silicon and germanium semiconductor metal. Some common examples are the **copper-oxide rectifier** (about 1925), and the **selenium rectifier** (1933), and these were often used to convert (ie., rectify) AC to DC for powering electronic devices. The construction of these devices usually included some other metal(s) and-or (pn junction) plates. Just like with modern silicon diodes, these early types of diodes could be placed in series so as to increase the total rectifying power (VI). Solid-state diodes required no warm up time like a tube diode, and they did not waste power (as heat) like a tube does.

If you are interested in homemade diodes, look up the zinc-oxide diode, and the aluminum-oxide diode. These are relatively easy to make, and the zinc-oxide diode has a very low turn on voltage of about that of a germanium diode often used in a (crystal, experimental, low-cost) radio receiver. The germanium diode has the advantage of being housed in a small protective glass case, and is relatively inexpensive, less fragile and more reliable. Modernly, new precision manufactured types of zinc-oxide diodes are capable of very high frequencies of many Gigahertz. Some zinc-oxide diodes are also LED versions. There are several websites that you can search for and know of, such as: **sparkbangbuzz.com** that have many interesting homemade diode and other electronic projects. Zinc metal is commonly available as dry-cell battery cases, and the protective covering of steel and of which is then called **galvanized** steel, generally meaning electrically modified steel since it prevents oxidation (rusting). A homemade diode will generally be of the fine wire or "cat whisker" type, and of which a diode conduction spot is to then be found by trial and error and then set. Some diodes have a metal to a (doped) semiconductor junction, and are called Schottky diodes, and some diodes have a junction of two (doped, pn) semiconductors. **Schottky diodes** also have a low forward or on-voltage of about 0.25v if the current is low (a few milli-amps), and these are ideal for low signals such as radio signals. **1N34A** (by the Sylvania Co. in 1946) germanium diodes are **still recommended for crystal radios** since they will generally produce a more faithful output (and audio signal) of the intended audio due to their low "turn on" or forward voltage. 1n34 types are also generally only for low frequency signals due to their relatively high junction capacitance, and therefore, their longer turn-on and turn-off times. A heated hot and cooled a piece of certain types of thin steel, such as some utility knife blades, can form a very thin, "blued" colored iron oxide, or perhaps a selenium dioxide layer or coating on it, and this makes quite a good Schottky diode for radio reception, and having a forward or on-voltage of about 0.2v to 0.3v. Some alternatives to the**1n34A** are the AA117, AA119, AA143, AAZ15, AAZ17, BAT46, 1N270, 1N695A, 1N949, 1N3287, 1N3592, 1N3773, OA47, OA90, OA91, and especially the **1N60 or 1N60P** germanium diode with a slightly less forward bias voltage needed. It is of note that diodes also do conduct with a lesser extent with a voltage less than their rated turn-on voltage, and the values mentioned here, are for their rated turn-on voltage where they begin to conduct well and the diode has a lower effective resistance to current. Some diodes can be, or may need to be biased slightly so as to improve the resulting electronic audio signal in a radio receiver. This can be done using a voltage, say between 1.5v and 9v, and a series connected high variable resistance, say 500k ohms or 1M ohms in a voltage divider configuration, and then connected this circuit across the diode. If would be wise to also include a series resistor, say 47k ohms, as a safety resistor to prevent high current damage to the potentiometer or variable resistor when it is set at a very low resistance setting.

In 1946, the first manufactured, practical, reliable and commercial (point-contact, "whisker" (ex. a very thin tungsten wire)) diode was made available to the public and industries. This diode is actually a pre-Schottky diode (which most likely inspired Schottky to study it) and a favorite of crystal radio receiver makers due to its low turn-on or forward voltage needed, about 0.35v, and is the 1N34A germanium diode. A few years before this time, these diodes were available to only the military, and were used in RADAR (Radio Detection And Ranging) systems to detect planes and their location(s) in the sky. It was a purified germanium (metallic, crystalline) point-contact (whisker) semiconductor diode. 1N21 (year

1940), 1N31 and other similar diodes were typically used in (high frequency) RADAR systems for finding airplane locations (direction and distance). This diode is technically a type of (Walter, 1886-1978, from Germany) **Schottky diode** which is a metal (wire point, whisker) and semiconductor junction diode, and has a low "turn on" (forward, conduction or barrier) voltage of about 0.35v (or less, and when the current is kept low, otherwise it will increase) and it has fast turn on (conduction) and-or turn off (non-conduction) switching time and can therefore be used for very high frequency circuits. It is a very practical and efficient diode to use with weak radio signals such as that received by many radio receivers. A common Schottky diode is the **1n5817** which has a max. rated current of 1A. and a max. reverse bias voltage of 20V. The 1n5819 is similar but with max. reverse bias of 40V. The 1n5622 is similar to the 1n5819, but it has a 3A max. current rating. It is of note that it is possible for some electronic tinkerers to make a practical homemade diode with various metals and-or semiconductors such as zinc-oxide diode that could have similar electrical characteristics of a machine manufactured germanium diode. Schottky and Erwin Gerlach invented the ribbon microphone in 1924, and which are generally said to be as sensitive or greater than that of some quality condenser microphones.

Russell Ohl (1898-1987), from the USA, while working for AT&T Bell Labs in 1939 is credited to purifying silicon to over 99% purity, and so as to eventually make the first practical and commercial "(PN) solid-state" diode. He is also credited with the modern understanding and concepts of the necessary diode barrier-junction (**PN**) region, and the concepts of solar cells to create electricity (as of 1941) using the light sensitive properties of silicon and the barrier region between the P and N joined pieces. A P or positive region essentially has a hole or gap in its crystal structure, and the N or negative region has an extra electron in its crystal structure. Light striking the barrier or junction region would create a voltage (ie., v = J/C, electronic energy so as to move electrons (ie., a current) with electric forces). These silicon **solar-cells** created by some engineers at **Bell Laboratories** ([Alexander Graham] "**Bell Labs**") in 1954 initially had a relatively low efficiency (about 5%) of converting solar light energy into electric energy (moving or flowing [like a water current] electrons with kinetic energy), but it was still very promising and also useful for electronic light sensors and small electrical devices and batteries. A solar cell is sometimes described as a large PN junction diode. PN refers to a positive (P) electrical polarity and-or majority current carrier type, and negative (N) polarity and-or majority current carrier semiconductor type of (purified and lightly "doped" (added in), metallic) materials. Solar-cells were used to power most of the man-made satellites sent to outer-space starting in 1958. The PN solid-state discoveries would lead Bell Labs to begin research for a solid state electronic signal amplifier based on the practical solid-state diode, its manufacturing process, and the basic concepts of the vacuum tube amplifier having a current control grid in the middle. This "solid state" (semiconductor) amplifier device invented a few years later in 1948 would be called a transistor. Many other similar (germanium or silicon, PN junction(s)) electrical devices, including the first practical and commercial **LED (Light Emitting Diode)** light soon followed these (seemingly more advanced) discoveries. Below is a crude, but helpful basic, and not to scale drawing of some of these electronic devices. [FIG 234]



The first practical (reliable, easy to use, commercial) **LED** (light emitting diode) light was invented by **Nick Holonyak** (1928-2022) at a General Electric Co. laboratory in 1962. The light emitted was red in color. These LED's required about 2 volts and 10mA of current to function reasonably. If the current is increased slightly (up to a few milliamps (mA) more, maximum), the light intensity will also increase due to the increase in power sent to it. The power (voltage x current) to an LED can be controlled or limited by using a resistor with an appropriate, calculated ohms value of resistance. The price of these LED's was initially very high and therefore not worth using with most electronics devices. As of the year 2020, a bag of 100 red, yellow or green LED's can be had for about $5USD. 7 or 8 segment LED numeric displays are composed of 7 or 8 individual, long LED's of which each can be individually turned on or off by a circuit and so as to display a number such as for calculators, watches, meters and other various counters. The general construction of an LED is very similar to that of a typical PN diode,and with using a correct voltage polarity (+v anode , -v cathode) to function, except that the LED is also designed to produce and radiate much more visible light. Holonyak is also credited to inventing the first visible **laser diode** in 1962. The Monsanto Co. began producing relatively low cost red LED's in 1968. These LED's required 1.65v forward voltage, and about 20mA of current. Red LED's are mostly used for circuit operation and-or as indicator lights, and sometimes for when low light levels are needed, such as for astronomers at nighttime.. Before white LED's were available, yellow LED's could be used to make a homemade reasonable efficient and long lasting electric light. Astronomers, if needing to see what they are doing, will use a red light so as to help maintain their eye's light sensitivity to faint light at night and which is commonly called their "night vision". Single LED's are typically produced as either a 3mm or 5mm housing width about the actual LED diode chip.

Before the technology was created to make white-light emitting LED's, a common goal was to make LED's having a particular color such as often: red, amber, yellow, and green. Later, a low efficiency blue LED's was roughly developed in 1972 at the RCA co. in the USA, and then a much more efficient design was created in Japan in 1992, particularly by **Shuji Nakamura**, and of which eventually lead to the very useful white LED. All LED's usually use a specific alloy layer of gallium and another element. Having a white LED, it can then be covered or coated with any color desired.

White light emitting LED's were always desired and were finally produced in 1996 and became widely available at about the year 2000, but they were still relatively expensive and were often used in high quality, efficient (lumens/watt) flashlights. At about the year 2010, white light emitting LED's became cheap in cost so as to be used as a part of many electronic devices including lights (ie., lamps). The advantages of LED's over other forms of electronic lighting is that they are cheap (low cost, sometimes 100 white-light emitting LEDs for just $10 USD as of the year 2020), small, require low power (ex., a voltage of about 3v to 3.3vmax rated (although up to about 4.2v is possible but may shorten the usage time or function life of it) and a typical current of about 20mA to 30mA max for a white LED, hence a power of about: **Pw max. = 3.3v max. X 0.030A max = 0.099W =~ 100mW**) to be used, produce more light or lumens per watt of input power and are therefore more efficient at converting electrical energy to light energy. Two 1.5v batteries in series is sufficient to light and-or power a white or most other colors LED. **Lumens** is the measurement of the light intensity per unit area (1 ft^2, or 1 m^2) at a standard reference distance (1 ft, or 1m) from the light source, and hence it is usually called the brightness level of the light being transmitted to the object being illuminated (ie., radiated, transmitted to) by that light. Compared to incandescent lamps, LED's produce a relatively low amounts of heat per amount of power input and-or light produced. A modern (2022) LED might be rated between 100 and 200 lumens per watt, whereas an incandescent (ie., thermally generated and radiated light) light bulb might be rated at just 10 lumens per watt, hence an LED can produce at least 10 times more light per watt. Because LED's are more efficient, they will produce more photons or light and which is rated as lumens per watt. LED's can be 45% efficient on average, whereas an incandescent light is about 15% efficient on average. This means that for an LED, 45% of the input energy is converted to light energy, and (100% - 45%) = 55% is wasted as heat energy. As of the year 2020 most light-bulbs designed for household lighting (some costing as low as $1USD) and high brightness streetlamps now use LED light-bulbs. White LED's can be covered with an opaque colored coverings and-or decorative shapes. The emitted color of LED's is sometimes expressed as "Degrees K" = "Degrees Kelvin". Incandescent lamp light color is about 2000°K, and has a slightly yellow-red hue, whereas a white LED light color is about 4000°K. Higher temperature LEDs will be rated at about 5000°K and have a slight blue hue, however, some people may not like this due to potential eye problems.

In general, white LED's, and LED's have a relatively low maximum reverse voltage of which they will usually be damaged, and this is only about 5V regardless of how small the current is, but it is very possible to protect an LED using a standard diode (such as an 1N4007) in reverse polarity and then placed across and-or parallel to it, and which will turn on first to 0.7V, and which also has a series resistor to limit current through it.

There are some modern,specialty LED's. Some LED's transmit invisible, low frequency infrared light, such as for sending remote control signals, and some LED's transmit high frequency, ultraviolet light which is relatively dangerous and precautions must be observed. Some LED's have a convenient built in current limiting resistor so as the LED will function when connected directly to a specific voltage. RGB LED's have three led color chips in them with a corresponding external lead. Some LED's have a small internal IC (integrated circuit) that will cause the LED to blink periodically. Small LED's are known as "rice lights" and are mostly used for various decorations, however a small flashlight can still be made using them. The value of light in an emergency is priceless. Some LED's are lasers that transmit a single frequency (ie., monochromatic light) of high power light though a very narrow (small) transmission angle and-or beam, and precautions must be observed so as to prevent damage and-or injuries. Depending on its power, a use and license may be required.
Alexander Graham Bell (1847-1922) from the United Kingdom, and later Canada, along with his electro-mechanical assistant Thomas A. Watson, invented the **telephone system** in 1876, which electrically converted (electronically simulated as an electrical signal composed of voltage and current) and transmitted an input sound (audio, voice, air pressure wave) signal using a long wire electrical circuit connection to a distant sound reproducer (ie., electrical transducer [causing a energy transformation, hence a "transformer" of sorts] or audio "speaker"). Bell's "talk piece" or microphone was a crude "liquid microphone". About a year later, Bell would significantly improved his telephone system by using Edison's and Berliner's more efficient and sensitive carbon microphone (input [mechanical, force or pressure] sound signal converter or transducer to an electrical signal). The invention of the telephone was initially based on some of the concepts of the already existing telegraph system and its technology. Both the telegraph, and particularly the telephone are extremely significant for both short and long distance communication. These device became very important, both personally and socially valuable. The telegraph communication methods were also adapted for use with the wireless radio communication systems, particularly with the (initial) use of Morse code before radio could transmit audio information well. The telephone system quickly became very practical and desired in businesses and households for people to communicate due to its ease, widespread availability, low costs, general privacy and without the need to learn Morse code to communicate such as generally needed for the telegraph (remote-graphing and-or sounding [audio bell or

buzzer]) system.

Alexander Bain, a clock-maker from Scotland, was the first to conceive how images could be transmitted via the telegraph system in 1843. His idea considered that an image or photograph could somehow be scanned (horizontal) line by line and dot by dot (ie., "pixels" = picture elements), and this concept was much like how a modern image is both scanned to be transmitted and also seen on a television screen. **Frederick Bakewell**, from England, succeeded in transmitting a crude image via the telegraph system in 1847. The first transmission of high resolution, fine detailed images and-or text was sent using a device called a **pantelegraph** that was invented by **Giovanni Caselli**, from Italy, in 1856. The first photo-electric system for image transmission, and which used a (selenium) photocell for the image and-or light intensity sensor was invented by **Arthur Korn** from Germany in 1901. By 1924, images could be transmitted wirelessly via radiotelegraphy.

Elisha Gray (1835-1901), from the United States, was a telegraph engineer like Bell was. At about the same time as Bell's telephone patent application, he independently filed a patent application for a telephone ("remote-sound", electronic communication) system. Gray was one of the founding members of Western Electric Company. Gray invented the first practical type of "**fax**" (facsimile = "making similar") machine and system called the **telautograph** in 1887, and which could reproduce detailed handwriting over the telephone system, and was more accurate than the ones previously invented in Europe that needed a complex system of a rotating drum, and it needed perfect (synchronized, coincidental) timing so as to have a reasonably accurate reproduction or facsimile (modernly called as a "Fax") image of the source image transmitted via the telegraph system. Gray is also credited to making what could be called the first practical electronic musical instrument and-or system in 1874. It was called an electro-harmonic or music telegraph. Since speech could not be transmitted over the telegraph system for various reasons such as the technology was not yet available or impractical, Grey considered transmitting musical tone signals (particularly their frequency's) using via their equivalent or representative electronic signals. With this invention, Grey invented a form of (mechanical) vibration microphone or "sound pickup", and a crude form of a loudspeaker which has an electromagnet to make the sound vibrations from the input electric signal. This instrument was basically an electric organ, and where each note and its corresponding current variations or "fluctuations" at a particular frequency were automatically determined by a corresponding, thin metal reed that could vibrate at a particular natural resonant frequency. Each acoustic and-or electric representational tone of it was therefore produced by what could be called a "(metal) reed oscillator", and which was powered by an electromagnet, and much like how an electric buzzer is operated as a type of (electro-mechanical) oscillator. What was Grey initially thinking? Grey most likely wanted to replace the "dot" and "dash" electronic Morse code pulses with two different and discernible audio tones at the receiver, thus improving the telegraph system for some people to decode the pulses more accurately.

Alexander Graham Bell was born and raised in the United Kingdom but immigrated to Canada, and then to Boston city in the United States of America (USA) just to the south of Canada. Bell often worked with educating the deaf and helping their community. Bell made an improvement in sound recording and playback by creating a modified version of Edison's phonograph system. Bell also invented the photo-phone where sound could be transmitted using sound modified ("modulating", varied, here the intensity) light waves transmitted through the air to an electronic sensor or receiver placed at a short distance away. This was one of the first significant uses of the newly discovered (by **Willoughby Smith** (1828-1891), from England, in about 1873) light or photo-sensitive, photo-conductive electrical materials. The light sensitive or reactive material used was **selenium** which is a metallic element that can vary its electrical (ie., electricity) resistance in direct relationship to the amount of light intensity upon its surface. Selenium is said to be a **semiconductor** material that does not conduct electricity very well like a typical metal, but still conducts better than a resistor. Semiconductors are usually sensitive to light, heat, etc., which will proportionally vary their electrical properties such as its electrical resistance when some type of energy is applied to them. It is said that the "band-gap" or amount of energy (joules or "electron volts") needed for a semiconductor atoms to release (from their orbit and force of electric attraction) or give off electrons and conduct electricity is slightly greater than that of a standard electric conductor or metal. The temperature level of something very hot can be sensed by using a probe that has temperature sensor (ie., a heat to electricity "transducer" or converter) made of a semiconductor material. In about 1879, **George Carey** (1851-1906), from America, conceived of a crude (electronic) camera system having an array of selenium photo-sensors that could sense the light levels of an object and so as to send the (crude, low resolution) image of it electronically (via many wires, one for each photo-sensor), hence it was a type of (crude or primitive, wired, direct connection) television. The image could be recreated and seen by using an electric light for each light sensor used, but probably a electro-mechanical solenoid operated flap could be used instead of a light, but this would not be as fast. His device was experimental, and it surely inspired many in the future. An image sensor(s) is now common in (digital) image scanners (copiers) and cameras of which have made photography very practical and affordable, and especially for quickly sending an image with modern electronic digital communication such as the internet ("web").

Charles Fritts (1850-1903), from America, essentially created the first solid-state electrical generator or **solarcell** in 1883. He created this device when he coated selenium (a semiconductor metal) with a very thin, nearly clear layer of gold on the light receiving side, and it had a metal plate on the other side so as to make a second electrical connection for it to function in an electrical and-or conduction circuit. It had a low efficiency (less than 2%) of converting sunlight energy to electrical energy. Surly this device must have eventually inspired some of the later solid state research, construction, manufacturing and technology such as with the diodes, transistors and other metals used for modern solarcells. His PV (photo-voltaic [pv], photo or light energy to electrical energy) solar-cell fabrication would be called today as a form of a Shottky (semiconductor to metal) type of solar cell where one terminal or solarcell layer was not a semiconductor metal, but rather a conductive metal. In theory, an area of a square meter of his pv-cells could provide about (1000w/m^2)(1.5% efficiency) = 15W (ie., 15 joules of energy per second) of power, hence it is enough to charge a battery over a period of time, and which can then deliver a much higher amount of power (energy / second), and in particular, a high current for a shorter amount of time when needed. P = energy / time = (voltage)(current) = VA

Before the PV device invented by Charles Fritts, **Alexandre Edmond Becquerel** (1820-1891), from France and who was the father of Henri Becquerel who made discoveries about radiation energy, previously made the initial discovery of the **photo-voltaic (PV) or "Becquerel Effect"** in 1839. With this effect, a generated voltage (emf) is created due to light energy, and therefore, a current through a circuit is also produced. His light sensor and-or (energy) converter used two platinum wires in a silver compound solution. It must be mentioned that at those times, the technical understanding of how these (semi-conductor, layer, junction) devices worked was mostly unclear, and a mystery until the research by Albert Einstein years later, and then by Bell Labs who created the first transistor (used for switching or amplification). The basic process of the photo-voltaic effect is that if a photon of light has enough energy, it can collide with and knock an electron out from its orbit about an atom of certain materials and-or electrons with a low enough (energy) "band-gap" that is equal to or less than the energy of that photon of light.

Thomas Seebeck (1770-1831), from Germany, discovered the **thermo-electric effect** in 1821 when using two different metals and heating their junction and noticing a small current flow. A thermo--electric generator converts heat energy to electric energy, and is therefore much like an electric heater in a "reverse" type of operation or function. This current flow is due to the voltage created at the metal junction(s) of which can also be connected in electrical series so as to create a larger voltage and current - much like how stacked (ie., in series) voltaic cells in a battery can produce a higher voltage and current. Seebeck's device had a low conversion efficiency and it was of little practical use other than for a very good temperature sensor (micro-volts per degree Kelvin) = (uV / 1K°) which is usually called a **thermocouple** device or sensor so as to measure temperatures, and it is an interesting topic for further future research, discoveries and products. The Seebeck coefficient (v / °K) for (PN) semiconductor and-or alloy junctions is many times that as compared to regular or common metal junctions, and arrays of these junctions can be assembled so as to create a device called a **thermopile** which has a higher output voltage and-or current. This discovery is also called the Peltier-Seebeck effect, and modern, more efficient ones are used in some more modern electrical devices (perhaps a simple radio receiver) such as to make some useful electrical power by using "waste heat" energy, and-or to create a cooling effect from the input of electrical energy. This use of the device in this reverse type of way is called the **Peltier Effect** and is essentially the reverse of the Seebeck effect. In one version of these devices, heat is applied to one metal junction or side, and cooling is applied to another metal junction or side, and the output voltage and current will increase with an increase in the temperature difference of the two metals and-or sides. If a voltage and current is rather applied to a **thermopile**, one side will increase in temperature and the other will decrease in temperature depending on the voltage polarity used for each side, and it is then possible to use it to make a small insulated refrigerator container to keep things cool inside it, and where the warm side has a reasonably large external heat-sink/radiator to help increase the temperature difference and efficiency of the device. The transfer of heat to one side is due to the heated electrons which have gained thermal energy and transformed it to their kinetic energy and will then carry it to the other side of the device which will then become warmer, and the other side where the electrons were form will become cooler.

About 20 years after Charles Fritts's solar cell technology, **George Cove**, from Nova Scotia in Canada, was the first to produce some small (about a square meter or more), relatively cheap (using zinc and other metals for the semiconductor) and practical solar-electric (pv = photo-voltaic) generator systems in about 1904 and later, and they had an appreciable energy conversion efficiency (estimated at 5%), and this is a reasonable value, but it was much less than the modern (as of 2021) 17% to 25% (more complex) solar-cells and -or solar-panels. Cove's PV (solar-electric) system was a great achievement at those times, but overall, it wasn't needed for the average person and home, especially if they already had convenient and high power electricity supplied via wires form the electric utility company. Also, clear skies, shadeless open space, and aiming it directly at the (apparently moving, changing position) Sun is always needed for best use and highest efficiency. In 1980, the average price/watt of solar-electric energy was about $20USD/watt. In 1986 the average price per watt began to be relatively affordable for the wealthy at about $10USD/watt. As after about the year 1996, silicon solar panels were in great demand by the general public, and they were becoming relatively cheap at about $4 to $5USD/watt generated. In about the year 2010, about $1 per watt became common, and due to the increased demand, manufacturing abilities, lower cost of transportation for supplies and distribution, and competition. This price is very reasonable and practical for the average person to afford some form of solar-electric energy. As of the year 2022, it is still hoped that the use of solar generated electricity will greatly increase to several times more, especially in terms of portable energy, energy availability and security, especially for critical applications such as for hospitals and vital industries such as to produce food products and medicines.

The first practical phone system, and many of its concepts are still available and-or being used today as of the year 2022, was created by **Alexander Graham Bell** and it used DC rechargeable batteries at the local phone company to power the telephone system. Each phone company or station had some employees called "telephone operators" who would take your request to be connected or (electrically) "switched" ("telephone operators" were also called "**switchboard operators**") by using a small cable or wire called a "patch cable" to connect the callers phone electric circuit directly to another phone that they are "calling" so as to communicate with someone using their own phone transceiver (transmitter and receiver). A small (magnetic, DC) generator inside each phone would be used to "ring" (by powering and sounding an [oscillating] electric buzzer or bell), signal or alert the telephone company operator of a phone communication request, and the operator would listen to your verbal request and then connect (via a short "patch cable") your phone circuit to the desired recipient's phone circuit and then "ring" or alert them via an electronic bell sound so as to "answer" or "pick-up" their phone and communicate. Years later, and made practical in the 1950's (but actually invented several decades before in about 1896 by **John** and **Charles Erickson** and **Frank Lundquist**, with their "automatic telephone" system which included electric "rotary dialing" (ie., for the assigned phone number of the recipient's phone), and automatic (ie., electronic) connection switching to each desired person, home, or business containing a phone(s) that was assigned its own unique "phone number" (technically a unique switch(s) setting at the local telephone station) when the phone system became automated so as to directly connect the caller and recipient phones, and without the need for the assistance of an operator. Here, a desired phone number was first entered or "dialed" using a "rotary-dial" - a circular mechanical switch that is selected and moved and set by the callers finger. This switch mechanism sent a series of electric pules to the phone station for each digit of the phone number entered. Still, if operator assistance was needed, perhaps when trying to find a phone number assigned to someone or someplace, a person could simply dial a "0" to connect to the operator. Rotary phones began to be replaced in about 1963 with "push button" or "tone" phones which sent fast and unique electric-audio tones to the phone station, and which when electronically decoded, it represented the phone number being requested or called. Many modern phone systems also use the special number of **911** to remember and quickly call for emergency assistance. Most phones today as of the year 2022 are wireless or radio telephones called as "**cell phones**", **"mobile phones"** and-or "**smart phones**" due to all their internal computer circuitry and abilities such as having access to the Internet communication system. Older phones that used a direct wire connection to the phone system and company are now called as "land-line" (ie., using wires or "electric lines") phones.

Preparing for communication problems.

During some local disaster of any sort, telephone communication, especially with cell phones, becomes problematic and-or unlikely, and you should consider obtaining some backup communication such as a radio transmitter of some practical sort. Learn how to use and maintain it, and tell other members of your household and-or community how to use a specific communication system. Write a guide on paper(s) if need be. These communication systems can be powered by a previously charged battery(s) and-or solar panel(s) electrical power system. Knowing what radio frequencies to use will be very helpful, and this book mentions some radio frequencies, especially with the CB (Citizens Band, public, legal, no-license required, but here are still several rules to follow) radio system. **In general, and in many countries and-or locations, radio receivers of any sort are legal without a license, but please check first so that you do not break the local laws and risk prosecution.**

More About Batteries

The word "battery" is actually another and older word for an "array" (one or several) of similar things, such as individual electricity generating voltaic cells that can be used to store (ie., "be charged up", accumulate) or create (by chemical energy) free electrons as potential electrical energy. This energy can then be transferred or delivered via conduction wires to another location and-or electric circuit, and in the form of an (electric, electron) current (flow, moving) that has (kinetic, in motion or active) electrical energy and-or power (voltage and current) to do things. Electric energy is called "electricity". Electrons have or carry (kinetic) energy with their momentum that consists of their small mass but high velocity. The movement or flow (or "current", from one point to another, somewhat like a water flow or current moving to a lower or ground level, and then having less energy) of electrons is naturally called a current of electrons. **Capacitors** (basically two plates of metal that are very close to each other) can accumulate (build up, increase or increment the amount of, store, "condense") and store the flowing electrons (ie., electrical charges) and then release those stored electrons as electrical power (P = V x I) much like a battery does. A single voltaic cell and-or a battery of cells voltage depends on the materials (ie., metals, chemicals, electrolyte) and construction used, and the amount of energy it can safely store and-or release is mainly determined by its size or volume. Common cell voltages (v, volts) are 1.5v for chemical, non-rechargeable batteries such as from these smaller to larger (volume) standard types: AAA, AA, C and D. There are also 1.2v similar sized rechargeable batteries, especially if a lithium type, however it must be then determined how useful this lower voltage and power will be for any particular device, unless that specific device was initially designed to use 1.2v rechargeable batteries such as the lithium types. Three 1.2v batteries in series can create a 3(1.2v) = 3.6v battery,and this is quite adequate for a white led which needs at least 3v , and about 20ma to 30ma to function as a lamp (an "electric torch" or light source)

Liquid fuels can have a energy density or concentration stated and-or rated as for example: (joules of energy / gram or Kg of fuel weight). Batteries can be stated and-or rated as having an energy density of (joules of energy / gram or kg of battery weight).

Lithium types of batteries have a higher energy density (Joules / Kg of battery weight) or (aH / Kg of battery weight), or more often as: (Wh / Kg) = J/Kg as compared to most other (non- lead-acid) rechargeable batteries which have a rating of about 40Wh/kg. In general lithium batteries have at least twice that of lead-acid batteries. A common and popular (as of about the year 2020, due to its portability, size, weight, and energy storage ability) **lithium** (internal metal material or construction), rechargeable battery is called an **18650 lithium-ion battery (LI-Ion)** due to its physical dimensions or size, and has a rated average and-or expected working voltage of about **3.7v (typically 50% charge or power left)**, but many may be safely charged up to a maximum of **4.2v**. A typical 18650 battery at 4.2v will have a fairly high rate of voltage reduction till it reaches about 3.7v at where the rate is of voltage reduction is a gradual downward slope till about 3.2v. When this battery is drained ("0% rated charge left") of its energy when down to about **3.2v**, and no less than about **2.75v to 3v**, it is usually considered drained and useless of its rated energy and-or circuit design needs, and the battery needs to then be recharged before more is drained and degrades the battery by internal crystal growths and corresponding higher internal resistance which reduces voltage, current and therefore power available. For comparison, a 12v lead-acid car battery is considered drained at any less than its 12v rated value, and yet 50% of its charge and-or energy still remains in that battery, and this should not be used since the battery can then get damaged inside. At less than about 3v, a lithium battery has given nearly all of its internal charge, energy or power, and the internal resistance of the 18650 battery has also increased significantly and will offer even much less output power due to the internal power loss, and this heat created can damage the battery and-or shorten its life and the number of further charging and discharging cycles. A **Lithium Iron Phosphate battery (LiFePO4 or LFP)** cell has a slightly less voltage rating than a regular lithium-ion battery, and that value is **3.2V** with a max of about **3.7v**., but some may charge to about 4v for when the batteries are in an array and so as to all be "equalized" to having the same voltage more effectively to say 3.2v or so. A LiFePO4 cell should not be allowed to go lower than **2.5v**, and hopefully the battery system has a **battery management system (BMS)** to prevent things like this. The BMS will usually equalize each cell on the battery. If 4 LiFePO4 batteries are connected in series, the charging voltage is then about 4 times that of 1 cell, hence: 4(3.2v) = 12.8v (and usually generally rated as a 12v battery, but may state 12.8v on the battery, and with the lowest safe voltage at 10v). Note that a lead-acid battery charger designed to charge lead-acid batteries to a max. of about 14.7 v will be too much voltage for the LiFePO4 batteries, hence they will need a charger that is capable and-or designed to do so, say generally to **13.5V max** (some people say this is actually below 100% of total possible charge, but it is safer and that the battery type maintains its voltage quite well as compared to a lead-acid battery. In short, charging to say 14.6V (if the BMS and-or charger even allows it) is excessive and the battery will drain quickly from that peak voltage so as to be about a consistent 13.5v), however some chargers can also be set to charge to specific voltages, etc. Also, although maximum discharge currents can be a high temporary (in time amount) value for most batteries, the charging current is still recommended to be only about 20% or less of the Ah or "C", current rating of the battery. Some advanced battery chargers, and some are inexpensive, have a setting for the specific type of battery that will be charged. Some chargers can essentially "reset" the BMS so as to allow the charging of a battery that has been drained to low, and the charging current should likewise be low and slow so as to not overheat the battery and damage it in the process.

A damaged battery and-or one which went too low or high in voltage is a fire hazard. Do not open or puncture a lithium battery for it short circuit (ie., unwanted electrical contact, low resistance, very high current) may get hot and begin a chemical fire that does not need oxygen and will ignite or combust even in water. Store batteries in a proper, certified and-or recommended container(s), and insulated each battery and-or container from each other and any other potential fire hazard. If possible, place a hot or damaged lithium battery into a metal container that had some sand or dry dirt in the bottom of it, and cover the battery with more sand, and then place the lid on the can, and move the container to an open area so as to prevent a larger fire. Contact the police and-or fire department if you feel the situtation needs it.

LiFePO4 batteries have less thermal issues and more recharging cycles than that of Lithium-Ion batteries, however Lithium-Ion batteries can store slightly more energy than that of LiFePO4 batteries.

Placing identical batteries in series (s) will increase the output voltage, and placing identical batteries in parallel (p) will increase the total energy capacity, current and-or time of use. For example, (n) batteries in parallel will extend the use time by the same factor of (n). Experienced electrical minded people can make a custom made battery pack, but extra caution must be observe when dealing with lithium batteries. One caution is to prevent overcharging (ie. > 4.2v), over discharging (ie. < 3v), and a short circuit load, and a **battery management circuit and-or module is recommended**.

For **charging and-or recharging lithium batteries**, there are commonly available, simple to use, small size, inexpensive circuit boards such as the **TP4056** (very common as of the writing of the book, 2025), **TP4069**, **TP5100 IC (**similar to TP4056, but for example, it has a 2A max charge current, and it can also charge two batteries in series)**,** and **CD42** which is a 5V USB to (3.7v to 4.2v) lithium battery (or parallel batteries pack to increase maH or aH capacity) with 5v regulated output. These circuits have various parts, ports (sometimes a 5v USB port), input and output battery protections (if needed, and-or when the lithium cell does not have any built in protection circuit) can be purchased so as to easily charge (typical, 3.6v rated, to nearly 4v max) lithium batteries more safely. These circuit boards have a USB input power terminal or jack port, and you may need to check if its standard size or miniature size, etc. The default (constant, regulated) charging current is set by an on-board current setting (or "programmable") resistor so as to be 1A max. and this is usually sufficient, however when charging smaller lithium batteries at only 10% of their rated max. (constant) current capacity, say 0.1A = 100mA charging current, the on-board current setting resistor should be calculated and increased in ohms so as to reduce the current to that desired value. Some of these circuit boards and-or lithium battery protection circuits also have a low voltage cut off feature so as to protect the lithium battery from being drained too low at about 2.5 or 3v. Note that a white LED operates at about 3v or slightly higher (say between 2.5v to nearly a 5v range - if the current is controlled to less than about 30mA, and 20mA is often the recommended and test current for its light output rating - about 1 lumen from a 15° beam angle of the LED). These common lithium batteries are about an inch thick and 3 inches long, and many can be electronically connected together in series so as to create and increase the total output voltage, or be connected in parallel so as to increase the maximum current availability and-or a longer time of use before that battery is drained of its energy (electrons and their charge) and needs to be recharged so as it can be used again as a power source.

Connecting sets of **similar** batteries in both a series and parallel configuration, both the total voltage and total current can be a multiple of just one single battery, and therefore the maximum stored energy and-or the maximum output power ability will be a multiple of just one battery. When a battery's stored charge (electrons) and energy is draining through the circuit, the voltage across its terminals will reduce since V = J / C. Any energy or power lost in the circuit is equivalent to the energy or power delivered, drained or removed form the battery. Once this voltage level of a battery has reduced to a certain rated, "safe" low value, the battery should be recharged before using it so as to always have the maximum possible energy available, and-or to prevent damage to that battery.

As of the year 2020, most electronic devices can now be designed to use rechargeable batteries as their power source, and so as to the reduce the incredible waste, time and costs of standard non-rechargeable batteries. The most common rechargeable battery in use as of the year 2020, contains a metal mixture that contains some lithium metal on one of its internal plates. Lithium is classified as a "rare-earth" metal and is therefore correspondingly expensive. There is always research being done so as to create rechargeable batteries either cheaper and-or with a higher energy density.

As of the year 2020, a typical "lithium battery" of any amp-hour (aH) rating has only about 0.3 grams of pure lithium metal per 1 aH of battery rating. This mathematically corresponds to 1 gram of lithium =~ 0.035oz of lithium per 3.3aH of battery rating. 1 oz =~ 28.35g of pure elemental lithium metal, as of the year 2020, will cost about $10900 USD which is about the price of a good used automobile or about 5.8oz of precious gold. The price per gram of lithium is about: $384USD/gram, and so it is well worth recycling it. Lithium-ion batteries have a "life" (usefulness) of about 400 charge cycles (full charged to fully discharged) on average, but can have many times more "partial charges" if the battery is only partially discharged and (slowly, low current, say (1/10) the max rated output of 1C , hence 0.1C.) recharged, and which is recommended so as to prevent crystal-like growths within the battery that will limit its (energy, charge, electrons) future storage capacity and "life". A typical constructed, currently popular, 18650 lithium-ion rechargeable battery has an amp-hour (aH) rating of about 2000 maH = 2 aH, but it may be more for some brands. This battery is constructed like a long, rolled up capacitor with two plates or electrodes, and of which due to its length, its internal resistance increases, and so as to decrease it, the plates are made to have a larger area for larger batteries with a higher aH or Wh capacity. A **"protected lithium-ion" battery** has a small internal circuit (often called a Protection Circuit Board - PCB) so as to prevent over-charging (>4.2Vmax), over-discharging (< 3V, and with about only 20% of its total internal charge remaining) and sometimes may have short circuit, current limiting and-or thermal protection, and these batteries will cost more, but it is still a good value, and these are a slightly longer (by a few mm) 18650 battery with a "button top" instead of a "flat top" regular 18650 battery. Most lithium battery charger devices (ie., a charge controller") and-or batteries include some battery protection circuitry (**BMS B**attery **M**anagement **S**ystem), but do not assume an electrical device, being powered by unprotected batteries as having any battery protection circuitry within it, and so it is wise to purchase batteries with the protection circuit already built in. For extended life or charge cycles, it is generally not recommended to charge lithium batteries to its max. possible 4.2v, but say 85% of this value which is about **3.5v**. If you are powering low power devices such as a LED flashlight,then 3.2v will do alright, and it will extend the battery life even further. If you are placing batteries in series to power a device, then you must account for what voltages are in effect with this system, and how to charge this battery. Sometimes each battery can be charged separately, or in series, or in parallel. It is best to charge only similar batteries of the same capacity and voltage rating if they are to be used to create a larger battery with a larger capacity or power output rating. Similar batteries in parallel will have a max. current rating of about the sum of the rating of each battery. If possible monitor the voltage (usually when operating, with a power load) of a battery, and small, inexpensive LED voltage displays are available, and of which can be occasionally operated by installing a push button switch.

It is possible to make a homemade, portable, and-or emergency power supply for an homemade (electric) **arc-welder** by connecting about three 12v large, high current batteries such as automobile batteries in series with thick wires that can transmit high amounts of current due to its low resistance. Technically, 1 to 4, 12v batteries will work, but lower voltages produce a lower amounts of current and-the corresponding generated heat to melt metal with will be lower. Higher voltages above 48v are generally not used for arc-welding. Common "jumper cables" (wires) for a typical automobile batteries are rated at about 400A, such as to power the starter motor (ie., "cranking" or [piston, movement cycle] "turn-over" so as to rotate the pistons and motor for needed air and fuel compression and then fuel ignition and a started, self sustaining motor) during a brief amount of time, however to charge an automobile battery, usually much less current is used and for a much longer period of time (ie., "slow charging"). A **spot-welder** is designed to give a brief high pulse or amount of current so as to quickly melt two pieces of metal together in a small localized area A spot-welder is often used in the process of electrically connecting batteries together using thin strips of nickel metal. An option to this method is to purchase specially made battery holders that can hold the entire amount of batteries needed, and which allow connections to be made by wire soldering or already have the connections made as part of the battery holder.

On the amount of power used from a battery:

A battery may be rated by the recommended, maximum amount of power that can be safely drawn (taken, removed) for one hour of time so as to keep it from getting hot. This value does not consider any high power drains of energy during just a brief amount of time; perhaps a minute or less.

Since 1 hour = 3600s, 1wH = 1 watt of power applied for a total of 3600s = 1 joule of energy used per second, and for a total of 3600 seconds, which may be intermittent and actually occur during a much longer period of time, and sometimes with a high amount of energy or joules being used, and sometimes with a low amount of energy or joules being used.
1 wH = (1J/s)(1H) = (1J/s)(3600s) = 3600 joules of energy. :1 watt-hour = 1wH : total energy available or used

To help rationalize this value, consider the energy needed and-or stored by lifting a mass of 1Kg a height or distance of 1 meter: E = joules = (force in Newtons)(distance in meters) = (ma)(meters) = (1Kg)(9.8m/s^2)(1m) = 9.8J =~ 10J (ie. 10 Joules per kilogram, and per meter of distance = ((10J/1Kg) / m) = 10J / 1Kg-m). If the distance was 1000 times more, hence 1Km of distance, the energy needed and-or stored would be 1000 times more at: (1000) 10J = 10000J.

Likewise 1 kilowatt-hour = **1 kwH** = 1000 watts of power applied for a total of 1h = 3600 seconds. 1kwH = (1000J/s)(3600s) **= 3600000 joules of energy** = 3.6 million joules of energy = 3.6 MJ of energy = 3.6 mega-joules of energy = 3.6 (10^6) Joules .

Watts = energy / second = Joules / second = J/s . V = J / C , J = VC and A = C/s , C = As , using substitution:
J = VAs = (power)(s) = **(watts)(s)** , also note above that: s = C / A = (total charge) / (rate or amt. of charge flow)

1 watt-hour = 1 wH = (1 watt)(1 hour) = (1 watt)(3600s) = (1 watt = VI of energy or power) for (1 hour or 3600s of time)
Note that 1 watt-hour of energy can be obtained by many other ways such as:
1wH = (0.5w)(2) = (0.5J/s)(7200s) = 3600J

1 kwH = 1000 wH = (1000 watts)(1h) or= (1000 watts)(3600s) = (1000J/s)(3600s) = 3600000J = 3.6MJ of energy

A lithium-ion battery rated at 3.6v, and 2000 maH = 2aH of current = 2 amps of max. rated current for 1 hour of time, will have a power rating of: P = (V)(I) = (3.6v)(2aH) (3.6v)(2a) for (1H of time) (3.6v)(2a)(1H) = 7.2wH = 7.2 watt-hours. Since 1 hour = 3600s, 7.2wH = can be thought of as: 7.2 watts applied for a total of 3600 seconds = (7.2w)(3600s) = 25920 watt-seconds = 25920 (J/s)(s/1) = 25920 joules in total. Some simple examples of using this rated power value would be using 1 watt of power for 7.2 hours, or 7.2 watts of power for 1 hour.

On the (output) current and-or power rating of a battery:

A battery may be rated as how long it can supply an amount of current an at the battery's rated voltage. This does not mean the a battery is completely drained of its stored energy, and in general it probably has at least half of it left. If the battery is not of the rechargeable type which can be damaged if it is drained of too much energy and-or for too long, that semi-drained battery and its energy can possibly be used for circuits that require a lower voltage. Two lower voltage batteries can also be placed in series so as to have a larger net or total available voltage equal to the sum of voltages.

1 aH = 1 amp-hour = 1 amp of current flowing or delivered for 1 hour of total time of which cold be intermittent.
1 aH = 1 amp-hour = 1A for 3600 seconds of time = 1 Coulomb of charge for 3600 seconds.
Voltage = joules of energy per coulomb of charge = V = J/C. Mathematically, Energy = VC = J = Joules.
Power = energy / s = J / s = VC / s = V (C/s) = VI with units of watts.

Small batteries with a low energy storage capacity and a current ability less than 1 aH are then rated with a lesser unit value which is usually mill-amp hours = maH. Ex. 200maH and 500maH. Sometimes you may find a battery rated as perhaps: 1500 maH = 1.5aH

A 5aH battery can supply a current of 5A for 1 hour.

The rated amount of amp hours of a battery does not mean that the output current being drawn by the load is this value, or must be less, but the amount of amps drawn could be a higher value, and as long as the battery's power rating is not exceeded at any one instant. If the battery's data sheet is available, it may state a maximum continuous current value. Many batteries also allow for a brief (less than a few seconds), high current (often rated) that can be drawn from it.

For example, a cay battery may be rated as 80 amp-hours of current train. 80 aH. means that up to 80 amps of current can be safely drawn for 1 hour of time, and before the battery needs to be recharged. Since a car battery is rated at 12v, if 80 amps of current were drawn by the circuit and pushed out of the battery at this voltage pressure (emf), the maximum rated amount of power that the battery can deliver at its rated voltage is: P = VI = (12v)(80A) = 960 watts of power = 960 joules of energy per second = 960 J/s. If the load circuit is drawing more than this amount of the battery's rated power, then that battery will be drained quickly (probably less than 1 hour of time) and-or damaged due to high heat.

Ex. A 20W device can be powered by a 10 aH rated battery for how long? aH is the product of the continuous current rating and time rating of that battery. The current drawn or needed from this device will be determined by the specific applied voltage to it. If the supply voltage is 12v, then the continuous current drawn for this device is (I = P/V = 20W/12v) = 1.67A Note that 1 aH = (1A of current) for (1 hour of total time of use), or= perhaps (0 .5A) for 2 (hours) etc, and where the product of the (total time) and (total allowable amperage) will equal the (a)(H) = aH rating. 10aH / 1.67A = 6.25 hours. This mentioned battery having a rated output of 12v and a 10aH rating will then have a wH rating of: (V)(aH) = (12v)(10aH) = 120Wh rating. 120Wh / 20W = 6 hrs of total time of use.

Related to the above topics is this article further ahead in this book: A general example of a car or automobile battery and (electrical power) inverter system

Testing the maximum current rating of a battery:

If a battery is rated at (n) Ah, then it should be tested for a few seconds if it can deliver that rated (n) amps of current or whatever rated or stated value it has the max. current. A current and-or amp meter will be needed for this, however a voltage meter can be used to indirectly measure it by measuring the voltage across that metal path, and then dividing by the resistance of that piece of metal used: I = (V across metal) / (Resistance of that metal). The resistance of the metal bar used should be low, and the bare should be thick enough not to glow hot and-or melt. In general, if a battery can only deliver 80% or less of its rated current, it should be replaced if more current is required by the devices(s). A lower current output means a higher internal resistance and power loss within the battery, and it may get hot and-or possibly start a fire or get shorted internally and potentially explode. At the max. rating of current output, say for a 12V battery, and of which is often charged to a higher voltage so to account for its internal voltage drop when it is connected to a circuit, its voltage should be at least 12V or slightly higher during that maximum current test.

For a given battery powered electronic device, such as a flashlight ("electric lamp"), help the consumer and-or user know how long a device will last with a given battery. To know this value of time, time duration test(s) can be performed by powering and-or using the device under certain conditions, such as the air and-or device and battery temperature used, etc.

A special note on using lithium batteries:

As of the year 2020 there are other battery types being considered and-or developed, and they use less or no rare-earth metals, and which could then be an alternative to using the various types of relatively expensive lithium-ion batteries. As of about the year 2020, there are similar size rechargeable lithium batteries that sometimes can be used to directly replace the common or standard sized alkaline batteries. These (usually **1.2v**) lithium batteries are usually slightly lower in voltage by about **0.3v** than the commonly available **1.5v** alkaline battery types in many stores, and this might be problematic for some electrical devices it is to power, especially if the lithium batteries are to placed in series and-or parallel so as to have certain value(s), particularly the voltage, otherwise, they are generally good to use and will save much money, and are therefore recommended. If you will purchase lithium batteries, be sure that you also have and-or purchase a lithium battery charger device.

Automobile ("car") batteries have a standardized, average useful voltage rating of 12v, and most can be charged up to be a maximum of 14.4v. The min. voltage is actually about 12.6v. The average of these two voltages is (12.6v + 14.4v)/ 2 = 27v/2 = 13.5v Since the internal resistance of a battery can build up and reduce output power, the output voltage of a battery should be checked under load (drawing moderate current, ex. with the headlights on) so as to measure the actual "running" or "working" output voltage level of that battery when its internal resistance to current is in effect with the load circuit. This is a reason why a battery is charged slightly above its rated voltage value, and so as to remain longer at its rated voltage value during use with energy discharging from it. Each of the 6 cells connected in series inside a lead-acid 12v rated automobile ("car" [cart]) battery can be charged up to have a voltage of 2.4v maximum. (2.4v)(6) = 14.4v For a 6v rated lead-acid battery with 3 cells in series, then the maximum voltage of that battery is: (2.4v)(3) = 7.2v

Automobile batteries are usually the lead-acid type, are very heavy due to having (dense and heavy) lead metal plates in it, and are not designed to be much below 12v at which point the battery can be damaged by sulfate crystal growth (from the sulfuric acid electrolyte) and-or it may then have problems recharging from the electricity generator in the automobile, and it is best to slowly recharge that battery using a low current if this is the case, and so that there is more time to effectively reverse the problem. A damaged battery may have a reduced current output, and may not be able to charge up to its rated voltage, hence its total power output will be reduce.

The liquid electrolyte between the plates of each cell in a lead-acid battery helps the creation of free electrons and current conduction through the battery without shorting out the plates of the cell with a direct connection. Automobile batteries are designed with large lead plates and so as to provide low resistance and to release a large amount of power (energy, joules, Power = (V)(I)), and particularly in the form of a large amount of amperes of current in a brief amount of time so as a high torque, electric "**starter motor"** can "turn" (move) the cylinders in the engine and cause the initial combustion to get the engine functioning without any further need for the high starting power. Once the car's engine is functioning or "running", the battery and a high voltage step-up **ignition coil** is still needed to produce a high voltage spark in the combustion cylinders when a piston in the cylinder routinely compresses the gas-air mixture near the spark-plug terminal. The spark will ignite the compressed fuel and cause it to combust, and the resulting hot kinetic gases will push the piston downward, and this motion and force will eventually be transferred to the wheels of the car via the mechanical rotating drive train or shaft, and causing the wheels to rotate which then move the car.

A battery will be recharged as needed via a (diode(s)) rectifier and voltage regulator circuit, and while the automobile engine is working and the generator (or "AC alternator") is recharging that battery. When an automobile is not in use, it is recommended to shut the power off to all unnecessary devices being powered by its battery so as to prevent the battery from being drained of its stored energy. If it gets drained, it is possible to "jump start" or recharge that battery by using high power "**jumper wires**" for the connection cables that are usually red and black in color and made of thick wire that connect that drained battery to the same polarity terminals of the battery of a running automobile or battery charger. These cables are relatively inexpensive and should be stored in the trunk of the automobile so as to have them available when in need. Portable and rechargeable "battery packs" can also be purchased for emergency use for when a battery is drained. Note that it will take about 400 "cold cranking" amps or more, but briefly in time, start an engine using a lead-acid battery, and that **most lithium batteries are not capable of providing this and starting a car motor**, and since it may damage that battery which is not designed for this amount of current through and out of it. Automobile battery chargers that use "household" 120Vac power can be purchased and can charge an automobile battery up to 14.4v at reasonably high currents if there is no overheating of the battery such as if it is internally damaged. If enough time is available, relatively low currents of just a few amps, say 1A (for low aH batteries) to 5A or 10A (for high aH batteries), is recommended to charge a drained battery. The recharging current to an automobile battery will also decrease as the battery voltage increases, and this is due to that the difference in voltage potential between the charger and the automobile battery is getting less, and there will be less effective voltage available to charge the battery, and this is generally why it takes so long to charge a battery. Some lead-acid batteries use water as part of their liquid (acid) electrolyte and it could become low in volume over time and use, and it then needs more water, and rather than use "tap water" with various minerals (ie., elements) in it that can reduce the function of the battery, try to use pure water only, and this can be purchased as **distilled or "evaporated" water** that is available at many stores.

As of the year 2021 there have been many recent developments in battery materials, construction and better storage ability or capacity. It is promising for the future when people and businesses are becoming more focused on "green (renewable, non-fossil fuels)" energy and energy security so as to have enough electric power available when needed, and this will require more localized power storage and-or generation stations, and of which will also include homes generating electricity from solar panels on their roofs.

As of the year 2024, the retail or store price of a lithium-iron-phosphate (LiFePO4) battery is about **$3.5 USD per aH** = (10000mAH) for batteries less than about 50aH, and is about **$2 USD per aH** for greater aH batteries. For an example, a 3.2V battery of this construction could power a 25mA white light LED for: (1000mA / 0.025) = 40 hours , hence almost 2 days of continuous use, however, if it is on for only a few minutes at a time, there could be many times more days of available use of that light circuit, perhaps 30 days. Be sure to buy a charger also. About the price in terms of rated Wh = (rated voltage)(rated aH current), Ex. 1 Wh of energy from a lithium battery is about (12V)(50aH) = 600Wh. If the price of this battery is $100 USD, the price per **Wh** is: (price) / (Wh) = $100 / 600 = $**0.17 USD / 1 Wh** For comparison, this is about the year 2024 cost for 1KwH of electricity in the USA, and which is a thousand times more power, but if the battery can be recharged say 1000 times then the lifetime use of that battery is then about $0.17USD / 1 Wh. Larger aH batteries are commonly about 10% to 20% lower in price per aH and wH due to that the sale price is essentially due to bulk size and-or energy capacity. The main problem with larger batteries is their increasing size and weight, and more difficult portability.

Some further lithium and-or rechargeable battery considerations:

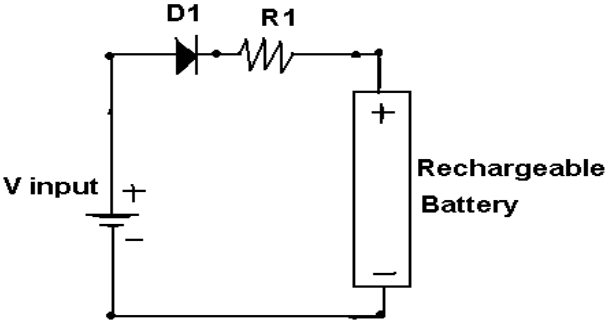
Typical Max. Voltage: 4.2 v
Average and-or Rated Voltage: 3.7 v
Min. Voltage (3 to 3.2 v)

Look on the battery label or data sheet for its mAH charge and-or storage capacity:

Ex. A lithium battery may be rated as: 3.7 v , 550 mAH , 2.4 Wh . 3.7 is the rated and-or typical (ie., average) voltage of the battery. 550 mAH = 0.550AH is the maximum (and safe, low heat) current drain, and is available for 1 hour total, before the current is reduced to a lower value since the voltage of the battery will be lower. 2.4 Wh is the total rated power available consistently. Pw = (VI) = (4.2V)(0.55A) = 2.31w calculated =~ 2.4 Wh rated. 2.4Wh can be thought of as 2.4W for 1 hour, or even 1W for 2.4 hours, and so on, and the product of (watts)(hours) is always 2.4Wh for this specific battery.

In general, the maximum voltage of a lead-acid car battery is about 1.2 times at of its rated 12v value, hence about 20% more than its rated voltage. For example, the max. voltage for a 12v rated lead-acid battery is: (12v)(1.2) = 14.4v. For a typical lithium battery with a 3.7v rating, the factor is slightly less at about (1.14) such as for the 18650 battery, here, the max. voltage is: (3.7v)(1.14) =~ 4.2v . This is about 14% more than its rated voltage.

Here is a simple, homemade rechargeable battery charging circuit example. [FIG 234A]



In the above circuit, V input is a DC source and-or supply of power (V and I), but it could also be an AC source if it is converted to a DC source and-or steady, constant power with components such as a voltage regulator (best, since it eliminates the internal resistance of the battery into the charging circuit), and-or capacitors and-or diodes such as with a "bridge rectifier". The source may very well be a 5V USB supply. The diode represents voltage regulation and-or a voltage drop such as 0.7V across a silicon diode, and which then leaves (5.0 - 0.7v) = 4.3v to charge the battery. If the supply voltage is higher by about 0.7V, you can use several diodes in series to reduce the supply voltage to that needed for the specific battery being recharged. A diode also prevents discharging the battery through the voltage source if it that voltage source gets lower than the voltage of the battery and there is then a new difference in voltage (ie., emf or [voltage, energy] pressure difference). The resistor chosen is to reduce the maximum charging current to the battery to say 10% to 20% of its rated capacity for heat, fire and possible explosion safety reasons. **(Imax of circuit being powered by the battery = Vmax / mAH)** , and for charging the battery safely us a resistor: **R = Vmax / (10% of Imax)** = 4.2v / (10% mAH). Ex. R = 4.2v / 0.1A = 42 ohms, and a 47 ohm resistor is a common and close value to use. Pr = I^2R = (0.1)^2 (47ohms) = 0.47W, hence a (1/2)W = 500mW = 0.5W power resistor is needed, or possibly use two, 22 ohm, (1/4 W) resistors in series, or two, 100 ohm resistors in parallel, etc.. Charging a battery that was drained to a low voltage is a fire hazard due to a relatively high internal resistance that will dissipate heat into the battery., and it is recommended to use a very low current if it must be done. For most circuits, consider an on/off switch an indicator light(s) such as an LED(s) in parallel with the supply battery with a series resistor to limit its current to a safe value. As the voltage of the battery being recharged increases, the current to it will decrease due to the "back or reverse emf" making the net potential difference applied and current lower, and it is then possible to then reduce the value of R1 to a lower value - perhaps using a resistor(s) switched in series or parallel to it., and so as to increase the current to the battery to its 10% or 20% (charging and discharging) rated **current capacity rating** (ie., "**C-rating**") value. Ex. 0.2C = 20% of its continuous current rating. Note the C-rating is different than, and usually much lower than the temporary maximum "surge" current rating of a battery. Many charging and-or discharging modules (pre-made circuits) have a constant current output and other battery protection methods such as overcharging prevention, low voltage shut off protection, short-circuit protection. Larger batteries will usually have a larger C-rating and can store more energy per unit of volume and or weight.

How fast the voltage (ie., potential energy) of a battery is reduced depends upon the amount of energy drained and-or used form the battery. Lithium batteries are said as not having a (plate or electrolyte) memory and-or required need to fully discharge slowly and recharge slowly, but still a lower charge and discharge current say 10% to 20% of the maximum rated capacity is recommended to reduce the internal heat (ie., power loss, due to resistance) within the battery, and therefore to prolong the life and number of charges (ie., charging and discharging cycles) that the battery will have. It is recommended to not drain the battery to less than 30% max, however, 50% max. is a more typical value of its rated total capacity - and that for a lithium battery is **not** (3.7v x 50% = 3.7v x 0.50 or= 3.7v / 2 =) 1.85v, but is rather about 3.5v and where the internal resistance of the battery has increased, limiting its current ability and increasing its internal heat and power losses. Keep lithium batteries away from both internal heat (due to current) and external heat sources (such as direct sunlight energy). Store lithium batteries at about 50% to 60% of their rated energy or power capacity (here, rated ability). In general, the smaller the volume a battery of the same given materials, the smaller its charge and energy capacity. While a lithium battery is discharging, its rate of change in voltage is relatively a low as compared to other battery types, hence it maintains is working or rated voltage quite well. A lithium battery can output a higher percentage of its total internal charge carriers (ie., electrons). **Considerations**: A load device needs a certain amount of power (ie., P = VI VA) to operate or function, and this is product of the current and voltage to it, and of which must be maintained for it to function, and this 50% (or some other value) "charge left" concept is rather 50% of the total time available for powering that specific device. **When the voltage of a battery is less than its rated value, the maximum output current is then less than its rated value, and the battery is then considered as drained ("0% available" , due to the battery now having both less than the rated aH and Wh available) or below its rated value**, and a connected load which depends on these (max.) rated values and-or power delivery may cease to function unless some voltage tolerance was designed (ie., by an electronics engineer) considered and "built into" its construction. A battery which is useless for some devices may still be able to power devices with lower power needs, however, this may eventually damage a battery unless in an emergency situation where every watt of power is needed.

Some common cylinder shaped lithium batteries, their identifier number and size, and max. current rating:

11640 = 560maH typ, , 14500 = 750maH , 18250 = 650 maH , 18350 = 1200mAH typ. ,
18650 = 3000mAH typ. = 3AH (common, and an example lithium battery) , 21700 = 4500 mAH

Capacitors store electric charges (electrons on one plate, and positive ions on the other plate) and their energy on its two closely spaced, thin metal plates (ie., surfaces, with area for the charges to fit) with the aid of the electrostatic (or electric field) force between them. Since the charges no longer have kinetic energy are not moving, there is no magnetic field created or involved in the storage of static or stationary electrons. The kinetic energy of the electrons has been transformed into electrostatic (field) energy which is a form of potential energy. Since the charges on a plate are similar, they are in repulsion to each other after being forced onto the plate with an electromagnetic force of repulsion by the same polarity, and attracted to the plate by the electric field of opposite polarity on the other plate. These stored charges can then be thought of as like a spring that has been either compressed or stretched and having stored or potential energy to do things. Capacitors were also mentioned previously in this book. For comparison, an **inductor** (ie., a coil of wire) will temporarily store the kinetic energy from electrons into a generated magnetic (field) energy around that coil.

A thin layer or coating of material called a dielectric is often placed between the plates so as to increase the capacitance ability and rating (measured in Farads units) of a capacitor. The dielectric essentially allows the electric (force) field to pass through it, but should also prevent the electrons from passing through it as a ("leakage") current. One possible dielectric material is ceramic, and then these capacitors are simply called as ceramic capacitors. One plate will hold electrons, and the other will hold positive ions. Positive ions are atoms that have lost an electron, and therefore have a net positive charge. A capacitor has a capacitance or capacity rating (in units of Farads) which is a measure of its ability to store energy, and it does this by a transformation and storing the kinetic energy of the electrons into electrons that will be held in position (somewhat like a compressed spring storing energy) by the electric (force) field (emf) of the positive and negative of charges on the other plate.

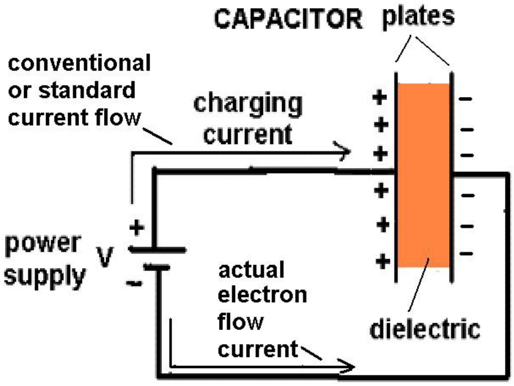
A capacitor will store its charge if there is no longer a complete circuit attached to the capacitor that allows electrons to flow and drain its potential energy, or that the voltage potential (emf, force or pressure) across its terminals has not decreased, creating a net potential difference and which would allow charge to flow towards the lower voltage potential and drain the energy in the capacitor. Remember that electrons have the same charge and will repel each other unless they are held in position by another force, and that force is the electrostatic (charge) force of the charges (ie., charged particles) on the other plate and-or the electric force from an external voltage source.

An older word for "capacitor" is "condenser" (ie., charge storage via electric forces, concentrating charge). A larger area of the plates will allow more charges to be stored on those plates, basically because there is more area or "room" to do so, and with less repulsion by the same type of charge. The charge, particularly moving or flowing electrons, is accumulated onto the surface of the plates when a voltage (emf) is applied across the plates. Even though electrons repel each other they can still be placed on a plate if there is enough room and there is enough voltage (emf) to force them to be on the plate. The amount of charge and-or discharge current is determined by any external resistance (R ohms) to that capacitor, and this will also increase the time of maximum charging and-or discharging of the stored charges as a current. A higher resistance to the flow of current means that the current and power (joules/second or energy/second) output of a capacitor will be lower to a load. In a circuit, the voltage (emf) or energy in a capacitor will decrease as each stored electron leaves the plate and takes some energy with it, and then the current to a circuit will also decrease because there is less electrons available and at a lower voltage applied to those left on the plate of the capacitor.

In general, the larger the capacitor and-or the larger the same type of capacitor construction and materials, the more charge and energy it can store. Having a larger capacitance in a circuit is not always desired, and particularly for high frequency circuits which require a capacitor with a fast charging and discharging time period, such as to reach the peak supply or signal voltage in a brief or fast amount of time. It is a fact that the smaller the rated capacitor, the easier that a higher frequency (ie., AC, or [DC] varying, pulsing) signal can then effectively pass through it via the electrostatic forces on the plates of the capacitor, and which will create the resulting charge (ie., electron) or current flow of that input signal. A small capacitor connected to circuit ground (ie., having a low voltage or 0v potential) will effectively cause electrons or current to more easily flow there, and this can be used to filter out or remove unwanted high frequency signals such as some electronic noise and-or high frequency oscillations causing a disturbance in a circuit. Because a small capacitor can more easily pass a higher frequency signal, it likewise effectively blocks the lower frequencies more, and a small capacitor is therefore a low-frequency signal (V, I, and frequency) remover or filter.

Capacitors have a maximum voltage rating which can be applied to and-or across the plates at which a "voltage breakdown" can happen and then it allows conduction through the dielectric and to the plates of the capacitor, and therefore "shorting (no more capacitance, very low resistance) out" and-or permanently damaging the capacitor and possibly the rest of the circuit, and even cause a possible explosion of the capacitor due to some internal hot gasses created. Often a capacitor with a voltage rating of the (input voltage) + (half of the input voltage or more) is chosen to be in a circuit, and this gives some circuit damage prevention. For example, if a capacitor will have 5v potential difference across its plates, then use a capacitor that has a voltage rating of at least: 9v + (9v / 2) = 9v + 4.5v = 13.5v or higher.

A capacitor can be thought of as a type of battery, but it has various other uses such as for blocking direct current, and for use in **electric oscillators** (create a periodic voltage and-or current, AC waveform, hence an AC signal generator), frequency "tuners" and-or filters, and even an AC voltage divider since capacitors have an effective resistance due to how it reacts (ie., [AC] reactance) with an applied AC signal and its frequency. In the circuit below, the capacitor is essentially in a parallel connection with the voltage source or supply, and that capacitor will charge and will be the same voltage as the voltage source, and then the current flow will stop because there is no difference in voltage potential (emf) for any current to be flowing. For example, if the supply voltage is +5v and the capacitor charges up to +5 volts and effectively in the opposite or reverse polarity direction, there is a net voltage difference of 0v, and which will cause no flow of current. A resistor could be placed between the power supply and the capacitor so as to reduce the charging current, perhaps to a safe level, and this will also cause an increase in the time it takes to charge that capacitor up to the supply voltage. The limited amount of current due to the resistor will also decrease even further due to the increasing "back-emf" or (reverse polarity) voltage (emf) of the capacitor. A formula for the voltage or current of a charging or discharging capacitor is shown ahead in this book. [FIG 235]



Considering the common conventional current flow analysis from the positive terminal of a voltage to the negative terminal of a voltage or potential difference, and which could be thought of as positive or real energy flow analysis, the positive terminal of the battery will repel and force like charges which then will gain kinetic energy and will also be forced and-or be repelled onto the positive plate of the capacitor as potential or stored energy. Likewise, opposite polarity charge will be stored on the opposite side of the capacitor. The unlike charges across the capacitors dielectric material will also attract each other due to their electric or coulomb forces, and the capacitor will store those charges, even if the input voltage is removed.

Super Capacitors can have a capacitance value in many Farads, however,their rated voltage is relatively low, perhaps just 3 or 4 volts maximum, enough to power a 3 to 4 volt LED, however, placing several identical capacitors in series can increase this working value, but it also reduces the total effective, series capacitance. Capacitors can have a high rate of charge and discharge currents as compared to a battery, and that the charge time of a capacitor is also much quicker. The (RC) charge and-or discharge time constant can be low if R is very low and C is very high, and this means a high current is also possible, and this means a high amount of power is possible (P = watts = VI = joules of energy / second).

To create practical **radio waves** at a specific or tuned frequency for transmission and reception, a stable (ie., non-fluctuation in frequency) **electric oscillator** circuit is required. To receive those same radio waves being transmitted at a specific frequency (such as that being transmitted from a certain radio broadcasting "station" and its transmitting antenna), an electric circuit called a "tuner" in a radio receiver is "tuned" or adjusted to accept just that particular frequency and reject, block or remove all the unwanted frequencies, particularly those higher and lower in the desired frequency and-or a limited band, bandwidth or range of nearby frequencies necessary to contain and convey the source information. A tuner circuit is actually a type of (frequency) filter circuit that allows frequency rejection and-or the selection of a particular output signal and frequency.

An oscillator circuit is designed to (electrically) resonate at, produce or generate a specific AC signal or frequency, and which usually has a (natural) sine waveform. A simple tuner circuit contains just an inductor (L) and capacitor (C) placed in a parallel electrical connection, and which they becomes both a filter and-or resonant (ie., oscillator) tuner circuit. This tuner circuit will allow (pass) a certain radio frequency and electronically reject all other undesired frequencies by sending them to the ground or lower (ie., 0V) voltage potential via a lower impedance or reactance path than the rest of the circuit. The frequency filtering will remove unwanted frequencies from being heard and-or interfering with the radio station and information broadcast that you want to hear. The parallel LC tuner actually has its highest electrical impedance (ie., a (frequency dependent) reactance or effective resistance to the AC signals) when the desired frequency of the input signal is equal to the specific natural oscillation and-or "resonant" frequency of that tuner circuit. The result is that the voltage of the desired frequency will be at a maximum value at the tuners output, and then it will be available to the rest of the circuit such as to a diode and earphones in series with each other in a radio receiver circuit. The energy from the desired or tuned signal radio antenna will give some energy to keep the oscillation happening, and so as it does not decrease in amplitude and stop.

There are many ways to make both mechanical (force, energy powered) oscillators and **electronic oscillators. The basic definition of an oscillator is something that oscillates or repeats itself constantly or "over and over" or "again and again", and hopefully at a constant rate or frequency (how many repetitions or cycles / time) during a particular amount of time such as a 1 second time of duration, length or unit.** In terms of electronics, an electronic signal and-or frequency generator contains an oscillator so as to be tuned to and-or create an electronic (varying) signal (V and I) having a desired frequency.

Some high frequency oscillators, such as in the relatively modern and-or advanced "quartz oscillators" commonly used in clock or "watches" so as to keep a high precision of the current time of day, or as for radio communication and test equipment and computers (for the synchronized processes and steps of a computer program(s)) use a tiny man-made, cut and shaped, frequency calibrated **quartz crystal** (silicon dioxide) oscillator circuit that is tuned or set to have a very high natural or physical electrical and-or mechanical resonant frequency due to its small size. This electrical oscillation behavior is effectively equivalent or comparable to that as if the crystal had both a small internal capacitance and inductance, "tank circuit". Crystal oscillators can have a high accuracy and with an error (+, -) of just a few seconds a year, and this is a very small fraction of the total amount of seconds in a year. The total amount of seconds in a year (365**.**25 days) is: (3600 s/hr)(24 hr/day)(365 days/year) = 31,557,600 seconds / year.

The crystal in a crystal oscillator will physically deform, compress, and-or bend slightly like a compressed and expanded spring when a voltage (ie., energy, emf, electrostatic force) is applied to or across it. This was discovered in 1880 by **Jacques and Pierre Curie** (husband of **Marie Curie**) of France, and it is called **piezoelectricity** (piezo is a prefix and old word for pressure, and as in a electricity generated by force or pressure). During a decompression (ie., a lesser force and-or pressure applied), the crystal will release its gain energy as a sinusoidal voltage at a very stable or constant frequency determined by its physical characteristics, dimensions or size, particularly after cutting it so as to be a certain desired frequency. Crystal controlled oscillators were first built in about 1917, and became practical around 1920. By 1950 large synthetic (ie., man-made) quartz crystals were being produced and having a very high quality were then being cut and polished (fine tuned, shaped) so as to produced crystals for high frequency crystal oscillators. Without these crystals is highly questionable if we could have much modern (2022) technology such as satellites, computers, digital clocks, and "smart phones".

Before modern, more accurate timing was developed by using crystal (or "atomic") oscillators was used for timing and electric powered clocks, the methods for timing were the position of the Sun and stars, sundials, water clocks (ie., raising fluid level in a calibrated container), and **pendulum** (a mechanical, swinging, oscillating mass) and spring ("wind-up", stored energy) powered clocks. The study of timekeeping is called **horology** (a word based on an old Greek word "hora", and means "hour" in English), and some impressive kits (projects) are available so as to build a wooden geared clock which has a pendulum to keep fairly accurate time. In 1637, **Galileo Galilei** developed most of the mathematical relationships for the swing time (ie., a periodic or routine amount or period of time) equation of a pendulum and considered the device for time keeping, and which included an (mechanical) escapement gear for it to function properly, but **Christiaan Huygens** (1629-1695) from Denmark and a contemporary to Isaac Newton, actually built the first pendulum powered clock in 1658, and it kept a highly accurate time of day. The escapement mechanism (much like a lever system controlling the movement of a gear) is used to control and-or allow some energy to the swinging pendulum which gradually looses some kinetic energy due to friction, and it also advances the gears of the time indicators ("dials", "pointers", "indicators", "hands"). The source of energy used to power the escapement is from the weight of an object that was initially raised to a height and thereby given some stored potential energy, and which will then slowly reduce in height and loose some of its potential energy when it periodically transfers its (falling) kinetic energy as kinetic energy to move the clocks escapement mechanism and time indicators or pointers. During each swing of the pendulum it would force and permit the advancement or slight rotation (ie., temporarily escape from being held in position) of the escapement wheel or gear by one tooth. The ticking sound heard in mechanical clock is due to this escapement system. A geared escapement system for timing mechanical devices had been previously known before Galileo, and since the 1300's. The oldest escapement mechanism is known is the crown (gear) wheel and-or verge escapement mechanism which was also used for mechanical devices such as clocks before Galileo's and Huygens more accurate pendulum clocks.

A **pendulum** is a mechanical (force powered, non-electric) oscillator. It contains a mass, usually called a bob, that is held in position by a length of a string or wire. The mass at the end of the pendulum can freely swing (ie., move) side to side and has a (desired) constant time or period of movement during each swing cycle or oscillation. This time period is determined by the length of the string. The longer the string, the longer the arc length or distance of motion of the pendulum mass object (or "bob") and the greater the distance of travel and time of travel, and therefore, the slower the oscillations and longer period time, and less frequency of those cycles per unit of time. The pendulum will cycle through converting its gravitational potential energy (after a person raises it a height) to kinetic energy as it swings. It is interesting to note that the mass and-or weight of the pendulum does not determine its period of oscillation, and the reason for this is that masses of different amounts of weight will fall at the same speed due to being influenced by the same gravitational acceleration (g = 9.8m/s^2 for Earth). Different sized masses and-or weights will also reach the ground or lowest part of the pendulum swing cycle at the same time when raised to and dropped from the same height. A larger pendulum mass will contain or store more kinetic energy ((mv^2)/2) and have more momentum (p=mv) so as to keep swinging, but a heavier weight may also cause more friction due.

Pendulum Swing Period = Ts = (2)(pi) (square-root of (length / g)) : theory, and accurate for small angles of swing. Credited to **Huygens** in about 1673.

In the above formula, length is measured with units of meters form the pivot to the center of mass and-or weight, and time is measured with units of seconds. Note that: frequency = (1 / Period) = (1 / Ts) hz or cycles per second. For a practical example, a pendulum with a string that is 1m long will have a (total swing, cycle) period of 2s to reach the same location it started from, and-or 1 second to swing from say left to right. A pendulum with a string that is 0.2485m = 24.85cm = 24cm + 8.5mm, (nearly 25cm), will have a (swing and-or oscillation) period of 1s. Note that 25cm = (1/4)m. If the string length increases by 4, the period increased by 2, or doubles, and this is the square root of 4. Because (g) = gravitational acceleration is in the period equation of a pendulum, a pendulum can also be used to measure the local gravity in an area. A (very near, metric) standard of 1s unit of time, and-or 1m unit of length can also be verified by a pendulum.

Although it is fairly easy to find the local (north, south) latitude by observing and measuring the angle that the North star (Polaris) is above the local horizon line, it is not so easy determining your local (east, west) longitude. It would take an accurate clock set to Greenwich local time in England. At you local longitude, when the Sun is the highest in the sky, it is local noon or 12 P.M. If the accurate clock shows 1P.M., this is still the local time in Greenwich, and you are 1 hour behind that time, and therefore, you are 15° west of Greenwich.

Some oscillators are composed of just transistors, resistors and capacitors, however some radios use crystal oscillators for the frequency transmission and reception. Transistorized oscillators are mainly based on the fact that a capacitor takes a certain amount of time to charge up when a resistor is in series with it. The first type of oscillators used for tuning (or selecting, adjusting, setting, choosing, allowing) a specific frequency radio waves are called **(LC) tank circuits** or **(LC) tuned or tuning circuits**. This circuit is simply a capacitor and inductor electrically (with a wire) connected in parallel to each other. When energy is applied to this circuit, it will resonate or oscillate current (electrons) "back and forth" from the inductor to the capacitor, and then back to the inductor and to repeat this process "over and over" periodically at a constant amount of time and frequency called the (natural or electrical) resonant frequency of that circuit. Smaller valued capacitors and inductors will have a lower time constant (RC and-or RL) for charging and discharging, and the natural frequency of that oscillator will be higher. The radio receiver and its tuner will be discussed below and in various places in this book.

For a periodic signal and its waveform from an oscillator or repetitive circuit: time = 1/frequency , and frequency = 1/time, hence the time and frequency values are mathematically reciprocal in value to each other. Time is the number of seconds to complete one complete cycle or repetition of the wave, and frequency is the amount of cycles per second of that wave. This will happen for as many cycles as possible and before the energy losses in the resistance of the metal connection wires essentially deplete the energy left or available, and the output voltage and current of the oscillator gets lower and lower in strength (ie.,amplitude or peak) until it is practically useless to the rest of the circuit. To keep the oscillations going and at a strong amplitude, a resupply of (external) energy to that oscillator circuit is needed. A transistor can be pulsed on for a short duration so as to supply some energy to an oscillator so as to keep it going. Due to the electric current or flow of electrons with their electric charge and kinetic energy, the inductor (ie., coil) stores its input energy in a created magnetic field, and the capacitor stores its input energy in a created electric (electrostatic) field or potential.

It is possible to build an electronic oscillator circuit without an inductor. One such circuit is called a (transistor) **multi-vibrator**, and it basically has two transistors, two resistors (R), and usually of the same value, and two capacitors (C), and usually of the same value. One transistor, resistor and capacitor group is connected to the other group a parallel and reverse type of configuration such that when one capacitor is charges up, one transistor will be on and the other transistor will be off, and until the charged capacitor is discharged, and this cycle continues over and over at a certain frequency and-or time period determined by R and C, and which is also known as an (RC) time constant.

The tuned LC (inductor and capacitor) oscillator circuit of a radio.

The simplest of (metal, semiconductor) **crystal radio** receiver consists of just a long antenna wire to receive some radio energy which is radio frequency (rf, high frequency) electromagnetic radiation, and with one end of it connected to the top of the inductor and capacitor - LC-tuner ("tank circuit"). Don't confuse this type of radio and circuit as having a quartz crystal tuner in it, but it rather uses a silicon crystal diode to help demodulate (ie., remove, extract) the low frequency audio out of the high frequency radio signal. The LC tuner-oscillator or transformer connected to the antenna will also have an "earth" or "ground" wire from the bottom of the LC-tuner or transformer and going into the soil so as to be able to make a complete radio wave energy receiving circuit. The ground connection will also conduct the (relatively small) induced or generated current, particularly of unwanted signals of higher and-or lower frequencies to be directed to the ground and effectively removed. Connected to the output of the LC tuner-oscillator is a (semiconductor metal, a crystallized or "crystal") sensitive diode which is then connected to (high-impedance, highly voltage sensitive, rather than current and-or magnetic force driven) earphones with one of its wires connected to the ground connection at the bottom of the LC-tuner so as to complete that circuit of (very small) current flow. To improve radio reception, the antenna can also be "tuned" to collect the desired radio frequency by adjusting its length and-or direction, and this will increase the collected radio signal energy, and then the output power available to the earphones will increase. It is also very possible to use an adjustable capacitor and-or inductor for the LC-tuner circuit, so as to make the LC tuner a variable frequency tuner or selector. This will help improve the section of more stations and their transmitted frequencies. When using a simple radio receive, such as a homemade crystal radio, strong signals, especially from nearby stations may greatly "drown-out" or interfere with the weak signals of other stations. There are many known ways and-or new ideas always being experimented with so as to improve radio reception, particularly for a crystal radio. Some will use a battery or solar-cell so as to give the radio and-or headphones a little more power to work with, and to have an improvement in the output audio level or volume. For some, it is a serious study, and for others, it is rather a novelty to have or try. The resonant or tuned frequency of a LC tank circuit can be shown to be:

$$\text{Fhz} = \frac{1}{\text{2(pi) (squareroot (Lh Cf))}} = \frac{1}{\text{Ts}}$$

: natural or physical resonant or tuned frequency of a LC tuner
L = the inductor, its inductance is measured in Henry's (h) units
C = the capacitor, its capacitance is measured in Farads (f) units
T = total time in seconds of each repetitive cycle or period ,
F is inversely related to the product of (LC)
This formula has a basic derivation in this book.

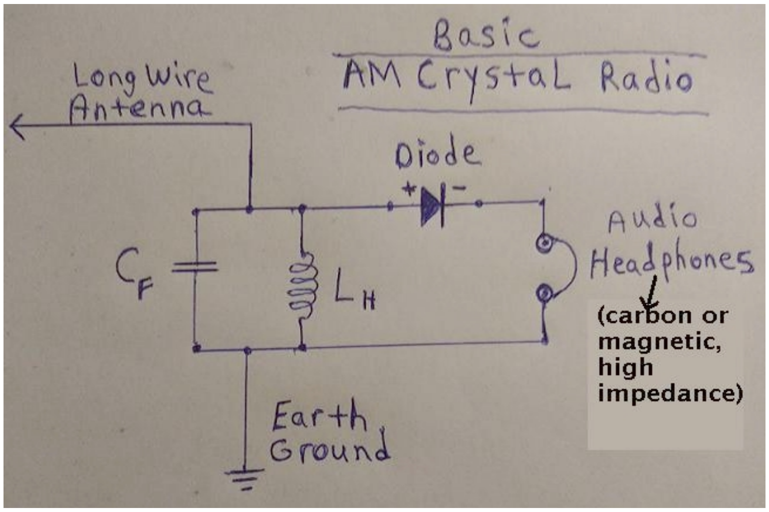
$$\text{Fhz} = 0.159154943 / \sqrt{LC}$$

, from this, you can solve for L or C needed for a certain frequency:

$$\text{Cf} = \frac{0.025330295}{\text{(F^2 hz) (Lh)}} \quad \text{and} \quad \text{Lh} = \frac{0.025330295}{\text{(F^2 hz) (Cf)}}$$

From the above formulas, it is clear that the oscillators resonating and output frequency is inversely related to both the capacitance and inductance values. For a given frequency, capacitance and inductance are also inversely related in value.

To "tune" a radio is to adjust the resonant frequency of the (parallel inductor and capacitor) LC tuner-oscillator or LC (signal, energy) "tank" circuit so as select (choose) a desired or particular radio frequency and filter (here, remove) all the other unwanted radio frequencies. The word "tune" is from the older process of tuning or adjusting an instrument such as adjusting or modifying the tension (force) in a string of a violin. The string will then have a set or fixed desired natural or physical frequency of vibration or oscillation. Shortening the length of that string will cause the natural or physical resonant frequency of that string be higher in frequency. Increasing the length or size of the string will lower its natural or resonating frequency. The ends(s) of the vibrating string are anchored to or connected to the body of the musical instrument. Vibrations and-or the energy of the string will be transmitted or conducted to that musical instrument's vibration "soundboard" or (energy, frequency, vibration) resonator surface, and these vibrations will then be converted into (compressed, pressurized, more dense) air vibrations that are radiated or transmitted outward to the less dense air about it. These compressed and vibrating air waves will radiate or travel outwards from that source, and can then be heard as audio (sound waves) and having the same frequency(s) as that of the vibrating string. [FIG 236]



For experimenting with an AM, crystal radio circuit as shown in the above drawing or schematic, it can be pre-made, homemade and-or purchased as a kit to build. This circuit shown above is considered the minimal and basic AM radio receiver circuit, and of which several helpful improvements have been made later. The following discussion is of the typical common parts, and in particular, of the typical capacitor and inductor values used for the tank or tuner circuit so as to be tuned approximately (via the above calculation) to a common 1Mhz AM radio frequency. Due to this receivers low tuning selectivity (ie., rejecting other close, unwanted and-or interfering radio signals and-or frequencies) issues, you will probably hear some stations "overlap" or interfere with each other, nonetheless, you should be able to at least hear one nearby, "strong" (high power and-or close distance) station so as to verify it is working and-or to help your circuit and reception experiments continue. There are many nice books about understanding and-or making and-or improving crystal radios. Some radio receiver circuit kits include all the necessary parts, including the high impedance piezo-crystal earphone. This type of earphone is a very voltage sensitive, miniature speaker that can flex and-or vibrate when a small voltage is applied, and the amount of current needed is very low, almost 0A. A piezo-crystal has a very high impedance since it is nearly a non-conductor material, and a piezo speaker or buzzer works via the supply voltage creating electro-static forces which will then physically bend the crystal material, hence causing a electro-mechanical vibration of which can then be transmitted to and through the air as sound.

A , the **A**ntenna, 10 ft to 100 ft of insulated "hookup" (connection, or speaker) wire strung off the ground and not during any possible high power (voltage and current) lightning, of which the antenna will essentially become a lightning (directing) rod. During a storm or potential storm, disconnect the outside portion of the antenna several feet from your dwelling, and having several feet of unconnected wire and-or gap (space). Do not connect the antenna or any other other part of the radio circuit to an electric power or telephone line which can then cause injury and-or fire. Because of the preceding facts, it may be best to place the antenna indoors, but if it is long, it will have to be bent so as to make it fit, and-or raised up near the ceiling so as to not cause a potential problem for the movement of people and pets. If the antenna is outdoors, you must disconnect and place it away from your dwelling if lightning might strike it, and it is best to not give the lightning a complete path to the ground and-or electric charges, and behave like a lightning rod.

In theory, the antenna length should be equal to the wavelength of frequency of the radio wave, and be perpendicular to its direction of travel, so as the antenna has maximum interception, reception or signal collection and efficiency of converting the received (rf) energy to electricity energy as the antenna, and much like a musical string, can electrically resonates at the same frequency as that of the desired radio frequency.

Modern portable radios have a relatively small antenna that is only a few feet long and-or is part of the tuning coil wrapped on a **ferrite** (fine ground iron oxide particles mixed with a binder and possibly some other metal(s), ex. ceramic magnets) **rod** which may also be part of a transformer-like construction. Because of this method, the (AM) radio should be physically turned to the direction of the transmitter and radio wave energy for best efficiency and performance. Most portable radios greatly amplify the very weak input signal, and that a ground wire is not absolutely necessary. It is possible to tune a long wire antenna for the best efficiency at a desired frequency by using something such as a variable LC tuner circuit, and this would be electronically and effectively adjusting its length so as to increase the radio circuit's (rf) to audio conversion efficiency. A ferrite rod or "loopstick" antenna is designed to convert the magnetic field energy of the received RF (radio frequency) signal and-or energy to an electric signal energy for the radio, whereas a vertical wire antenna is designed to convert or transform the electric field energy of the RF energy to an electric signal energy for the radio circuitry to utilize and amplify. In general, a loop antenna with no additional core material is also a directional antenna, and it can also help eliminate some unwanted radio interference from other directions. The fine grain ferrite material used for electronics can quickly change their magnetic polarity,unlike a regular magnet. Ferrite can pass a magnetic field easilly, but it is not conductive to electrical current, including eddy currents such in a solid metal transformer design, and which can get hot and waste electrical power, and-or be dammaged.

L and C comprise the basic (frequency) tuner or selection circuit. Somewhat oddly, this circuit is desired to have a very high impedance to the selected or tuned frequency, and for the power matching purposes of the diode and earphone circuit it is to be say about 50K to 100K ohms. The high impedance will then direct some of the signal through the diode and earphones to be heard as sound, rather than all of it going into the ground, low voltage potential, first.
The signal an antenna receives can optionally be filtered by an inductor and-or capacitor so as to remove higher and-or lower frequencies that may interfere with the best reception of a desired frequency. Antennas can also be tuned to simulate a proper match for a desired frequency and its wavelength, by using an inductor or capacitor so as to simulate a longer or shorter antenna.

L , the **I**nductor, is often just a fixed value, but it could have selectable outputs "tapped" along its length so as to tune in the desired radio frequency and-or close frequency range and then fine tune with the capacitor. For this circuit, use **~ 220uH.** 220 uH = 220 (10^-6) H = 0**.**000220 H Use about 100 turns of thin, 30 gauge, enamel coated insulated, copper wire wrapped around a 1" = ~ 2.5cm to 2" =~ 5cm cylinder form of a non-conductive material such as plastic, wood or cardboard. A coil with a larger diameter, but with the same number of turns will have a higher inductance, and therefore, a much shorter length of wire on that coil can be used so as to obtain the needed inductance level.
A typical inductor for a crystal radio will use from about 20 to **30 AWG** multi-strand wire, but solid will work also. Some advanced designs use just a selectable portion of the wound inductor coil, and this is done by creating some taps or connection points along its length, and of which the diode can be connected to by a wire. This will affect the tuning and-or frequency range of the receiver, and could help improve signal strength (ie., sensitivity) and selectivity. Other designs might also magnetically couple (ie., much like a transformer function, isolated, no direct connection electrically) the antenna and-or some "feedback" coil to the receivers antenna and-or tuning coil

C , the **C**apacitor, can be fixed in value, but is often adjustable to as to select the desire frequency: 115 pF
Or by using a variable capacitor that has a range of 0 to 240pF. 115pF = 115 (10^-12) F = 0**.**000,000,000,115 F
Others have simply rounded this value to an average value of about **220 pf**. It is quite possible to make a capacitor out of a piece of writing or typing paper, glue, connection wire and aluminum foil for the plates that are less than a square inch each. It is possible to trim this capacitor with scissors, and as long as it is not "short-circuited" or "shorted-out" when the two plates are in contact with each other. A fixed value ceramic capacitor(s) will also work.

The parallel inductor and capacitor are electrically connected or "hooked up together" so as to be in series with the incoming or received radio signal energy, and are performing the function of a frequency band-pass signal filter that can reduce or effectively reject the amplitude of frequencies that are higher or lower than the desired ("tuned") frequency. The desired frequency will be adjusted or "tuned in" for best reception, and it is of note that other frequencies, both somewhat higher and lower will also pass through the radio circuitry, and this frequency range composes what is called the **bandwidth** (ie., range of frequencies, BW) of that LC (energy, oscillation) tank circuit and-or tuner. Many radio stations are assigned so as to have a maximum transmitted bandwidth so as to not interfere with other stations and their assigned bandwidth. This bandwidth also allows the inclusion of the audio signal or "information" along with the main or fundamental carrier, radio frequency, and the radio receiver (ie., the tuning circuit) needs to have a wide enough bandwidth so as to properly receive all the information clearly. Tuners that are said to have a high quality or **Q-factor** have a more narrow bandwidth or less of a frequency range. The Q-factor of a tuner also helps determine the selectivity of a radio frequency and-or the rejection of other unwanted frequencies.

A LC tuner circuit for a radio will resonate at a particular resonant frequency (Fr), and it will resonate longer when the Q-factor of it is high, and this occurs when the load impedance (ex. R, for resistance) is also high so as not to drain (ie., "damping", reducing) any energy from the oscillations and a resulting further decreasing amplitude.
Qf = R sqrt (C / L) = (Fr / Bandwidth)

D , a small signal or low power **D**iode. A silicon diode is often used today, but a germanium diode is more sensitive and efficient with less signal power loss, and is more practical for a "crystal radio receiver". The diode is also called a "rectifier", and for this radio it removes one half of the AC radio wave signal received and so as the audio or "information" portions of each cycle of the AC wave do not effectively cancel each other out after being converted to sound in the headphones, and where out of phase sound waves or half cycles will be effectively canceled out and have an amplitude of 0. The natural resonance of a piezo-crystal earphone designed to work with audio frequencies, cannot vibrate much with high frequency, (rf) electric signals, and so as to efficiently converted them to sound. These high frequency sounds can not even heard by the human ear anyway. It needs to be noted that the diode has a fairly high signal impedance (ie., resistance) to the low voltage (and current) rf-input input signal from the antenna and the output from the LC "tank" circuit, frequency selector, filter or tuner. A Schottky diode is possible since it has a low voltage drop when used with low currents, however, it may have a relatively high reverse "leakage" current. You may wish to do some research and-or find diodes with a very low forward voltage drop.. Received (rf) signals (voltage, current) from the antenna are often very low in voltage, and therefore, a very low current is being generated and flowing in the circuit. Having a lower diode impedance allows more of the received or input (rf) signal's voltage to be applied to the headphones and produce a louder sound. Perhaps the most popular diode for a crystal radio is the germanium **1N34 or 1N34A**, however nearly any other type of diode can be used, but some diodes may require a small forward bias voltage so as to set the diode near its conduction voltage, and since the voltage available from the received radio signal is too low to even allow those diode to function (ie., conduct, "turn on") and pass a signal through it. Reducing the available voltage will reduce the volume of the sound output from the high impedance earphones. A simple method to bias a diode is to use a 1.5v battery cell and an adjustable resistor, say 50K to 100K ohms, in parallel (ie., across) the diode so as to limit the current to a very small value. Some adventurers have even placed two or more diodes in parallel to get every drop of power (here, mostly in the form of a voltage) to the (piezo) headphones.

Headphones , Headphones are essentially small speakers that have only a relatively small amount of power output and are therefore placed close to your ears. Headphones, like a loud-speaker, are an electrical energy to audio or sound energy transducer or converter, and can therefore be considered as a type of (energy) transformer. **WARNING**: If the sound is too loud, and-or for too long, hearing damage will usually occur.

For crystal radios, use high impedance carbon, or (fine wire) magnetic earphones which contain a high impedance to a low impedance transformer (2 coils). A relatively inexpensive "crystal (piezo)" earphone can also be used.

You can also use a high input impedance, electric audio amplifier for the sound or audio. and this will also amplify the weak, input audio signal to be used for an 8 ohm impedance, loud-speaker or 16 ohm headphones output. The output signal of the high impedance amplifier or circuit may even be sent ("ie., "connected") to a computer's "line-level [a certain std. max. amplitude]" signal input. A "line-level" input typically has about a 10k ohm input impedance, and about 1mv max. peak to peak, maximum input signal before (amplitude) "clipping" or limiting of the signals waveform takes place and the signal gets distorted. The audio signal from a (non-crystal) radio can also be sent to a computer amplified ("electret") microphone input (~1k ohm input impedance, and ~100mv max. peak to peak input signal). The computers audio circuitry can sometimes amplify these input signals and-or send an output signal to an amplified speaker system.

For the crystal radio's tuner circuit to remain at high impedance to the input signal, and for maximum circuit efficiency, anything connected to that tuner or LC circuit needs to be a very high impedance since it is essentially connected in parallel to it and will reduce the impedance of the tuner like how two parallel resistors effectively creating a lower resistance. Then for maximum power transfer to the headphones, those headphones will also have to be a high impedance type so as to match that of the high impedance tuner and diode. For maximum power transfer from one impedance to another, those impedance's should "match" or be the same value, and this concept of "impedance matching" is used for the concept of maximum power transfer and vice-versa. Some advanced crystal-radios may use a high impedance to low impedance transformer to match the circuit impedance before and after the transformer such as to the headphones, and so as to have greater efficiency and some more audio volume. Using common 8 ohm to 32 ohm headphones will not work for this circuit since the output power of it is too low to physically move or vibrate these speakers so as to make sound (air pressure waves), and there is also an impedance mismatch which will reduce the electric power transferred to the earphones. Some crystal radios may include or be experimented with using a **high value resistor in parallel with the crystal earpiece** so as to help reduce excessive charge buildup on the earpiece and to help it perform better in terms of current flow. Experiment with the best sounding value, generally about 50K ohms, possibly higher to 1M ohms, or use a variable resistor. Some radios may also use a low value of capacitance in parallel to the crystal earpiece so as to more easily (ie., due to having a lower impedance) pass high frequency noise and-or RF through it to the ground rather than through the earpiece.

G , **G**round, a wire going deep into the ground, such as being connected to a metal radiator and-or water pipe.

Connection or "hookup" wires are quick connection wires, and are therefore helpful for quickly building, testing and experimenting with all kinds of electronic circuits. These conductive wires have a small spring clamp (or "alligator clip") at each end so as to easily connect (or disconnect) and hold the wires and-or components electrically together without using soldering and-or desoldering so as to make another circuit test. These wires can be purchased relatively inexpensively, and having a few dozen for general circuit experimentation is recommended. The inexpensive types are flexible, plastic-rubber coated, but have a relatively thin internal multi-strand metal conductor, usually copper, and are therefore safe for only low currents, say less than 1 Amp. 1 Amp or less of total current (**I**t) is typical for many low power circuits.

The LC parallel "tank circuit" in a crystal radio is used as a oscillator and tuner. It will oscillate at its natural electrical frequency determined by the capacitor and inductor. At the desired adjusted or tuned frequency the impedance (ie., ac resistance due to the ac signal reacting with that component) of this circuit is at maximum. Consider this thought experiment: If the input frequency is very high above the tuned frequency, it will more easily pass through the capacitor and to the ground. If the input frequency is lower than the tuned frequency, it will more easily pass through the inductor and to the ground. In both cases the signal is essentially lost as it travels more easily (ie., less resistance) to the ground before passing through the rest of the circuit. While the resonant signal and-or frequency is in the tank circuit having the same natural resonance, the signal will oscillate back and forth by charging one component (L or C) while discharging the other and so on. Due to some resistance still present, some energy is lost and the signal will diminish in amplitude, however more signal from the antenna will boost it back up.

An inductor and a capacitor can be placed in series and this will create a signal filter that will pass a certain frequency much better than others, and because the impedance of the inductor and capacitor will have the same value of impedance at one specific frequency, but the two impedances will be opposite in phase or polarity.

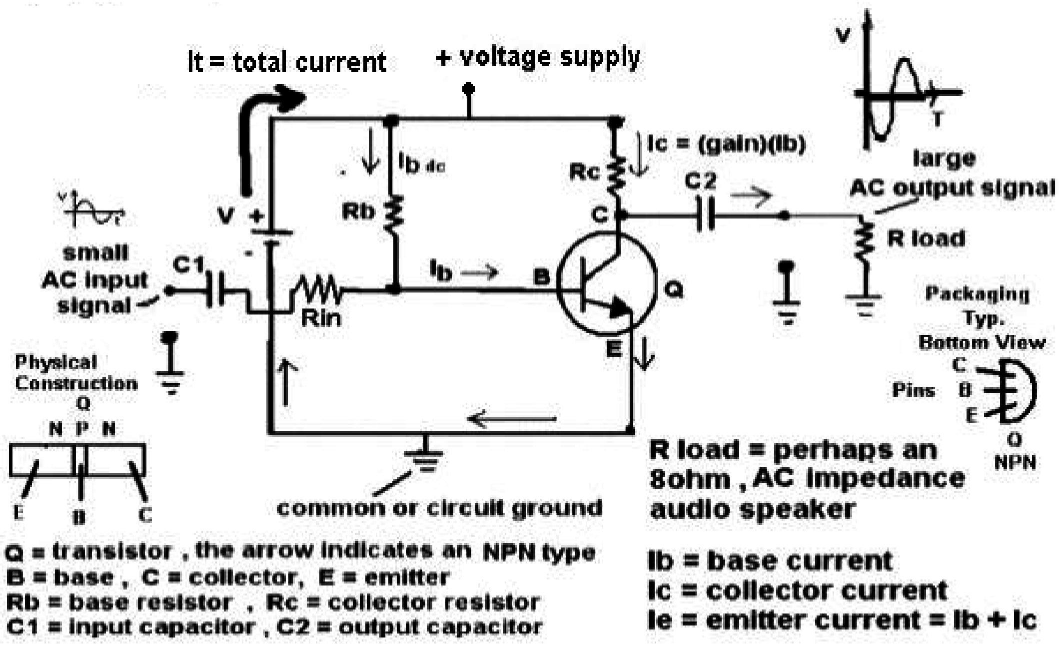
High frequency noise can often be eliminated in a circuit by simply connecting a small capacitor to ground, and of which it will have a low impedance to high frequencies, and those signals will take the path of lease resistance or impedance to ground. An inductor can be placed in series with a circuit so as to reduce and-or block high frequency signals. A capacitor can be placed in series with a circuit so as to pass only high frequencies. The specific values of the capacitors and-or inductors must be calculated and-or experimented with, and it also depends upon the frequencies in question that will be encountered, unwanted and-or desired in the circuit.

Modern crystal radio kits and-or designs often include some type of amplification (tube, transistor, or IC chip(s) such as the popular **LM741** [for small or weak signals, high gain op-amp] and-or the **LM386** [audio amp] and-or impedance matching for a commonly available 8 ohm speaker and-or headphones for the sound output, or for the line-input or microphone input of a device such as a computer so as it can be used as a higher output power sound amplifier. The cutoff-frequency where the gain of the LM741 is reduced to only 1 is about 1Mhz near the center frequency of the AM tuning band or range of frequencies, and so this may not be the best choice to use for high frequency RF signals like common AM radio signals, but is rather best for audio frequencies and applications. The reader will have to research what op-amps or transistors (BJT's and FET's) are capable of amplifying RF signals from the antenna and-or the output of the tuning circuit and-or filter.

In these modern times, there have even been low cost, relatively simply to use IC's specifically made for AM radio receivers, and which then require a minimal number of extra parts such as a power supply (ie, a battery 1.5v to say 3v), a tuning capacitor, a tuning coil on a ferrite rod - sometimes called a "loop-stick antenna". The most common and modern (2024) IC for this is the **TA7642**. It is sometimes called a "radio on a chip". This IC looks much like a common three terminal or lead transistor, and inside it contains several RF amplifier stages for high gain, hence making the radio very sensitive to the received low power signals. The sound output can be heard with an earpiece (piezo, magnetic) or boosted with an audio frequency amplifier stage so as to be heard with a 8 ohm (AC impedance or effective DC resistance at 1000 hz) rated speaker.

A BASIC TRANSISTOR AMPLIFIER CIRCUIT [FIG 237]

In the circuit below, the voltage supply depends on how much electrical power you want to control. For starters, say its a 9v battery, and then mainly the resistor values used will be determined by that 9v value and-or desired current. Typically, the DC base current, or DC bias-current, of a common, small single transistor used for audio amplification is about 1mA. With USB devices very common as of the year of this writing - 2024, you might try designing a simple amplifier that is supplied by a 5V dc USB power supply and-or port.



Rin = input resistor, fixed or variable to set input level, this can also be a potentiometer (adjustable, variable voltage potential setter, usually via an internal resistance and voltage divider) with one terminal connected to the ground, and so as to divide the voltage of the input signal so as to have the desired level to the transistor base from the center terminal of that potentiometer. A safety resistor can also be put before the potentiometer, and provide some transistor and-or potentiometer safety in case the input signal has too much current and-or when the potentiometer is set to a low or 0 resistance which can damage the potentiometer and-or other part of the circuit.

An electronic amplifier will amplify (increase, gain, magnify) the power of an input signal such as an electronic, AC waveform equivalent, representation or facsimile of a sound waveform. Power = P = VI = (voltage)(current). The increase in power can come from an increase in output voltage and-or current of the input signal. Since the input signal controls the transistor amplifier, the output signal of it will be of the same waveform shape and frequency (cycles per second) as that of the input signal. This transistor amplifier circuit and-or configuration is called a "common emitter" since the emitter is common to both the input circuit and output circuit. In brief, Rc and Q (the transistor) form a voltage divider circuit and as the input current to the base (ie., control terminal) of the transistor increases, the transistor will conduct more and its resistance will decrease, and this will cause the voltage across it to decrease and the voltage across Rc will increase. If the current to the base is decreased, the opposite will happen. For transistor (signal) gain or amplification values:

Gain (A) in voltage = Av = Vout / Vin , Ex. If Av = 10 and Vin = 0.1v = 100mv, Vo = Av (Vin) = (10)(0.1v) = 1v
Gain (A) in current = Ai = Iin / Iout
Gain (A) in power = Ap = Po / Pi = (Av)(Ai)

The values of the components in the circuit are determined by many factors such as the input and output impedance needed so as to have maximum power transfer. An FET transistor has a high input impedance, and rather just amplifies the input voltage. The transistor (Q) in the above circuit is a **NPN** polarity, BJT (Bipolar Junction Transistor) and is mainly used to amplify the input current. NPN means a P or Positive carrier type semiconductor layer placed between two N or Negative carrier type semiconductors layers. B-E junction and-or terminals to it, should test like a good diode, and the B-C junction and-or terminals should test like a good diode - conducting in one direction and not the other direction and-or polarity of the voltage applied.

As of the year 2020, small plastic transistors for small input and output signal (voltage and-or current, ac waveform) amplification can be purchased inexpensively at just a few dollars (about the price of a 5lb bag of fine ground wheat flour) USD for 100 of them. When they were first produced in the 1950's, they cost perhaps the equivalent of the year 2022: $10USD each, often due to that they were partially "hand made". Many circuits designers also try to use the same transistors having the same ID numbers, dimensions and operating characteristics, and which are also commonly available. A "generic" type of circuit and transistor, such as that shown above, will usually permit the use of many similar types of transistors with similar electronic characteristics (ie. "parameters") such as its gain = Ai, highest frequency (ie., fo = frequency cutoff where the gain is reduced to only 1), maximum collector to emitter voltage = Vce, maximum current = Imax, maximum power handling capability Pmax or Watts. High power transistors generally have a low gain (ie., input signal amplification) of perhaps 20, while small signal transistors can have a gain of 75 to 200. The most common BJT transistors for hobbyists are the: **2n2222 npn** , and **2n3904 npn**. Their respective pnp complement are: **2n2907** and **2n3906**. The most common low power JFET transistors for hobbyists are the: **2n3819 n channel**, and the **2n5457 n channel** which has a complement of the **2n5458 p channel**. The 2n3819 has a (gain = 1) cutoff frequency (Fo) of 700mhz. A general purpose low power MOSFET is the **2n7000 n channel**. If a device is not available, a substitute can be used if it has similar electrical characteristics, parameters or settings.

In general, a replacement part of the 2n2222 transistor is the 2n3904, BC547, and BC548. A substitute for the 2n3906 is the BC557.

A transistor is much like a sensitive electronically operated valve or switch such as when the transistor is fully on (low resistance, high conductance) to the flow of current when there is enough input base current applied to do so. A small amount of input current will cause the transistor to have a higher conductance through it. A relatively small amount or range of input current can therefore control a large amount or range of current output with the aid of a transistor. When a transistor is used as a switch, this is similar to the concept of an electronic relay that pulls and closes a lite-weight metal switch when a small current creates a magnetic field in a coil of wire. With the switch closed, much current can flow through it and onward to the circuit being powered. A purely electronic transistor is faster than a electro-mechanical relay, has a longer durability or "life" of use, and has no audio and radio-frequency (rf) noise due to possible sparks. A computer's CPU (Central Processing Unit) is an integrated circuit (IC, "chip") that contains and uses transistors as (binary, two states - on or off, an "on" transistor = 1 and an "off" transistor = 0) switches to control and perform basic logic, simple math, conditions (ie., comparisons, evaluations), and data access so as to perform the steps of a program.

When a transistor is not operating as a switch, but somewhere in-between full on and off, the transistor can be used to amplify an input (varying) AC signal. A small amount of input current at the base or input lead of the transistor can cause or control a larger amount of current to flow from the collector to the emitter. The resistors (Rb and Rc) are also chosen so as to set the initial operating voltage and-or current settings of the transistor, and this is sometimes called "biasing" the transistor. Sometimes the current gain (ie., the amplification) of the transistor can be set and-or stabilized to be fairly consistent by using a resistor(s) in the circuit.

For the class-A amplifier circuit above that uses just one transistor, that transistor will amplify the complete waveform of the input AC signal, and rather than just half of it per transistor as for a (higher output power) class-AB type of amplifier circuit which requires both a NPN type and PNP type of transistor. The bias settings of a class-A amplifier are such that without any input signal applied, the output DC voltage across the transistor is set at half of the supply voltage. Ex. For a 9v battery power supply, the DC voltage measured at the collector to emitter terminal will be 9v/2 = 4.5v This will allow the largest possible voltage change, range or swing of nearly 9v less about 0.6v needed to keep the transistor turned on, and in the linear region of amplification. The voltage changes across the transistor will also be at the output, and all due to a changes in the AC input signal. If the input signal gets too large, a distorted output wave will be created wince the transistor has a limited, maximum output voltage, here +,-4.5v.

The output signal or waveform of this amplifier shown above is also out of phase with respect to the input signal and-or its waveform, and by 180°, and is said as being an inverted signal. This is generally not a problem, and if needed, the output signal can be inverted again using another transistor amplifier, and a small portion of this signal can be used as a feedback (or return) signal to be combined and-or added to the input signal as positive feedback. Negative feedback can be used to reduce input signal noise, such as if a small capacitor allowed only the high frequencies to be the feedback to the input.

How does this signal inversion happen in a single stage or transistor amplifier? Signal amplification by a transistor happens since when the input signal voltage increases or rises, it puts more current (ie., electrons that can carry charge) into the base or central region of the transistor and it then can conducts more, and therefore, the transistors internal resistance (R) decreases. The voltage drop across the transistor will decrease since V = IR. Since the output signal is taken from or across the collector and ground, its voltage will also decrease.

The capacitors (C) shown in the circuit above are used as "(AC signal) bypass" and-or "(AC signal) pass through" capacitors which will block a steady DC current, and also keep the bias settings of the transistor constant by isolating it from any external (ie., such as input and-or output) circuit DC power. The capacitors also allow AC signals to flow into and out of that amplifier circuit. Capacitors and-or inductors (such as a "choke") can also be used as signal filters that can block (not allow) and-or pass (allow) certain unwanted (such as noise) frequencies, and for example the filtering depends on the (Farad, charge storage) value of that capacitor used and the frequencies of the AC or varying signals. In general, smaller capacitors tend to block low frequency signals and pass high frequency signals.

A "load" resistor or device can receive or "draw" some of the available signal (v, I, power) from the transistor amplifier circuit. This "load" is also considered as a "load" (quantity or value) of current, hence a "current load" or quantity. A common load device for an electronic audio signal amplifier is an 8ohm speaker and-or coil in it. An 8ohm speaker is a common or standard value that a circuit can be designed for. Technically, 8ohms is the impedance or effective AC resistance of the coil when a 1000hz frequency, electric and-or audio signal is applied to it. This is due to the magnetic field and "back-emf" (in reverse polarity and-or opposing that of the source) voltage created in the coil when there is a change in current such as during the applied AC signal's waveform. The DC resistance, or the "wire resistance" of this same speaker coil is about 6 ohms, and the impedance of that coil will rise as the frequency of the input signal increases.

Since a class-A amplifier is biased to be always ON (functioning) with current flowing thorough it, a current on-off switch should be used so as to not waste any battery energy or power when the amplifier is not in use.

The above circuit for a transistor mostly considers the necessary DC (steady, fixed, V, I, R) biasing or operational settings. What happens to the AC signal is somewhat of a different nature. We want to consider both the positive and negative halves of the AC signal, and not just the positive half of the AC wave (ex., a sine wave). A simple description of what happens is that the incoming AC signal to this amplifier will electronically "sees" or "encounters" the battery with its low internal resistance, and which can then be considered as 0 ohms in ideal conditions. This effectively shorts the positive and negative "rails" or conductors together for the AC signal. For example Rb will then effectively be connected across the input of the AC signal, and Rb will also essentially be across or in parallel to the transistor. Rb will then also be part of the AC signal's encountered input impedance of that amplifier, hence it will also be a part of the AC biasing of that amplifier. Consider if the DC biased transistor had a very low internal "on" impedance or resistance, then Rc is also essentially connected across that transistor in terms of the AC signal. For a class-A amplifier circuit as shown above, and for the most signal output, the value of Rc could very well be set to the average value of the transistors internal (collector to emitter) resistance. Rc will also help determine that amplifiers, AC signal's output impedance seen or available for any circuit connected to it, and of which should be matched for best power transfer, to or by any connected device for best power and -or signal transfer. A typical value for Rc may be about 1000 ohms = 1k, but it may be as low as 10ohms, or as high as 50k ohms. A typical value for Rb may be about 4.7K to 10K ohms, and since the DC bias base current to a transistor is relatively a small value, say about only 1 milli-amp (mA) or less. For a high input impedance amp with this simple circuit, you can try setting Rb at say from 100K to 1M ohms.

The author has found that the electronic sound signal from devices such as a modern **mobile phone** can be amplified by using an inexpensive, common 5mm to 5mm male earphone jack plug connected from the phone earphone jack and to the microphone input jack of a computer so as to be amplified and heard by the computers amplified speaker(s).

In the above transistor circuit, if Rb is made perhaps 100k ohms to 1M ohms, the base to emitter junction will be biased to a very low voltage and hence this will not be conducting very much and will be a high input impedance, and this is ideal for a low voltage radio signal to be amplified. This type of amplifier is usually called an RF (radio-frequency) or high frequency amplifier and-or a high (input) impedance amplifier.

More Advanced Uses Of Transistors And Their Manufacturing Technology

Soon after the discovery of the transistor and having affordable, stable and practical versions of it, the transistor began to be used in many circuits and many with new designs, and where a vacuum tube is no longer needed which made many circuits price prohibitive to even consider for manufacturing for the general public. The first transistor and "pocket (size)" and-or portable radio was the **Regency TR-1** and it was available for purchase in 1954. This radio does not need a ground wire since the transistor RF (radio frequency) gain (ie., amplification) is high so as to amplify weak signals, and the battery acts as the ground. The first transistor based computer was made in 1955 and was a closet sized, "mainframe" type of computer, but it was still much smaller than the room-sized vacuum tube versions available at the time. It required much less power, and it was also much faster and reliable.

The first integrated circuit (IC, or "chip") with tiny transistors and other circuit components began to be independently conceived in the late 1950's by several people, and much credit is given to **Robert Noyce** (of the Fairchild Semiconductor Co., and later, the Intel Co.), and **Jack Kilby** (of the Texas Instruments Co., "TI") due to their work for the process of the miniaturization of silicon based components such as transistors. Kilby, along some other members of an engineering team at the Texas Instrument Co. is also credited to the first all electronic pocket-sized calculator in 1967, called the **Cal-Tec Calculator** and which had several individual integrated circuits in it, and of which each one would calculate just one of the four common math functions (ie., to add, subtract, multiply, and divide). For the result, up to 12 digits of precision, it was printed on a thin (about 1 cm wide) strip of (thermally or heat sensitive) paper. By the early 1970's, new editions of it were being sold as the **Pocketronic Calculator** which was manufactured by the Cannon Co. in Japan. By 1972, the Texas Instrument Co. began to manufacture calculators that had a small sized LED (ie., electric light) numeric display for each digit of a number to be displayed.

The IC invention and miniaturization process eventually allowed the creation of a "computer on a chip" IC. The first IC microprocessor was the **Intel 4004 microprocessor IC** and it was available in 1971, although the military and space industry (such as the U.S.A, NASA and the Apollo program) was considering and-or already using a microprocessor on a chip for several years, but this was generally of for specific and limited use. The Intel 4004 had over 2000 transistors on a single IC or "chip". This IC and its technology and fabrication eventually lead to the modern (2022) "Pentium IC", computer processor designs which have a magnitude or two more of transistors, and are also much faster and more efficient in terms of both a lower power requirement and less wasted heat energy. A company in Japan called the **Busicom Corp**. wanted the Intel company to make several IC's for an all electronic calculator, and **Marcian Hoff** suggested they simply put all the IC's on a single chip so as to reduce costs. Engineers, **Federico Faggin** (previously from the Fairchild Semiconductor Co.) and assisted by **Masatoshi Shima** (from Busicom Corp.) designed the ("4 bit") Intel 4004 microprocessor for the calculator, and which was said by some as also being capable of having a (very practical) square root function ability. A later financial agreement with the Busicom Corp. allowed Intel to share the proprietary rights of this IC it put a lot of money and effort into, and which was also needed so as Intel could make newer microprocessors that were more or less based on it. About the same time as the Intel 4004 IC , Intel also created the 8008 IC which had some advantages over the 4004, like having much more RAM memory, but it also had some disadvantages to the Intel 4004. Future versions of the microprocessors would implement the best qualities of both of these microprocessors into the 8080, 8086 and 8088 IC microprocessor which became part of the low cost and practical personal computer (PC) revolution available or sale to the general public in about 1974, and from various companies.

Light that we can see is essentially a type of (electromagnetic) radio wave and-or energy having a very high

frequency. Light energy is said as being composed of tiny bits or packets of (electromagnetic, (rf)) energy called photons. "rf" means radio frequency, and-or electromagnetic radiation. Light is now often considered as a visible "rf wave" and as being a part of the entire "rf spectrum (band, range) of frequencies" which include (invisible, unseen) radio transmissions and heat radiation.

Our eyes have specials cells designed like very small (rf) antennas that are naturally tuned to sense light and its intensity and color. If the (rf) frequency is too high or too low, we cannot normally see or sense these radio waves with our eyes, however, special sensors and-or cameras can be used to effectively see these frequencies of light.

Theoretical particles of light are called photons (from the word "photo" which means "of light") and each has some (electro-magnetic, field) energy. Each color of light has a particular frequency of its wave energy. White light is a visible construction or composition of light waves of many frequencies that are otherwise seen as different colors such as red, blue, green, etc. The visible result of these colors or frequencies being mixed together is a bright or white light because all those simultaneous waves of light effectively (visibly) simulate a much higher frequency of light seen. As a basic verification example, consider how two different colors of light can be mixed (combined) together to produce a third and different color of light. When white light strikes an object, the reflected frequency or color of it that we see is due to the fact that all the other light frequencies were absorbed by the atoms on the object and converted to mostly heat energy.

There are some people born who can not see much color and-or differentiate between certain colors, but modernly, as of about the year 2010, there are special glasses available which can help some of those people see some colors.

Some rare discoveries indicate that ancient Greeks had some primitive magnifying lenses. These are called **magnifier lenses** or glasses. Their rarity is mostly likely due to that clear glass manufacturing was rare and-or that larger clear crystals were difficult to find and-or shape. It is not too difficult to imagine that many were broken after several years of time by accident. In nature, a drop of water is similar to a magnifier or vice-versa, and its curved surface surely indicated what shape of clear lens is necessary so as to make something appear bigger, and which eventually lead to both the telescope and microscope image magnifiers, particularly with two or more lenses.

Sir **Issac Newton** began to study light and optics in the late 1660's and was one of the first people to scientifically study and publicly demonstrate (in 1672) that a beam of white light can be separated into a rainbow of 7 main colors by using a specially (triangular) shaped, thick piece of clear glass called a (light or optical) **prism**. A rainbow or spectrum of colors of white light can sometimes be seen being emitted (ie., refracting and-or reflected) by some crystals or gems such as quartz and diamonds when in the bright sunlight, and sometimes when sunlight is reflecting from ice (frozen water) or snow (small frozen ice crystals, crystallized water). He then showed that these separate colors of light can then be combined back into a beam of white light by using another prism. Newton proposed that light is made of particles instead of waves. Today, as of the year 2020 with the popular "wave-particle duality" theory of light, it is not too difficult to imagine light as being a wave of light particles, much like a sound pressure wave that is a wave of air particles having a varying density (due to varying force or pressure upon the air from the source of the sound) or amounts, and of the same wave frequency as the source of that sound. A color is due to that it is a certain frequency of electromagnetic and-or radio frequency (rf) energy, and therefore, that energy has a periodic waveform and can be called a wave. If light passes directly (ie., perpendicular to its surface) through a flat piece of glass, that glass will not separate the colors and-or frequencies into a rainbow or spectrum.

A magnifier and-or telescope lens that was ground and polished so as to have a high quality and without image distortion will have no apparent "**chromatic aberration**" (ie. color and image distortion) which is a prism-like effect of separating the received light from the image and into a visible (chromatic, color steps and-or separation) rainbow of colors, and particularly due to the outer edge or rim area of the lens where the incoming light has a greater angle to bend, especially when the focal length is short and the colors will not have a great distance to converge back into white light. The amount of diffraction or bending of the light in and out of the lens will also vary slightly by the frequency (ie., color) and-or wavelength of that light. In general, the red (long wavelengths) and blue (short wavelengths) will be separated more than the middle RGB frequency green wavelength of which a single lens is generally "tuned" for. Corrective lenses can reduce this. Denser glass will bend or refract light more when it is entering and-or exiting the glass, particularly when the light transmitted is not perpendicular to the surface of the glass, and then the density of the glass essentially creates what can be described as a resistance and-or friction with the light and it will slow down and bend. Special glass lenses called "Extra low Dispersion (ED)" lenses contain additional natural elements and have a higher refractive index for the red and blue colors, and therefore have less chromatic aberration. **Spherical aberration** or "shape aberration or distortion" is when the lens is simply made or ground with the wrong curve shape, and there is then more than one focus point created rather than a single focus point and-or "focal plane (area)".

A simple magnifier lens can be used to project an inverted (ie., "upside-down) image of an object onto a white surface such as a piece of paper, and this is the essence of a camera device that is used to make photographic images. In a camera, an image is made when the light coming from an object or subject passes through the lens and to be focused onto a light sensitive material (film, or a photo sensor array) and recorded or stored as an image of that subject. The first cameras often had a pinhole for the lens, and which only allowed a small amount of light into the camera, and was therefore a slow camera system, but it provided a sharp or well defined image, and also allowed a large distance or depth of field that was in focus. Many simple lens systems, including a the pinhole opening and even many large telescopes initially will show the viewer an inverted or image of the subject. This has to do with the way light rays from a subject will pass through a lens and are diffracted (ie., bent by some angle).by that glass and shape of the lens. If need be, another lens can be used to upright an inverted image.

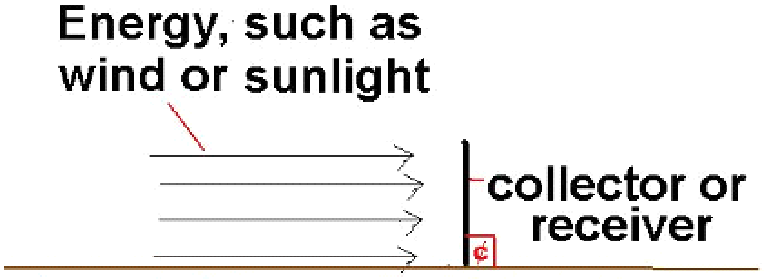
Today, as of 2020, the costly light sensitive paper or film material has been mostly been replaced by a light sensitive electronic image sensor in an (electric) digital camera. Here, digital means that the camera image senor saves the light or pixel (picture element, a small part of) data of the image as binary (1's and 0's) numeric data in the cameras memory and-or a file. Digital cameras have made photography very inexpensive, quick and practical for the average user. Most modern "smart" phones (ie., telephones) have a built-in camera(s) and internal computer circuitry so as to access the (electronic) internet communication and information, and-or run useful programs (ie., "apps", applications) such as a photo editor, perhaps to increase the brightness and-or contrast of the photo so as to make it more presentable and-or printable.

As mentioned previously, the light energy not reflected off an object is usually converted directly into heat energy in the atoms of the object. If a photon or "particle of light" has enough energy, it can collide with an electron and free it from the electric force of an atom by increasing the kinetic energy of that electron, and this creates electrical energy and this is the basis of how **photo-voltaic** devices such as solarcells function. Current in a circuit is electrons that are free to move and have kinetic energy, and can be influenced or directed to flow via an electric force connected to that circuit.

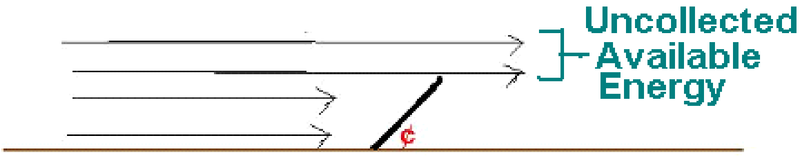
A photon or particle of light energy striking a **solarcell's** atoms can have enough energy or force (the application of energy) to free an electron from the atom it is bonded or electrically attracted to. Solarcell is similar to and associated with the words: Photo-voltaic (light energy to voltage, electrical energy or power), Solar-voltaic and cell such in reverence to the device which Volta called a cell and which produced a voltage and thereby a current of electrons. The function of a solarcell is to convert solar (from the Sun) or sunlight energy into electrical energy. Free or "loose" electrons have gained some (kinetic, moving) energy from the photon collision and can then be used in an electric circuit so as to do useful work (applying energy to other things, and through a time length). Note that an electron is not destroyed when its energy is used up, but it will be slowed down and then it will be easily attracted to and reside in **positive ion.** A positive ion is an atom that has a net positive electrical charge because it is missing an electron and has a "hole" or empty position for an electron to reside. Positive ions are created by electric or chemical processes and-or forces, and are also used for other electric and-or chemical processes such as for charge storage in capacitors and-or batteries.

One electron may not have a noticeable amount of energy to do a noticeable or practical thing, but a very large amount of free electrons and their summed up total energy can have a high power ability and do useful things such as work when most of their kinetic energy is converted to another form of energy such as heat or light. **Most (silicon based) solarcells or any size have a typical rated voltage of about 0.5 volts when functioning in a circuit.** It is of an advanced technical note and in the realm or study of maximum power transfer that solarcells do have a small internal resistance when illuminated and producing electricity via a complete circuit, and if many are placed in series, their total resistance increases proportionally, and for a load to have maximum power to it and a low internal power loss in the solarcell(s), it is best that the load resistance equals that solarcell's or solarpanel's internal resistance. The internal resistance or **"characteristic resistance" (Rc)** of a single solar cell can be found from: Rc = Vmax cell / I max. cell Ex,. for a typical 6" x 6" solar cell, 0.52v / 5.2a out max = 0.1 ohms effective internal resistance The total resistance of a typical 12v rated solarpanel with 36 solar cells in series is then: Internal source resistance = Rs = (18)(0.1o) = 1.8 ohms. Internal voltage drop or loss and-or internal power loss will increase with an increase in the circuit or load current drawn. Power loss max for a solarcell = I^2R = (5.2a max. for this solarcell ex.)^2 (0.1) =~ 2.7w). A typical solarcell can only create a limited and-or maximum amount of power and current: I max = (Vmax / Rs). A shaded solarcell, solarpanel, and-or areas of either will cause a high resistance region (area), and the cell(s) will obviously not produce as much output power (output power = input power - internal power losses and-or conversion losses), but will then loose that power internally, and of which can damage those cells(s) by excessive electrical heating and power dissipation. **In general, larger solarcells, especially in the width dimension have a lower internal resistance, and a higher output current, lower internal voltage loss, and therefore a lower internal power loss.** An **ideal voltage source** has a very low to 0 ohms of resistance and therefore has no internal voltage loss and produces a relatively high current.

The maximum amperage (the amount of electron flow or current per second) or current that a solarcell can produce (in a circuit, with 0 or no resistance [ie., short circuit current rating] to the flow of current) depends mostly on the surface, receiver or collector area of that solar-cell and the effective intensity of the (Sun, solar energy) light striking the surface of the solar cell. When the solarcell is perpendicular (90°, right angle, straight-upon) to the Sun light rays, the effective surface area of energy collection is at its maximum value and the generated electricity will be at its maximum value for that system. It could be said that in this condition, the solarcell and its surface is not tilted (or angled) away from the Sun and its light. [FIG 238]



A. Collector is perpendicular to the energy input.



B. Collector is not perpendicular, and is less than 90°

In the above figure, the effective collector area, Ae is: First, let At = total collector area, and h = heicht = side opposite ¢, Sin ¢ = (side opposite the angle) / (hypotenuse) = (h) / (At) = Ae / At , mathematically in this drawing and-or analysis: **Effective collector area = Ae = At Sin ¢** . If the tilted collector is made longer so as to collect and-or apply more of the available energy, its area will then be increased, and the energy density ratio of: Area / joule in, and-or Area / watt out will then be lower. than the perpendicular collector which has a smaller area. A larger solar collector also has a larger internal resistance. For the kinetic energy of the light to free electrons and make an electric current, the "collision" of the energy onto the surface of the solar collector needs to be direct in order to have the highest transfer of energy efficiency.

The low 0.5 typical output voltage of a solar cell can effectively be increased or "summed up" when they are electrically combined or connected in series (like a row) so as to make higher voltages. Solar-cells in series are electrically connected in a charge attraction, opposite electrical polarity connection, from one to the other. This is very similar to connecting (identical) batteries in series so as to have a higher usable output voltage (V = J / C) available, and where each battery is increasing or boosting the kinetic energy of the electrons passing through it. A higher voltage (ie., electric force, "electrical pressure", "electrical potential") will also create a higher current flow in the same circuit. Another way to increase the generated output current flow of a solarcell is to increase its surface area. Since this is not possible for the average person to do, a practical and effective way to increase the surface area of a solar cell is to electrically connect them in parallel to one another, and with all their positive terminals connected together, and all their negative terminals connected together. If the solarcells are (and should be) the same size, type and have the same electrical characteristics (ie., "ratings", output voltage and current), the output current of parallel connected solarcells will be the sum of current from each solarcell, but the output voltage will still be 0.5v for parallel solarcells. As indicated, when connecting solarcells together, either in parallel and-or series, to help avoid potential solar-cell damage, such as over-heating, solarcell damage and safety problems, it is recommended to use (identical) solar cells of the same type, ratings and size. The wires carrying the output current from a solarpanel (series and parallel connected solar cells, a "battery" or array of solarcells) and-or battery should have a maximum current rating that is greater than or equal to the maximum amount of current that will be flowing through it.

Because sunlight energy has a maximum amount of energy per square meter, a solarcell collecting that energy is limited to receiving a certain maximum amount of energy, and therefore its output electrical energy will be limited to a certain maximum amount of watts which is determined by the energy conversion efficiency of that particular solarcell and-or solarpanel. An 18% to 20% energy conversion efficiency is a typical value as of the year 2020. For example, if an 18% efficient solar panel receives 100 watts of sunlight power, then (100w)(0.18) = 18watts of it will be converted to electrical energy and power (energy/time, voltage and current), and most (100% - 18% = 72%) of the rest will be converted (and usually wasted) to heat energy, and some will be reradiated or reflected. If heat energy is desired in the form of warm air, a **solar air heater** can heat air for free after it is either purchased or made and installed, and with the sunlight and energy shining on its black, heat-absorbent collector surface inside an insulated rectangular box-like shape, and located a few inches beneath a layer of tempered glass. **Solar air heaters are very efficient, often 80% to 90% efficient at converting solar light energy directly into heat energy.** A solar air-heater is also less expensive (perhaps, half the price) than a solar electric panel of the same size. Due to the high conversion efficiency of a solar air heater, it is not recommended to use a photovoltaic solar panel to make heat (warm air, such as to heat a room or house) with an electric air heater of which requires high current and will quickly drain your energy storage (ie., accumulated charge, electrons, current) batteries. Clear glass or transparent plastic will allow the lower frequency, near-infrared solar radiation to pass through it, and this is ideal for warm greenhouses where plants are grown in cooler climates and-or weather and seasons of the year. Glass will block much of the higher frequency light and-or energy such as ultraviolet (or ultraviolet) light (UV).

If a solarcell is rated at 0.5Vdc and can produce 4A of output current, the theoretical or effective internal resistance of that energy source can be found using Ohm's Law: I = V / R , therefore, R = V / I = 0.5v / 4A = 0.125 ohms = (1/8) ohms = "an eighth of an Ohm". If the solarcell is producing less than 4A due to that there is less sunlight on its surface, its internal resistance will be higher. Here is how to calculate the output power: The maximum amount of output power of this example solarcell energy source is: P = (V)(I) = (0.5v)(4A) = 2watts = 2 Joules of energy per second.

A **solar panel** (or **solarpanel**) is simply a convenient array of electrically connected solar cells so as to increase (ie., multiply) the available output power which is many times more than that of a single solarcell. Many modern silicon solar cells are in the range of about 18% to 24% efficient, and are often priced according to their efficiency, and the 18% type is very common as of the year 2021. That is, they will convert 18% of the light energy into electric energy, and therefore waste (100% -18% =) 72% of it when its converted to heat (molecular vibration) energy on the surface of the solar cell and-or having a low (light to electric) energy conversion inefficiency to begin with and is therefore incapable of a higher efficiency. In terms of efficiency, they would make a better solar heater than an electric generator, but the usefulness of electricity in our modern world of electronic technology (devices, machines, lights and phones, that need and use the power of electricity to function) is important enough to tolerate some energy losses or waste. Energy availability or security is important, and reducing wasted energy or losses by creating more efficient solarcells and devices is an ongoing challenge.

The available and-or maximum amount of solar energy per square meter is about 1000W/m^2. Because of cloudy skies, sunlight incidence (application, input) angle, fixed positioning as opposed to more efficient solar (Sun) tracking or aiming, internal resistance, wire and battery resistance, diode(s), voltage regulators and converters, etc., the actual power available from a solar panel, especially the current, will be reduced below the maximum possible value and-or the solar-panel's rated output value. To help overcome these types of problems, and have a more consistent or stable amount of expected power, the solar panel should be designed and created so as to produce a slightly higher voltage or output power, say 30% more than what is actually needed due to an estimated 30% energy loss or waste in entire solar electric system. Often a solar-panel is designed so as to have an output voltage that is 1.5 times higher than it is rated. For example, a 12v rated solar panel is often designed to produce (12v)(1.5) = 18v open circuit without any load or device being powered. Once a load or resistance is connected to a solar panel, the voltage of the solar panel will drop in value, and this is due to that its internal resistance no longer has all of the generated voltage across it.

To power devices (ie., [current or power] "loads") that require "home power" or "utility power" voltages of about 120v, when using a rated 12v solar energy system or solar electrical generator system, (SEGS), a converter called a power **inverter** can be used, and this is a 12vdc to 120vac converter. An inverter often has a transformer to "step-up", increase or "boost" the input voltage, and at the cost of reducing the output current. Remember that power output cannot exceed power input. If the voltage is increased by a factor of 10 in a step-up transformer, the maximum, safe current output of that transformer is reduced by that same factor of 10. The inverter is connected to a large battery(s) that has already been charged up to about 12v or slightly higher. A diode in series with the battery prevents it from discharging its current back into the solar panel when the output voltage (emf) of the solarpanel becomes lower than that of the battery, such as during cloudy weather and at nighttime. Some solar panels may not have this diode since the charge controller usually has one. Some electric power inverters may still function at voltages slightly lower than 12v, perhaps as low as 10v.

A solar panel that is rated at 20% max. efficiency of the incoming or incident light energy can convert or transfer a maximum of 20% of that solar energy (ie., sunlight, photon energy) into electricity. If the flat plane or surface of the solar panel is directly perpendicular to the direction of the incoming or incident light energy of the typical available solar energy of about 1000 W/m^2 on a bright sunny day at the equator, it can convert that 1000 W/m^2 into a maximum of:
(0.20) (1000 W/m^2) = 200 watts/m^2 of usable electricity energy. At higher angles or latitudes from the equator, the solar energy available will be less. The solar panel will be rated and sold as a 200 watt (max power, = joules/second) solar panel, and here, it is when the offset or difference angle of the incident rays of solar energy to the perpendicular surface of the solar panel is 0°. That is, the solar panel is directly facing, aimed or "pointed to" the Sun and its light energy in the local area. When the Sun's position in the sky changes and-or the solar panel is effectively tilted away form the direct incident light, then less energy is available to it and it will collect less energy since the available (to the incoming light) effective collector area is now actually less, as if using a smaller solar panel. The output voltage will still be near 0 .5v, but the output current will be decreased by a larger factor value as the (incidence or "normal") angle increases, and is especially noticeable starting at about 30° away from the solar cells 0°, perpendicular (or "normal") reference line to the incoming sunlight rays. A basic theoretical formula relating the actual output power to the sunlight offset or incidence angle is:

(actual output power) = (COS offset angle) (max. rated output power of the solar panel)

Ex. If the solar panel is rated at 200W max. output, and its surface is tilted 30° away from the direct, 0° offset, sunlight, the output energy is calculated to be about:

(COS 30°) (200W) = (0.866) (200W) =~ 173 Watts maximum panel output, and before any other system losses.
If that solar panel was directly facing the Sun, the output energy of that solar panel would be:
(COS 0°) (200W) = (1.0) (200W) = 200W

With modern solar cells and efficiency techniques, if the plane of the solar cell is not exactly perpendicular, and is tilted away by up to say 15° to 30°, the output is not reduce too much. Many solar panels on roofs are set at a fixed angle throughout the day as the Sun appears to travel from the eastward to the westward direction. It is possible to mount a solar panel on a sun tracking motor that has light sensors (perhaps small solar cells, LED's, or photo-resistors) so as to follow or "track" the Sun's current position in the sky. This will maintain a more steady or constant amount of power output throughout the day, and to achieve maximum efficiency and power from your solar electrical generator system (SEGS). During the summer months, direct sunlight on the solar cells can heat them to a hot temperature and their efficiency (current output) is reduced, and because of this, it is often said that solar cells and panels work (produce more power) better when it is cooler in the winter months.

As mentioned previously, to help overcome various power losses and still have enough electric power available, solar panels are constructed so as to have a rated output voltage of about 1.5 times the advertised voltage. To accomplish this, more solar cells are connected in series so as to produce 18v with no load or circuit applied to or using that power. Connecting solar cells in parallel means more total surface area and more current generation without the associated power losses due to solar cells connected in just a series configuration where the total resistance of that circuit increases for each solar cell used. Connecting solarcells in series will not increase the current because the effective or total resistance of each solarcell in series is then a multiple of the resistance of one solarcell, and this high resistance will limit the current to just that from one solarcell. Placing solar cells or panels in parallel is also problematic since one may be at a different output voltage and-or resistance than the others and they will electrically conflict to some degree. In that situation, it is best to always use an output power diode on each solar panel so as no current can then flow back through it in the reverse direction. The preferred type of diode to use with a solar energy system is of the Schottky diode variety which has a low forward or "turn-on" voltage and power loss, but any high current (perhaps 6A to 10A max.) power diode should work reasonably for relatively low power systems. You will have to use a diode capable of safely handling or passing the expected maximum current, and power loss in it - Pd = (Vd)(Id), for a solar electric generator system (SEGS).

Solar cells and-or solar panels can be compared by various factors such as the advertised or rated solar energy to electricity conversion efficiency which is typically about 18% for the (lower cost, blue color) high quality amorphous ("multi-crystal mix") silicon solar cells, and 22% for the more modern (year 2020 , black color) "mono-crystalline", single or solid crystal silicon. Solar cells and-or solar panels can also be rated and compared in terms of maximum power, voltage, and current output, or possibly even amps (current) or power output per square centimeter of surface area. Solar cells and-or panels can also be rated and compared in terms of price per output watt. On a clear day, the sunlight energy per square meter is about 1000 watts per square meter of Earths surface area when directly illuminated by the overhead Sun and its sunlight energy. Since there is (1m x 1m) = (100cm x 100cm) = 10000 square centimeters per square meter, that is about (1000 watts / 10000 square centimeters) = 0.1 watt / cm^2 = 100 milliwatts per square centimeter. If the efficiency of the solar cell or panel is 20%, then the wattage per square centimeter is reduced to just: (0.1watt)(0.20) = 0.02 watts = 20 milliwatts (mW). The (max.) current generated per square centimeter is therefore: I = Pw / Vv = 0.02 / 0.5 = 0.040A = 40 mA per square centimeter in ideal conditions. An area of (1W / (0.20W / cm^2)) = 50 cm^2 will produce 1W of power.

As of the year 2020, the total cost of a pre-made solar panel with an aluminum frame and a tempered safety glass protective layer is as low as $1USD a watt. Some 100W lightweight, more portable solarpanels do not have the aluminum frame and heavy glass, but still have a protective plastic layer coating are as low as $50USD, hence 50 cents per watt. These somewhat fragile solarpanels can be "stiffened" or "firmed up" and protected with a lightweight wooden square frame on the back and sides, and-or attach a "tilt stand" so it can be aimed more directly at the Sun. You can search websites such as the Amazon.com and-or Ebay.com for solarpanels and other supplies for a solar electric generator system (SEGS), but locally in your area there may be a store such as Harbor Freight, Lows, Walmart, and Home Depot, etc. selling these products and having experienced workers there who may help you choose and-or install a solar-electric system. Many stores also have an associated internet website where you can browse many items both shown and not shown at the store location(s), and to then make purchases "online" via the Internet, and possibly have the items delivered to our house. Sometimes shipping is "free" or relatively inexpensive. A purchase helps both you, your community, the store's business and the product's manufacturing company so as the supply and demand of beneficial things can continue.

Though the cost of solar energy photo-voltaic panels has decreased significantly as of the year 2023, there is still a cost associated with all the other equipment and-or labor needed to install a complete solar electric system. When you consider energy security and-or availability when it is needed, the cost is well worth it and could be considered inexpensive and-or paying in advance for future electricity, and even if just to charge the battery in a flashlight so as to have light to help do things. Many portable devices as of the year 2020 use rechargeable batteries, and so as to also reduce the expense of purchasing more batteries, reduce wasted raw materials, and prevent batteries from being put in "garbage dump landfills".

To make a complete and functional basic solar electric generator system (SEGS), this is what is often

recommended:

1. **Solar Panel** A solar panel (solarpanel, or solar-panel) is an energy collector, and specifically, it is a solar or light energy collector. On a more technical level, it is also an energy converter or transducer since the energy of the light (ie., the energy of the photons) is converted to another form which is electrical energy.

   This panel may include a blocking diode so as the battery or other electronics does not send power back through that solar panel and causing the battery to drain power through it and-or preventing damage to the solar panel. This high-power diode capable of handling the current generated at the solar panel will have about a 0.7v drop or loss through it, or sometimes less if it is a Schottky diode with a lower forward voltage drop, and therefore a power loss in it that is equal to Pd = (voltage across the diode)(current through the diode). Ex. (0.7v)(5A) = 3.5W. A solarcell will have a "soft"- still a relatively high internal resistance and begin to conduct at about -5v reverse bias, much like an LED diode - and of which a series, reversed biased or connection diode with it can prevent current through it..

   Most solar panels are designed to generate a voltage that is about **1.5** times their rated output voltage. For example, a 12 volt rated panel will usually be designed to produce an open circuit (no load or current) of (12v)(1.5) = 18v. This will allow for an internal solar panel power loss or drop due its internal resistance having a voltage and power loss, and it will allow for other losses in the other parts of the solar electric generator system (SEGS). **A charge controller will usually include a blocking diode.**

2. **Charge Controller**. This is much like a voltage regulator which takes an input of 12v to 18v and creates a steady output voltage of 12v to13.7v which is noted as good for charging 12v lead-acid batteries. Some also have current charging options and control. Some may offer convenient 5v USB (Universal Serial Bus) power supply output on two pins or wires so as to charge up phones and power some devices such as LED lamps. Besides calling it a voltage regulator, a more accurate name would be a battery charging controller. USB versions 1.0 to 2.0 have a 5v output with a +,- 5% tolerance or "window", hence 4.75v to 5.25vmax USB3.0 has 5.5v max. Note that USB version 1.0, 1.1, and 2.0 have a 0.5A max current output. USB3.0 has a 3A standard max. output. You may research USB specifications. USB-A, USB-B, and USB-C are the names given to the connectors, and of which are also male and female ends. Adapters and-or special "mixed" cables are also available and common. Some charge controllers may already include a "blocking" or safety diode. Some charge controllers offer a 12v dc rated fixed output such as used for automobile and RV (Recreational Vehicle, campers, etc) appliances. For lower values of DC power, a DC voltage regulator can be purchased so as to have a reduced DC voltage, and an example is with the LM317 IC chip that is an adjustable DC voltage regulator, and it is discussed in this book. A charge controller is more properly called a battery charging controller. **NOTE:** Before connecting the solar panel to the charge controller, first connect the charge controller to the battery, and it often must also have a high enough voltage to be sensed by the charge controller as being a valid voltage to charge the battery. After connecting the charge controller to the battery, then connect the solarpanel to the battery. A 12v consumer device can then be connected to the charge controller's 12v regulated output port/jack, and it will also function if the Sun is not shining onto the solar panels creating power, and the power will be rather provided by the charged battery connected to the charge controller. A charge controller and-or power inverter may also electrically disconnect the battery from being discharged too much below its rated voltage and-or charge storage capacity, and since it may damage the battery by various chemical processes and mineral growths.

3. **Battery**. A battery can be used to accumulate ("build up") and store energy, and in particular, electrical energy such as from a solar panel. This energy can then be used when it is needed, such as during power outages ("grid down", or loss of the supplied power from elsewhere), and the "energy security" (ie., availability) is well worth it when it is needed and there is no other source(s) available. Small batteries are more portable.

The most popular type today in the year 2020, is some type of lithium-ion or lithium-iron type. These batteries are relatively lightweight as compared to a lead-acid battery. LiFePO4 is a Lithium-Iron-Phosphate battery. Lithium-ion batteries can be discharged much more than standard and heavy lead-acid batteries, and are a form of "deep-cycle (charging, and discharging)" battery where nearly all (about 90%) of its stored energy can be used without worry of battery damage. While discharging, a lithium-ion battery will maintain much of its rated voltage. It is recommended to recharge batteries as soon as possible and to try to keep them at their peak voltage so as to prevent internal crystal growths, and to have maximum power when needed. Recharging a battery should cease when the maximum rated peak voltage of the battery has been reached so as to prevent damaging it. Lithium batteries rated 3.7v can usually be charged to 4.2V (max.).

SLA is Sealed Lead-Acid battery and is similar to a standard lead-acid battery, but is also made to be a "deep-cycle" battery. Typically, a 12V rated lead acid car battery is charged up using 14.4V (max.) and this is also the recommended maximum applied voltage to it. A 6V rated lead acid battery would be charged using a voltage of half of that to: (14.4V / 2) = 7.2V (max.). These batteries are sealed so as to prevent the electrolyte from evaporating and-or leaking out if the battery is tipped over.

In general, the max. voltage of a battery is about 1.2 times that of its rated value,and which is about 20% higher.

Some other battery constructions and types are GEL (like a jelly) and AGM (Absorbed Glass Mat) and these are said as being more user friendly than regular lithium batteries. GEL batteries have a higher energy density than lead-acid batteries, but somewhat less energy density than lithium-ion batteries. Portable devices and tools often have an attachable battery pack that is Nickel metal based. NiMH (Nickel metal hydride) or NiCd (Nickel and Cadmium) and these have a higher energy density than lead-acid batteries, however not as high as lithium-ion batteries.

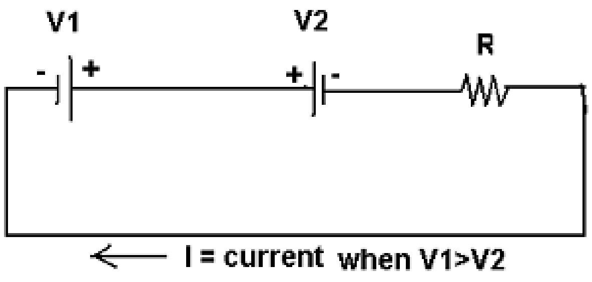
.

A lead-acid "car battery" type will work, but its battery drain considered as safe before potential battery (sulfate [sulfur] buildup from the sulfuric acid electrolyte, charging prevention or "life" reducing) damage is much less than that of a deep cycle or lithium battery. In general, the bigger the battery, the more maximum rated power or watts = (energy / second) available, heavier (if lead), and the higher the cost. A lead-acid battery is often lower in price than other types and of the same capacity, and can safely provide a high current when needed, such as to power a starting electric motor for a car.

A battery after being charged up over time, will usually have many times of power available than the solar panel(s) can produce per second and are rated for. A battery and-or a "battery-bank" (multiple batteries) are needed for running high power devices such as a motors and other devices, and especially at night when the Sun is not shining and delivering light energy to the solar panel(s).

Charge a battery at a recommended amount of current, say 10% to 20% of its amp-hour rating. A battery will get warm while charging because it has an internal resistance to the current flowing through it. As the battery increases in voltage, it will effectively become a "back-emf" (ie., reverse voltage) and where the net effective sum of voltages in series creates a less effective supply voltage and-or voltage difference to be applied the charging battery, and this will also reduce the amount of charging current to the battery and increase the charging time. Still, this is a safe way to charge a battery. To then get more current into that charging battery, the charging resistance to it can be reduced, but do not increase the voltage supply of the charger as an attempt to get more current into a battery since this may lead to overcharging the battery, and it will then have a higher voltage than the safe rated maximum voltage that it can be charged up to.

[FIG 239]



V1 = supply voltage , emf

V2 = charging battery or capacitor, emf, but since its polarity is reversed than that of V1, it is considered a reverse and-or back emf.

When V2 = V1, Vt or the effective charging v or emf = = V1 - V2 = 0, and I = 0V / Rohms = 0A

R is current limiter, for a safe amount of current. $I = \frac{\text{Effective charging V}}{R} = \frac{Vt}{R} = \frac{(V1 + (-V2))}{R} = \frac{V1 - V2}{R}$

4. **Inverter**. This is also called a power inverter. It will take the 12vdc to18vdc output of the solar panel and convert it to common household power of about 120vac, as used in the USA. Like the energy storage batteries, inverters come in all manner of sizes, maximum rated output power (watts), and corresponding prices. The trade off of increasing the voltage using a transformer-like voltage step-up system like an inverter, is a decrease in the available current, but the available power, less some small internal losses from the inverter, will be close in value to the input power. If the voltage boost or increase is 10, the current output will decrease by the same factor, hence it will be a tenth (0.1) of that at its input. An advantage of this is that cheaper, thinner output wires from the inverter can be used. With just one large capacity 12v battery, an inverted can be used to temporarily run high power devices such as tools (drills, saws, etc.) that contain high power motors which require a high input power to function properly. Two 12v solar panels connected in series and two 12v batteries connected in series can create a 24v solar electrical generator system (SEGS) of which the current, from the battery to the inverter, needed for a certain amount of power will be half as that of a 12v system, and this will reduce the cost of the inverter (especially if its a true or pure sine wave output type having thick wire coils for higher currents and power output ability) and have less (here, half) the battery drain because the voltage is now an increased factor of the power used, and therefore the current can be less, and at a safer and cheaper value with thinner wires needed to deliver that amount of power.

   If a DC to AC 120v inverter is rated at 600 watts, the maximum output current is: From: P = V I ,
   I = P / V = 600w / 120v = 5 amps. Since the inverter essentially boosts the input voltage of 12v to 120vac, a factor of 10, the output current will be reduced by a factor of 10, hence to use 5A of current at the output, then (5A)(10) = 50A from the battery will need to be input to the inverter. The cable to do this will need to be rated at 50A or higher, and particularly if it is long, rather than just a short distance of say 3 feet. The battery will also be needed to be rated as being able to safely deliver 50A max, hence use a 50aH rated battery.
   Pin = (12v) (50A) = 600w = Pout = (120v)(5A)

   When first connecting the battery to the inverter, the capacitors in the inverter may be drained of charge and there will then be an inrush of current from the battery which can cause damage to you and the inverter system. To help prevent this, a procedure called "**pre-charging**" can be done. For a 12V rated system, use a 10 ohm to 20 ohm power resistor with a power rating of 20W or more. Place this resistor in series with the negative wire and-or terminals, and keep it in place for about 20 seconds. **When sparks are possible**, **please use protective eye wear**. Be sure that the inverter is not powering any devices or "load" when doing this procedure. For each 12v higher solar electric system, use an additional 10 ohms to the total resistance value needed. Just the same, please considering discharging an inverter before handling and-or storing it, and this can be done by connecting the resistor to the terminals of the inverter.

   Using small "wall transformers", is a way to step-down the voltage of 120v to other voltages necessary. A DC to DC converter can lower the 12v input from a car battery, solarpanel or other electric power source so as to output another DC voltage level, say 5V, and this device is based on a DC voltage regulator circuit. The cheapest DC to DC solution is a low cost LM731 premade circuit, and another option would be a "switching" type of converter that can maximize power transfer, but those are more expensive, and may introduce noise into sensitive electronics including radios. Some of these types can also boost a voltage.

5. **Wire**. Usually, the wires or cables to connect the parts of a solar-energy system come with the components purchased, however, having some 10 to 14 gauge copper wire can be used in most cases, depending on if the maximum current needed is only about 20A or less as for 10 AWG (gauge). For lower currents, then a lower gauge wire can be used. A 100W solarpanel usually produces about 6A max. of direct current (dc) when the output is shorted (ie. directly connected together, practically 0 ohms load resistance) or sent only through an ammeter (current meter) when measuring the output current. For low power devices, some crafty people have managed to use speaker wire having or exceeding the necessary power handling needed.

Rated for A 12Vdc System   For A 12Vdc Battery   12Vdc Rated   12Vdc To 120Vac   120Vac LED Lamp

Solar cells (or solarcells) can be cut to be various smaller sizes from a larger full-sized manufactured solar cell, and in particular, often for a certain value (and without excess, waste) of current needed since the voltage output will always be about 0.5v no matter how big or small a solar cell area is. The area size needed, often for device portability is a reason to cut solarcells to a smaller size of area with particular dimensions, and this may also be done so as to increase the output voltage using several small series connected solarcells, usually of the same dimensions. For example, to power a white-light LED and without concern about storing any power, about 3v voltage is needed and about 20mA of current so as to have a reasonable amount of light from it. In order to have 3v, a series of 6 equally (same area) sized solarcells can be placed in series. (0.5v)(6) = 3v. The area of each solarcell is such that is will provide at least 20mA of output current. Since the solarcells are in series, that same 20mA of current will flow through each and also through the LED in that series circuit. Due to some resistance in the circuit, cut the solarcells slightly larger than needed and ensure (measure) that 20mA of current is actually flowing through it. Solarcells are often cut into smaller solar cells of a certain size needed and so as to also not have any wasted solarcell left over. Solarcells are very thin, brittle and difficult to cut without using something such a laser (high powered, concentrated light beam, energy) cutter, and it is recommended that you first obtain them already cut into smaller sizes if they are needed, and-or to have available for future projects.

As indicated above, the most common types of solar cells are very thin, about one-eighth of a millimeter thick ~ 1mm/8 =0.125mm = 125um, about the thickness of an index or playing card, and are very brittle due to being a rigid glass-like crystal structure and will easily crack if they are bent and-or too much pressure is placed on their surface. For comparison, it is slightly thicker than a human hair which is about 0.1mm = 100um = 0.0001m thick. To cut solar cells is difficult, and special lasers or saws and methods must be used. Silicon dust is **toxic** to breath and therefore a mask and eye protection must be used when cutting them and cleaning up any solarcell dust. The best cutting methods seem to be with high power lasers. For most people, the best and modern low-cost (actually often cheaper than building a solarpanel) option and recommendation is to buy a completely made solarpanel(s) and other parts for a solar electric system of the size and power needed. Some full sized solarpanels are heavy and are not very portable for a person to carry, while others are small and inexpensive, and can even store energy in an internal battery bank until it is needed.

A solar cell area that is cut into a smaller area will should have an output current of:

$$\frac{A\ \text{cutcell}}{A\ \text{uncutcell}} = \frac{I\ \text{cutcell}}{I\ \text{uncutcell}}$$

: same ratio , I cutcell is the current from a solarcell that was cut to a smaller area.
If a solar cell is cut into (n) equal areas:

$$\frac{A\ \text{uncutcell}}{n} = \frac{I\ \text{uncutcell}}{n} = I\ \text{cutcell}$$

How big should a solarcell be cut for, or purchased to charge a given battery? Since it is usually recommended to charge a lithium type of battery at a maximum of 10% of its rated amp-hour (aH) rating, a solarcell or solar electric system only needs to have a maximum output of 10% of this aH rating. It a battery has a 1 amp-hour rating, the charging current at 10% of this value is therefore, 1A (10%) = 1A (0.10) = 0.1A = 100mA. Use the above formula to solve for the corresponding area of the solarcell(s). Don't forget that a recommended diode will also drop the available voltage of the solarpanel by about 0.7V, and therefore, reduce the available current to your battery and-or device. To overcome this, design the solarpanel so as to be 0.7v higher than needed, and probably a bit more at 1v since two solar cells will produce 1v. Another option is to use a higher voltage solarpanel and a voltage regulator and current limiting and-or safety resistor to charge a battery, and this method also eliminates the need and expertise to cut solarcells.

Some new solar panel designs use a "half cells" (half-size of usually a full 6" x 6" solar cell) size, or perhaps "quarter sized cells" and so as to get a higher voltage from a smaller solar panel that has many more solar cells in it. A theory is that this will also reduce the power loss in each cell a little since the internal resistance will be less, and therefore making the solar panel a small percentage more efficient. Just remember that output current is charges (electrons), and that is what is actually needed and used to charge (accumulated, to be stored) a battery so as to store power. If the charging current is low, it will take that battery longer to charge. Pre-cut solarcells for homemade solarpanels are very useful for projects.

If the output current is lower than expected in full sunlight, the solarcell might have what is called micro-cracks. You can determine if a solarcell has micro-cracks by shining a bright light through it from the back side, and then observing for them. Sometimes a dealer may have received and sold these accidentally and-or at a reduced cost, or possibly they were returned and then resold. This is a reason to purchase a pre-made solar panel.

Some newer solar panels may include some solarcell(s) or solarpanel **bypass diodes** that will conduct current around any (hopefully just temporarily) shaded cells so as to prevent those shaded cells from getting hot, creating a power loss and possibly being destroyed, and then ruining the function of the entire solar panel. Bypass diodes will also prevent a parallel solar panel(s) from sending current through an shaded solarpanel. If your solar panel does not have these, then prevent any shading on the solarcells in a solar panel, such as not letting people stand too long between the solar panel and the sunlight. These diodes can also be installed by an electrician if needed.

Here is a photograph of a basic solarcell kit that can be purchased so as to make a homemade solarpanel by an experienced hobbyist. The photo shows a stack of 3in by 6in solar cells, the dark solar cell surface with many thin, lengthwise conduction wires on it, and the back of a solarcell with its electrical connections. Also shown is a 40ft spool of thin "tabbing wire" so as to connect each solar cell in series, and a 4ft spool of wider "bus wire" which can carry more current safely. A large 6 amp diode is shown next to a U.S. penny coin (0.75in =~ 19mm wide, diameter) as a practical reference size and measurement. Some kits come with some type of soldering "flux paste" or "flux pen" which greatly helps solder adhere to the wire and-or metal surface it will be jointed to, and you are encouraged to obtain, learn and use this for a more professional result. A 60W soldering iron is typical or average for many soldering projects. Delicate electronics like IC's, small transistors and capacitors will use about 40W with a pointed tip, and performed quickly so as to not overheat and ruin them. A flat tipped soldering iron is good for various flat tabbing wires. **Generally, though this**

seems like the right and economical thing to do, these kits are intended for knowledgeable and-or experienced builders, experiments and-or for some type of custom solar panel designed for a certain area size and-or output voltage, current and-or power level. For most people without the desire and-or expertise, resources, tools and ability, it is highly recommended that they rather purchase premade solar panels, or lower current portions of, because they will be cheaper (as of say 2020), less problematic, less worry, and more reliable. It is almost impossible as of the year 2025 so as to make a solar panel cheaper than what is already availa\ble, and 99% of the time, with much, much leass trouble and headache to build at home. Portability also needs to be considered, for standard solar panels are bulky (ie., large, unwieldy - difficult to move or carry) and generally heavy, mostly due to their size, tempered glass, frame, and often a clear protective epoxy resin. Lite-weight, lower power, portable solar panels are now commonly available. These can be placed within more protective transportation and-or storage cases such as plywood if needed. Here are some parts of a solar panel kit. Although, it helps to have extra power when needed, consider the solar panel wattage only needed for a device(s) since to waste created energy is not desired either. For example why need a 100W heavy panel when only a 30W panel is needed at best, and especially if it is for portability. [FIG 241]

Technically, the large surface area of a solarcell is much like the junction of a common p-n diode. A common p-n diode actually produces a small amount of light (usually infrared) since its area is small. If the p-n diode is illuminated by light, a reverse voltage and current will be created. A solarcell has much more junction area than that of a p-n diode, and therefore, it will produce much more current. It is even possible to create a very small amount of ("glowing") visible light from a solarcell if it is connect to a battery in reverse bias, and of the minimal voltage needed.

Solarpanels are a good way to power and-or recharge portable electric devices and-or power storage batteries. If you need to carry a solarpanel, you will need to then consider the lite-weight portable versions rather than a heavy solarpanel designed for the roof of a house or some supporting structure. Having something is said as being better than nothing. You can even purchase portable radios and flashlights that include a small solarpanel for recharging, either built in and-or external to the device.

[This space for book edits.]

COULOMB'S LAW (of physical force between electrically charged particles and-or objects)

This topic and article is about the physical force of attraction or repulsion of electric charges and-or of charged objects containing those (net or total effective) electrical charges. An equation was created by **Charles Coulomb** of France in 1785 so as to express the value of the electric force and in relationship to those charges (Q1 and Q2) and the distance (d) between their effective center points of attraction or repulsion. In short, the electric force of attraction or repulsion is measured as a being a common physical force with units of Newtons (N). From this equation, an amount of charge can also be determined by the force and distance between those two charges. The charges for this equation are also considered as static, resting, non moving, so as to avoid the magnetic field and forces created due to moving current.

$$F = \frac{k(Q1)(Q2)}{d^2}$$

: Q=charge , Charges Q1 and Q2 are measured in units of Coulombs (c) of electric charge.
k (or Ke) is the Coulomb's Law Constant = 1/**[**4(pi)Eo**]** =1/**[**(12.566371)(8.854(10^-12)**]**C^2/Nm^2)
Eo is the permittivity of a vacuum, and is also called the "electric constant"
with units of Farads / meter when used in terms of the capacitance of a capacitor.
Permittivity is a measure of the ability of the substance to allow the electric field.
k =~ (8.98755179)(10^9) C^2/Nm^2 =~ (9)(10^9) C^2/Nm^2 for air.
The unit for this value for k is: (Nm^2/C^2) , k and then F will decrease in denser mediums or substances between the charges. **k** is sometimes called the **electro-static force constant**.
F = Fe = the electric (not gravitational) force of attraction or repulsion in units of Newtons = N
(d) or r = radius from the centers of the net charge, and has units of meters (m).

On the atomic scale, the distance between the nucleus and electron of a hydrogen atom is about 52.9pm =~ 53 (10^-12)m = 53 picometers, according to the (1913), **Niels Bohr** popular atom model. This value is also equal to that electrons orbital radius about the nucleus (center). This distance is also considered as the (average and-or probabilistic) minimum distance that an electron can be about an atom, but for other elements which have other electrons in "higher" or farther radius orbits, their distance from the nucleus will be more than 53 pm. Electrons in more distant orbits have a weaker (Coulomb) attractive force applied to them from the nucleus which contains protons which have an opposite and positive electric charge, and of which is even lessened or weaker from all the other electrons present in that atom and having some repulsive force. Loosely or weaker bound (by force) electrons in farther orbits will require less energy to be free and then have kinetic energy, and this is what electric current is composed of. 53 pm is called the **Bohr radius**

Coulomb found and verified these mathematical relationships while experimenting with charged metal covered balls (and possibly, sometimes using metal plates) near each other and then measuring and calculating the force of their attraction or repulsion with a sensitive torsion (twisting force, here, using a thin hanging string) balance with a thin "pointer" (ie., a needle, indicator) or rod on it to indicate the amount of twisting force. A coulomb (C) is a practical unit of measure for a specific quantity of charged particles, such as electrons, and-or their net charge. These particles are difficult to see, count and-or numerically quantify with a number, and the Coulomb unit is very helpful because it is practical. Others have also studied the electric force using capacitors with closely spaced, large metal plates of which can accumulate and store charges (ie. electrons, or positive ions (atoms)), and this would actually be somewhat like a type of (electric charge sensing) galvanometer with larger plates that move in the presence of an net electric force due to the net charges.

If two uncharged (or de-charged) objects such as hollow metal spheres are identical, and if one is given a net charge, and due to like charges repelling (via electric forces), half of its charge can be transferred to the second metal sphere upon electrical contact which allows the transfer or conduction of the charged particles and-or their charge. The result is that each of these objects have the same amount of charge, and without actually knowing exactly how much other than that they are now both equal in charge. It could also be said that the original sphere held twice the amount of charge,and this could be expressed as: (100% charge amount) / 2 = 1/2 = 50% = 0.5 charge amount on each sphere. The sum of charges on each sphere is: 0.5 + 0.5 = (1/2) + (1/2) = 1.

If an amount of electric charge is divided in half by Coulomb's reasoning and method, this smaller amount can also be divided in half with another uncharged sphere, and the resulting charge on the last sphere is (1/2) / 2 = (1/4) = 0.25 of the starting amount of charge as that on the first sphere. According to Coulomb's electric force formula, when the amount of electric charge is reduced or divided by 2, but the original or starting force value of it is was not divided by 2, or in half, such as the charges were, but the resulting force was rather divided by 4 according to his experiments and measurements, and this is how he constructed his formula. Consider mathematically, and regardless of distance: A half of a half is: (half)(half) = (half)^2 = (1/2)(1/2) = (1/4) = (1/2)^2 = (0.5)(0.5) = (0.5)^2 = (1/4) = 0.25 .

Coulomb naturally knew that the greater the distance between those charges, the less the force between them. This is like the effect that the greater the distance from a source and-or its initial and total energy, the less sound and-or energy received. The same can also be said about a candle light. The less distance between electric charges, the greater the force between them. The relationship between force and distance was found to not be a linear or direct mathematical relationship. but rather a reciprocal (here, due to a division to represent a force reduction if distance increases) or inverse of the mathematical square of it, relationship, and this is why (1/d^2 or 1/r^2) is used in Coulomb's formula. Consider candle light that will pass through a square shaped opening representing 1 unit of area (= length^2, and will be projected onto a wall at a distance away. If the projection is 4 times larger, and-or the distance has doubled, the amount of light energy per unit area is now only (1/4) of that at the square shaped opening area. The total light energy is still the same, but it is less intense per unit area now, and this is also due to an inverse squared relationship.

Note that Coulomb didn't initially find the charge of a single electron or proton, but rather used the net or total effective amount of force from the charge of many electrons and-or protons called a Coulomb (quantity or number) of charge, and this amount is considered as a (manageable, measurable) unit of charge and is called the Coulomb (C) unit. Coulomb knew that the force was not only directly related to the quantity of each net effective charge (Qc) on each object, but also to their mathematical product of the charge on each metal surface. As a thought-example, a charge of 5, and another charge of 5 will sum to 10, but their product as a simplified numeric force value is (5)(5) = 5^2 = 25, hence resulting in a much higher force, much like an amplified force. This force is also an equal and opposite force as according to the known concepts of force.

As indicated previously, Coulomb also knew that the force was (inversely) related to the square of the distance between the charges, and this causes the force to decrease rapidly as the charges are separated more, and this is similar to the force of magnetism between two magnets, and the force of gravity between two masses. Coulomb also discovered the mathematical inverse square law of the force due to magnetic fields. These equations are very similar to that of the law of gravity or gravitational force and its equation that was previously developed by Sir Isaac Newton.

The concept of electrons and a way to measure current flow was not yet known or available, but what Coulomb did was to first charge a metal sphere, and then use that to charged sphere to charge another metal sphere, and in practical theory, the total quantity or amount of the electric charges is equal to the sum of the charges, and here, because of the way it was done, each sphere has half the total charge, but now each sphere has the same amount of charge on it and will repel each other with the same amount of electric force. Each would also have same force upon another charged object, and which indicates that those spheres do indeed the same amount of electrical charge. Given a fixed distance between two charges, we see that a quantity of charge on an object can be indirectly measured by the force (F) it would have on another quantity of charge (Q) on another object. As for the quantities of charge being multiplied together so as to find there resultant force value, this was done by measurements of using known relative amounts of charge and then measuring the (equal and opposite direction) resulting force. The resulting force was found to be related to the product of the two amount charges. It should be of no surprise that a small amount of charge has a lower amount of electric force ability associated with it, and that a large amount of charge has a higher amount of electric force ability associated with it. It is then also of reasonable consideration that a smaller amount of electric charge will have a low amount of influence upon a larger amount of electric charge, and that in an opposite manner, a larger amount of electric charge will have a high amount of influence upon a smaller electric charge. The resulting influence upon each other is a force that is an equal and opposite force upon each other. Unlike two forces exerted in the opposite direction upon an object, this resulting force is not simply, and mathematically directly related the sum of the two amounts of charge, but rather their product which is much like the product of the two sides of a rectangle, and the result being its area (ie., an analogy to the resultant force). Q1 and Q2 both affect each others force ability or potential, and are both a factor of each other and of the resultant equal and opposite force.

Coulomb was rather measuring charge as he knew it as something that caused a force and was involved with electricity, rather than as being a charged microscopic particles known today as electron particles, and that each has an electric charge and are therefore called charged particles or simply as equated to being charges. Coulomb did not know the number of these charged particles a unit or charge such as the Coulomb, but he knew that an amount of charge can be repeatedly divided. into smaller charges which have smaller forces associated with them.

Ampere created a unit to measure the flow of electric charge, which is called a current of charge or simply current:

1 Ampere = 1 Amp. = 1A = the amount of current that will flow through a resistance of 1 ohm when a 1 volt potential difference or emf (electromotive force) is applied to it. And by Ohms law:
current = I = voltage / resistance = V / R

current = $\frac{\text{1 volt}}{\text{1 ohm}}$, we see that a unit for current is needed, and this is what is used:

Since an amount of (flowing) current should also be measured as a flow rate of electric charges, A unit of 1A of current was defined as 1C of charge passing a point per 1 second:
And:
1A = $\frac{1C}{1s}$ = $\frac{\text{1 Vv}}{\text{1 Rohm}}$ also: 1C = 1A-s = the total amount charges in a current of 1A of current for 1 second. 1C = 1Amp-second

In general electronics studies, electron (e) is the smallest charged particle or mass. A net amount of total charge on an object is due to the (algebraic) sum of these individual charges: positive charges such as (net) positive ions (atoms that lost an electron(s)), will have a positive sign (+), and negative charges such as electrons will have a negative sign (-):

Net charge of an object = positive charges + negative charges

1 C = 6.24 (10^18) electrons. : 1 coulomb (number) of charge(s) and-or its carriers such as electrons
A coulomb of electrons or charges, and:
This is derived below. For consideration: 1C / second = 1 Ampere . By this definition, an Ampere (A) is a rate of flow of (an specific amount of) charge past a point per second, and-or the quantity of charges past a point per second.
Amps = Coulombs of flowing charge / second . 1A =1Qc / 1s = flowing charge / time

Dividing both sides by 6.24 (10^18) we can find the amount of charge or the number of coulombs that 1 electron is:

The charge on 1 electron is : **1 electron charge = 1.6025641 (10^-19) C** : a small fraction of 1 coulomb of charge

Total charge, Q = (number of charges)(charge of each charge) = (number of electrons)(charge of each electron) ,
Total charge = (number of charge carriers)(charge of each carrier) now consider:
If we assign 1C as the value of this total charge: 1C = (number of charge carriers)(charge of each carrier)
If each charge carrier is an electron particle, and is given its individual charge amount the same unit as C:

Total charge = Qc = (number of charge carriers)(1.602)(10^-19)C which can be expressed as
1Qc = 1C = (number of charge carriers)(1.602)(10^-19)C mathematically:

number of charge carriers = $\frac{1C}{1.602(10^{-19})C}$ = **6.24 (10^18) charges or electrons in a coulomb= (1C) of charge or electrons**

We can assign 1C of charge carriers = 6.24(10^18) elementary charges and-or electrons = 1C of electric charge.

Extra: The ratio of 1C of charge to 1 mol of charge is: $\frac{1\text{ C}}{1\text{ mol}}$ = $\frac{6.24\ (10^{18})}{6.022141\ (10^{23})}$ = 1.036176 (10^-5) : a ratio
0.0000136176 , hence small

Taking the reciprocal of this value, we will have the ratio of 1 mol of charge to 1C of charge =~ 96500 : a ratio
That is: 1mol / 1C = 96500 , and mathematically: 1 mol = 96500C , It could be said that in 1 mol of charge, there are about 96500 coulombs of charge. Extra: 96500 is called **Faraday's Constant** (Used in chemistry, electrolysis)

This can also be calculated as:
coulombs of charge in 1 mol of charge = (number of particles in a mol of charges or particles)(charge in an electron)
coulombs of charge in 1 mol of charge = (6.022141)(10^23)(1.6025641)(10^-19) = 9.6509 (10^4) =~ 96500C

Extra. Ex. Since 1A = 1C / s , If a current of 1A is flowing, how long will it take to total 96500C = 1 mol?
Setting up a proportion type of equation: (1C / 1s) = (96500C / Xs) , Xs = 96500s = 25.805h

Ex. If 1A of charge is flowing per second, how much charge will have flowed in 2h?
First, 1A = 1C / 1S , 2h = (2)(3600s) = 7200s . Equation: (1C / 1s) = (Xc / 7200s) , Xc = 7200C

Coulomb developed his Coulomb's Law or electric force formula with the aid of the previous (about 1687) understanding by **Joseph Priestley** (1733-1804), from England, of charged objects repelling each other, and having a force inversely related to the square of the distance between those objects. Priestley is generally more famous for discovering oxygen gas in 1774 after heating up mercuric oxide to a high temperature, and he discovered some other gases later. Priestley found that oxygen gas increased combustion and-or fire, and for developing a way for people to carbonate water in 1767, so as it will contain dissolved carbon dioxide (CO2, a molecule with 1 carbon atom and 2 oxygen atoms) gas and retain it in a fluid when that fluid is pressurized. This carbonated water or ("bubbly") "soda water" would later lead to the more desired flavored and sweetened ("fizzy", due to the many small textured bubbles) soft-drinks that we have today which are informally and simply called "soda" or "soda-pop", probably due to the similar bubbles found when using "baking soda" (sodium bicarbonate) with water. The labeling on the soda beverage may indicate carbon dioxide as carbonic acid. This soda is made when it is a cold liquid and CO2 molecules and microscopic bubbles are forced into it under pressure at slightly higher than the 14.7 psi normal air pressure, and at about 18 psi. When the container with some internal pressure and the carbon dioxide gas is opened, the internal pressure (about 50psi when the soda is at room temperature) is then reduces to 14.7 psi and the dissolved compressed gas will start to "come out of the solution" (ie., dissolution) and expand into bubbles and rise to the surface in the water. This will then reduce the carbon dioxide level and "fizzyness" or "effervescence" of the drink, and the drink is then said to be "flat" or bland, and not as enjoyable. This reason to keep soda drink or beverage as cool as possible before and after it is opened is because an increase in temperature causes an increase in pressure and the faster the (pressurized) CO2 is released out of the soda solution into the lower pressure region outside the container it is in, and that will result in wasted soda.

In a circuit, the number of charges (ie., electrons) passing a point will increase as the time of that flow of current increases. The total amount of these charges that passed a point would simply be the product of the number or amount of flowing charges per unit of time, and the total time, hence:

total charges = (flow rate of electrons or their charge)(time elapsed in seconds) : total electron charges and-or electrons

If the flow rate had units of coulombs (C) of electrons or charge per second:

total charges = (charge / second)(time elapsed in seconds) = (Coulombs/s)(s) = Coulombs of charge

Therefore, if you know the current amount, or simply the current, and the total time, you can calculate the total number of electrons that flowed passed a point in a circuit during that time:

If 1C of electrons passes by a point in a circuit in 1 second of time, the flow rate is 1C/s and this flow rate is defined as:
1 ampere unit of current = 1A. Amperes = Coulombs per second

1A = 1C / 1s : 1 amp is or has a flow rate of 1 coulomb of charge (ie., electrons) per each second of time elapsed

If electrons carry or have the charge, 1C of charge is also said as being the amount of charge in 1C of electrons.

total charge = (rate of charge)(total time) = (charge rate)(total time) = (coulombs/second)(seconds)

1C = 1A x 1s : 1 coulomb of charge or electrons will pass by a point in a circuit that has 1 amp of current applied for 1 second of time. In general: **C = A s and A = C / s**

Ex. If the current was 2A applied for 10 seconds, the total number of electrons or charges that flowed was:

(2A)(10s) = 20 amp-seconds = (2C / s)(10s) = 20C = 20 coulombs of electrons and-or their charges

1C = 1 coulomb = 1 amp-second = "an amp for one second" = "an amp of current flowing for one second"
= "a current of 1A for 1s of time will be a total of 1 coulomb of charge and-or electron charges"

From: A = C / s , we have **s = C / A** so as to determine how long it will take an amount of charge to move past a point when the flow rate of it is A. , A = C / s is essentially a flow of charge (time) rate = the amount of charge per second

Here are a few related equations in terms of energy:

$$1W = \frac{1J}{1s} = 1V\,1A = 1V\,\frac{1C}{s} = I^2R = \frac{V^2}{R}$$

: 1 watt of power = 1J/s is delivered and-or used up = 1 volt moved 1 amp of current. From this, we can derive:
Note mathematically: **J = VAs = (watts)(s)**

$$1V = \frac{1W}{1A} = \frac{1J/s}{1C/s}$$

Simplifying this fraction, we have:

$$1V = \frac{1W\,s}{1A\,s} = \frac{1J}{1C} = \frac{\text{energy}}{\text{coulomb}}$$ per , and 1C = 1J / 1V , and (1C)(1V) = 1J = W-s

1J = (1C)(1V) can be thought of as:

1J = (1V)(1C) = energy = work = (force)(distance) = Nm = W-s

V = J / C = energy / coulomb : voltage is shown here to be the energy per coulomb of charge

Electromotive force (emf) applied to charges will give that charge a change in its kinetic energy which is its movement energy, or to give the charge potential energy which is stored energy. Potential energy means the potential ability to use that energy so as to do work. Energy stored in a battery is potential energy.

If a coulomb of charge has 5 Joules of total energy, its potential energy is said to be 5V. 5V can be thought of as 5J/C. If that coulomb of charge used up or lost 2 Joules of energy in a resistor, it now has 3 Joules of energy left for that coulomb of charges, hence 3V, and it is said to have changed its potential energy by 2V. 2V can be thought of as 2J/c. This difference or change in energy and-or the voltage is often called a potential energy difference or simply the potential difference. The potential energy of stored or static charges can also give nearby charges (ie., electrons) some motion (kinetic energy) due to how charges repel or attract.

For charges to flow in a circuit between two points, there must be a potential energy difference between those two points which is essentially a voltage or energy difference between those two points. Current is said to flow with or from a high potential to a lower potential as the energy in the charge (electrons) is depleted to 0J such as when the electrons recombine with a positive ions (atom missing an electron) in the battery. Ex. A 5v battery is connected to another 5v battery using the same terminals on each, and the net pressure upon the charges in the circuit is (+5v) + (-5v) = 0v, and therefore there is no net pressure or force (emf) is upon the charges to influence them and cause them to flow due to electric forces. Simply stated, there is no potential difference for current to flow.

An analogy to electrical potential (energy) difference (the net electric force, or net emf) would be two similar containers of the same height connected by a pipe or tube at the bottom of each one, and with a substance, say water, and at different heights or depth in each one that is creating a different internal pressure at the bottom of the container than the other container. It could be said that there is a (net) difference in pressure between those two containers. When those containers are joined together with a pipe or conduit (ie., "conductor" or wire as for electricity), the difference in pressure (ie., stored energy) will cause the higher pressure substance (water, or current in terms of electricity) to flow to the container at a lower pressure. The flow will actually stop if and when the pressures are the same or "equalized" and there is no longer a pressure or potential (to use that [stored] energy, to do work) difference.

Another analogy for a voltage potential difference is with a mechanical balance scale. If the weights on both sides of this scale are the same, their will be no difference in force and therefore, there will be no difference in torque so as to cause the scale to rotate or move downward on one side. If the weights are different, their corresponding torques (ie. rotating forces) will no longer be the same and scale will then move by the available, torque due to the net difference in those two weights and their torques.

It will take energy from the battery to force current through a resistance, and this can be described as wasted energy and there will be a loss in voltage (ie. energy, J/Qc or= J/C) across that resistance, and which is also called a voltage drop. Likewise, this can also be described as charge (electrons) containing (kinetic) energy, and it is passing through a resistor (r) which can be described as a friction or collision force in the opposite direction of its motion, and that charge will loose some of its (kinetic) energy (J = VQ or= VC) in that resistor, and this will be called a voltage loss or drop or a potential energy loss or drop:

Vr = Vloss = joules / coulomb. This is usually an energy loss, unless it was for intended heat, etc.,

Since force is the application of energy, and voltage is a measure of the potential energy per coulomb of charge, voltage is often called potential energy, potential difference, electrical force, or electromotive force (emf), and since more potential energy means more (potential) force and ability to do things such as work.

An electric energy source is often called a voltage (J/C) power supply or power source, and its output voltage is often called electromotive-force (emf) which applies energy to the electron charges. Since 1**C**/1s = 1A, a 1 Volt power source can give 1 Joule of potential energy to 1 **C**oulomb of (forced, induced flowing, current) charge in 1 second of time. A current of 1A can therefore deliver 1 J/s of energy = 1 watt. **A resistance that looses and-or wastes 1 joule of energy per second when 1A = 1C/s flows through it is defined as a resistance of 1 ohm.** The voltage loss or drop across this resistance is said to be: voltage = energy/coulomb =J/C = 1J/1C = 1V. Hence J = VC. If 1joule of energy is wasted per second, then that amount or rate of energy usage is:

Power = P watts = J / s = (VC) / s = (V)(C / s) = (V)(A) = (voltage) (current) mathematically:

Joules = (watts)(seconds) =w-s and 1J = (1 watt)(1 second) = 1 w-s : one watt of power usage for 1s of time
Given an amount of voltage applied across a resistor, it will be its resistance value that will limit and determine the current through it. If there was only a very low resistance in a wire, the amount of current induced into the wire would be a high and dangerous (heat, burning hazard) value. Energy from the battery would be quickly applied to a large amount of the electrons and therefore that energy is quickly drained from that battery's supply of its total available energy. Though a resistance is thought of as energy or power wasting thing, it can limit the current or voltage, and therefore power to a safe value where needed, particularly if the supply voltage is higher than needed.

If the resistance (R) doubles then the current through it will be half. Current (A) and resistance are inversely related:

nR when $\frac{A}{n}$: mathematical relationship between R and A when there is a change in either and when the voltage is the same. Here, (n) is a multiplying factor.

Ex. In terms of the factors involved: $2R = \frac{A}{2}$ or= $0.5\,A = (1/n)\,A$ OR $2A = \frac{R}{2A}$ or= $A = \frac{0.5R}{A} = (1/n)\,R$
(here, n=2)

From also **V = I R or= A R** , and given a certain or fixed voltage, we see that the relationship between R and A is an inverse relationship, and they are not necessarily reciprocals, and that if one changes by a factor of (n), the other changes by a factor equal to the reciprocal of that same factor, hence by (1/n).

More force will be needed to push a certain amount of current through more resistance, hence a higher amount of energy is needed, therefore a larger voltage potential: V = J/C will be needed to force the same amount of current through a larger resistance. In short, the electrons will need a higher kinetic energy. If the resistance (R) increases by a factor of (n), then the voltage needed for a given amount of current must be increased by that same factor. If the voltage is not increased, but left the same value, then the current will be reduced by that same factor:

$$V = (A)(R) = A\,R\,(1) = A\,R\,\frac{(n)}{(n)} = \frac{(A)}{(n)}\,(n)R = (n)A\,\frac{R}{(n)} = (1/n)\,R$$: here A = I = current

If the voltage (V) or voltage force applied across that same resistance is doubled then twice the current (A) will flow. Voltage and current are directly related.

nV leads to nA
$nV = n(A)(R)$, when R is constant: $nV = (nA)R$ or when A is constant: $nV = (A)(nR)$

If 2 volts is across a resistor, it fundamentally means V = 2J / C of energy per coulomb is lost through that resistor when forcing each 1C of charge through it. If the current or charge rate is 3A = 3C/s , then the total energy lost through that resistor per second can be found using a proportion:

$\frac{2J}{1C} = \frac{xJ}{3C}$ and $x = \frac{(2J)(3C)}{(1C)} = 6J$: hence the energy wasted in 1 second is (V)(A) = J/s = watts

As for the specific value of this resistance (R) that passes 3A of current per second through it with a voltage of 2V applied across it, this can be thought of as 3C of charge that looses 2J/C of energy per second:

$\frac{2J}{1C} \times \frac{3C}{s} = \frac{6J}{s}$ = six joules will be lost each second = 6J/s = 6 watts : P = (V)(A)

and:

$$R\text{ ohms} = \frac{V}{A} = \frac{\frac{J}{C}}{\frac{C}{s}} = \overset{*}{\frac{J\text{-}s}{C^2}} = \frac{(6J)(1s)}{(3C)^2} = \frac{6\ J\text{-}s}{9\ C^2} = \frac{2V}{3A} = 0.667\text{ ohms}$$

: * see the note below
This can be interpreted as: 0.667 volts per 1 amp of current are needed to force that current through that value of resistance.

Js = Joule-seconds : this can be thought of as an amount of energy applied for a number of seconds, hence like a measure of the total amount of work or force applied to move that charge through that resistance. The resistance formula with (J-s / C^2) units indicates a measure of the energy needed, used or lost per coulomb squared of charge so as to force and move the charge through it. This specific and unique equation for R has a similar form to:

From: Pw = VA = (A R) A = A^2 R therefore: $R = \frac{Pw}{A^2} = \frac{\text{total energy}}{\text{current squared}}$

This ratio could be thought of as the energy needed and-or lost per unit (ie. amp) of charge or current as it travels through that specific resistance.

* From current = I = charge / s = Coulombs / s = C / s , and V = J / C ,
C = Is = J / V , therefore, C^2 = (C)(C) = (Is)(J/v) = IsJ / V , and
Js / C^2 = Js / IsJ / V = V / I , and since V and I are inversely related by a constant value of the resistance, this becomes: **V / I = R** : **Ohms Law** , and-or=: **I = V / R**

Joules (J) are the defined and standard units of energy which is defied as the ability to do work. The units of work are therefore the same as the energy that it took to do that work, and which are Joules.

Energy = Work : fundamentally , in quantity

Energy can be described as the ability or potential to do work = Work is the result of energy being applied. **Force** is the application of energy: F = (mass) (acceleration). **Work** is a measure of the transformation and-or transfer of energy, hence the energy used up and-or required to do something, and it is equivalent to the amount of energy involved: Work out = Work in = Energy used, and both have the same units of Joules. Work = (Force) (distance)

Energy in, or done = Work out, or done :and both have units of Joules (J).

1J = 1 Joule of energy is defined as the amount of energy used when applying a constant force of 1N through or over 1m of distance.

1J is also the amount of energy used up or needed to increase the temperature of 1cc = = 1mL = 1 gram of water, by 1 degree Celsius temperature. Joules are the accepted scientific units for heat, energy, and work (essentially the total of needed, "used up" or transferred energy).

To power a 2 watt light for 5 seconds, the total energy required and-or used is:

Here, showing various related equations, so as to have a greater understanding:

Total energy = (energy rate)(time) = (energy used per second)(number of seconds) = (power)(time) =
(watt)(seconds) = (2 watts)(5 seconds) = (5)(2)(watt-seconds) =
= 10w-s = 10J/s x s = 10 Joules of energy

The charge on an electron (e) is the natural and smallest fundamental electric charge unit. In other words, 1 electron is 1 unit of electrical charge. The charge of an electron in terms of, or with coulomb (C) units of charge will be shown below. Current is composed of electrons and-or their electric charges.

The specific charge of just one electron was found and averaged through many experiments by people such as **J.J. Thomson,** and then later by **Robert Millikan** with his famous **"oil drop experiment"** in the year 1909. In brief, this experiment used electronically (electric, electrostatic force) levitated tiny, spherical oil drops of a known, calculated volume and mass, and therefore knowing the number of atoms and electrons [charged particles] in that mass. These tiny drops were placed between two metal plates with at a high voltage difference applied to them and which created a high electric (force) field between them so as to levitate (held in a steady position in the air) those charged drops of oil, as if weightless and-or not affected by the downward force of gravity. The amount of electric force to levitate a drop is equal to the amount of the force of gravity upon it, hence its weight. Since this (physical, a force) levitation was due to an electric force, this force is essentially a result of Coulomb's Law and-or the equation for the electric forces of two charged objects. With this equation, and the force known, the quantity of charge of 1 oil drop could be calculated, and then divided by the number of electrons in that oil drop so as to find the amount of charge for just 1 electron. After many experiments, he calculated an average value for the charge of 1 electron to be about:

Charge of an electron = 1 electron charge = -1e = -e = Qe = - 1.602176634 (10^-19)C

Charge of an electron or proton. The electric charge of a proton atomic particle is the same as that of an electron, therefore having an equal value of a fundamental charge unit, but opposite in sign with a positive sign (+).

The total charge of a mol of protons divided by the charge of a single proton is equal to Avogadro's Number = (Na)

The total charge of a mol of electrons divided by the charge of a single electron is equal to Avogadro's Number = (Na)
Mathematically:
(charge of an electron)(Na) = (charge of a mol of electrons) = (96485C of charge) : with Faraday's Constant
Hence there are about: (96500 C / mol of electric charge) = (~96500C / mol of electrons)

Extra: A mol of Atomic Mass Units = 1 mol of amu = is defined as having a total amount mass of 1 gram. Protons and neutrons are equal in number in each atom, and they are also equal in mass. 1 gram of atom matter has 0.5 grams of protons and 0.5 grams of neutrons. 0.5 grams of matter corresponds to half a mol = (mol / 2) of protons, neutrons or amu. The amount of mass form the electrons is negligible. Because of the above concepts, and that hydrogen atoms do not have neutrons, 1 gram of hydrogen atoms will have 1 mol of protons.

Charges tend to concentrate on sharp points, angled edges, and corners of metal, and therefore, there is a higher chance of arcing ("sparks", "lightening") there when the emf of the total charge exceeds the breakdown voltage of air and distance to another object, and then lets a current to flow from those spots. Sometimes electrical objects and-or insulators are deliberately made round in shape so as to help distribute the charges more and therefore reduce the chance of arcing. A **lightning rod** to protect structures (houses, building, towers, etc.) from lightening has a pointed or relatively narrow piece of metal high in the air above a structure so as to divert a possible lightening strike away from the structure and into the ground around the structure. The lightning's energy will be diverted into the ground via a high conduction wire attached to a reasonably deep (several feet, maybe 1 meter), metal rod(s) and-or metal plate(s) in the ground.

Not too long after **Volta** created the ("volta pile", "voltaic pile") battery in about the year 1800, and which is a relatively easy and reliable way to make usable amounts electric power more available and practical. **Georg Ohm,** in 1827, discovered by observation and measurement the fundamental mathematical and physical relationship of voltage, current, and resistance of an electric circuit or path that the current is passing through and delivering energy. This relationship is known as Ohm's Law. It is nearly intuitive, easy to remember, and is the most useful formula about electricity: **I = V / R** : Current (I = A, or Ia) is directly proportional to the applied voltage (V) or (electromotive) force to move that current, and is inversely related to the amount of resistance (R) in the circuit or path that impedes the flow of current. The units for current (I) are amperes (A, named after Ampere). The units for the voltage is volts (V, named after Volta). The units for resistance is Ohms (ohms, named after George Ohm):

$$I = \frac{V}{R} \quad , \quad \textbf{therefore mathematically:} \quad V = I\,R \quad \text{and} \quad R = \frac{V}{I} \quad \text{: Ohm's Law}$$

A common analogy to the flow of current (moving electrons, or "flow of electricity") and Ohm's Law is with water flowing through a pipe. The pressure (ie., force) due to the weight of the water at the start of the pipe corresponds to voltage (ie., emf, electro-motive force). A force can apply energy to things such as cause water and-or electrons to move after transferring some kinetic energy to them. A larger amount of force can move a larger amount of water or current. The moving current of water corresponds to electric current. If the pipe is wide (ie., its diameter) enough, a large volume or amount of water can flow per second through that pipe, and this corresponds to the amount of current per second or amperage (amps). The pipe itself corresponds to a wire (ie. electrical conductor, conduit, or "path"). If the pipe somehow gets narrower, it is like increasing the reverse force, pressure or resistance in the opposite direction to the flow of a current, and the rate of water flow will be reduced. The **flow rate** = amount per time = (gallons or pounds) / second , correspond to: (current = electrons or coulombs of electrons) / second = **I** = A = C/s. The height and weight of the water at the start of the pipe determines the pressure (force / unit area) and this corresponds to the voltage (joules/coulomb , = J/C) or "voltage pressure" of a circuit.

Electric current will naturally take the path of least resistance, and which can be thought of as the least opposing force, resistance (such as friction) or pressure to its flow. In brief, water will flow through an unclogged pipe much more than a pipe with debris in it, or is a clogged preventing (blocking) the free movement or the flow of the water. A small passage hole, or nearly a clog in the pipe will represent a very high resistance or "open circuit", and which results in none or a minimal flow of current. A broken pipe is analogous to a short circuit where electric current is dangerously flowing in the wrong location.

Electricity is also found in many electro-chemical processes in the human body. A spark is the visible light produced from electric current passing through and interacting (ie., colliding) with air atoms and releasing some energy as light. Air is usually a non-conductor of electricity, except when the voltage (potential, force, emf) value across it is high enough so as to overcome ("breakdown") that resistance and force current to "break through" a high resistive barrier, either with a physical hole or causing that barrier substance to conduct electricity. Once a small current is flowing, it will help widen and-or reduce the resistance of the path in and through the substance. The air will then behave like a "short circuit" (direct or short, low resistance path) conductor with many free charges (electrons and positive ions) flowing and carrying energy. In this state of very low resistance, the current flow can be high and dangerous. The break-down voltage value of a non conductor such as air depends on the distance of air it will have to travel through. More distance means more resistance, and therefore it will have a higher breakdown voltage level or threshold. The breakdown voltage of air is about 30kv = 30 thousand volts per centimeter of distance. = 3000 volts per millimeter. This breakdown voltage is sometimes called the dielectric strength of the specific material.

Verifying the existence of atoms, molecules, and the value of a mol.

It was previously mentioned in this book that Dalton in 1811 named atoms are the smallest, individual and unique particles of an element. Since that time, it was difficult to convince others of the existence of individual atoms and molecules. In 1827, **Robert Brown** (1773-1858), a botanist from Scotland and later England, noticed the random-like vibrations and-or (short) movement of small particles (living = organic, and-or unliving = inorganic) in water while he was looking through a microscope, and called this motion as **Brownian Motion**. The motion of the small particles was due to collisions from (invisible to the eye and microscope) water molecules which have various (ie., random) velocities and corresponding kinetic energy and directions due to previous collisions with other water molecules. This collision of a particle by a water molecule would give the small particle, such as pollen, motion and-or change its direction. Water molecules can also receive and gain kinetic energy, usually from thermal energy, and these molecule can move and will collide with anything in its way including other water molecules and-or larger particles.

Albert Einstein would study Brownian Motion and made some further discoveries of Brownian Motion in 1905. Starting in about 1908 and later years, Jean Perrin would study Brownian Motion further and made some advances. From the equations developed from all these studies, a relatively close value for the number of particles in a mol of particles was also made and which could be compared to other values calculated for a mol elsewhere. Avogadro's Number = Na = 1 mol. From this value, the mass of the particle (atom, molecule, etc) could be made from: (total mass) / Na For example, from 1 gram of hydrogen = 1 gram of hydrogen atoms = 1 gram of protons, and we can then find the mass of 1 proton. 1 gram of hydrogen / Na = 1 gram of protons / Na = mass of 1 proton

As mentioned previously in this book, the mass of a neutron is nearly equal to that of a proton, and in most practical cases, they are considered the same value, however, the true mass of a neutron includes the additional mass of an electron as part of its mass. It is now understood by scientists that neutrons come from atoms that were affected by extreme force and pressure where a proton and electron forms into a neutron.

The concepts of Brownian Motion have also been applied to other areas of science and-or statistics. Brown formalized the word of "nucleus" within a biologic cell, and made significant advances in microbiology with his microscope instrument. Today, it is possible to view rough or low resolution images of atoms by using advanced forms of electron microscopes that can magnify up to ten million times. Note that since individual protons, neutrons, and electrons (which orbit the atom at a very high velocity) are much smaller than the nucleus of the atom, that it is most likely that they will not be individually resolved by any microscope, except for a "cloud" of many moving electrons about the nucleus, and that can be imaged. Atoms also vibrate due to thermal radiation energy striking them. The general image resolved when viewing atoms is usually the surface layer of the crystal lattice arrangement of atoms. It is possible for people to purchase and-or invest with others in an electron microscope, and even a used one in working condition is of significant scientific valuable in terms of what it can do to see small things that optical microscopes cannot due to that the long wavelength of visible light is used to transmit the image (shapes, colors) of the object to the viewer's light sensitive eye or camera sensor after striking the object and reflecting from it. To resolve smaller objects, a smaller wavelength is needed, and that can be achieved by using many electrons which have a small particle size, or by using higher frequency electromagnetic waves such as x-rays. The **DNA** helix (ie., a double spiral, like a twisted ladder with two side rails with rungs connecting to them in between) structure of life was found using an x-ray imaging microscope which projects the reflected image of the object onto photographic film as the sensor. He words "helix" and "helical" are older word meaning "spiral" which means "twisted" or "coiled",especially to make a longer structure.

NATURAL RADIOACTIVE ELEMENTS

It is thought that heavy elements which have a high amount of mass were created at "the beginning of time", energy and matter such as during the "Big-Bang", and-or then also created from the high pressures created during exploding stars of which may also have previously concentrated some heavier elements at its highly pressurized and dense core location. Earth too is thought to have some heavy elements that have sunk to its core and are then of much higher concentration, and that some of it can eventually reach to the surface via volcanic activity or plate tectonics (ie., surface, land movements). Radioactive atoms on the surface of Earth contribute to the natural background radiation (from Sun, stars, mineral ores) we experience. Heavy element concentration near Earth's surface, either in mineral ore and-or atom form. is relatively low, and the amount of radiation from these that are radioactive is correspondingly relatively low and without issue.

In 1896, **Antoine Henri Becquerel** (1852-1908), from France, is credited to the formal discovery that some elements such as uranium, and without external stimulus or energy applied, produced "spontaneous", high-energy, penetrating rays of invisible light called radiation. To help comprehend this invisible light, energy or radiation concept, if you were to shine a light or laser from left to right in a vacuum (ie., having no reflection and-or light scattering due to particles of mass in it) front of you, you would not see that beam of energy, but it is there. A heater or heat radiator is a metal structure designed to make and radiate heated air, such as to heat a room. The word radiation means an outward release, emittance, or transfer of energy, and which extends "radially" in 360° or spherical-like pattern from the source of that radiation. Heat energy is generally invisible to the human eye, but special cameras can convert this invisible form of (light and-or rf) radiation it receives into a visible image on a screen.

The radiation Becquerel discovered was invisible (like heat is) and traveling outward like invisible light rays from its source at the center of that radiation. This "invisible light" was discovered using a light sensitive photographic plate, and is somewhat similar to how X-rays are produced from a Crookes tube were discovered a year earlier by Rontgen. His contemporaries at the same time and study were **Pierre and Marie Curie** (1859-1906 and 1867-1934 respectively), from France and Poland respectively, who discovered many things about radiation while working in France, such as the glowing light (ie., a form of radiation) emitting and highly radioactive unknown element they eventually purified (essentially filtered away from other unneeded substances) and-or concentrated it together into a larger amount and called it radium. This radium was refined - concentrated (unwanted debris removed) and isolated from the hard, black mineral called Uraninite ("pitchblende"), which contains the element uranium. The isotope, radium-236 has a half life of 1600 years and is considered as the decayed form of uranium of which the isotope form uranium-238 has a half life of 4.5 billion years. Unstable atoms which have an excess of energy and-or particles, can decay or change into another atom after releasing some energy and-or particles. Radium will decay into the element lead. Uranium, radium and lead are metals. She also discovered the element polonium in the pitchblende. Becquerel was the first to formally discover a radioactive element or material, although a few people have previously noticed some effects that uranium caused on photographic plates. Becquerel essentially discovered both nuclear or atomic energy and radiation. The SI unit (Bq) of measuring the rate or intensity of radiation is named after Becquerel. 1 Becquerel or Bg is the decay of or within one nucleus of an atom per second, hence it is also a rate of decay. **1 Bq = 1 decay / 1s**. This decay will cause the release of a pulse of energy which is the emitted radiation or radioactivity.

1 **Curie (Ci)** is 37 (10^9) = 37 billion Becquerels per second, such as emitted from 1 gram of radium-226. How much radiation life forms have absorbed per unit of time generally has other defined units such as **grays** , **ergs**, and **rads** (a word from the word "radiation"), and this and other related topics of radiation is beyond the scope of this book, and you may research these.

1 gray = 1Joule of radiation energy absorbed by 1 Kilogram of matter = 1J/k. :by Louis Gray (1905 - 1965), from England
1 gray = 1 **sievert** = 100 rads). : by Rolf Sievert (1896 - 1966), from Sweden

A combined or total amount of radiation of 1 gray = 1 sievert = 1000 milli-sieverts = 1000 mSv = 100 rads = 100 rem during 24 hours = 1 day of time could cause radiation sickness. A cumulative total of about 100 mSv of radiation per year, such as for nuclear energy workers, and hopefully even less, such as the natural background radiation level (about 3 mSv total / year, or 0.333 rem / year) is generally considered as tolerable to the body and will generally not cause long lasting damage to the body. A cumulative total of about 1 sievert / year = 1000 mSv / year is considered dangerous and can cause cancer in some people, especially if that dose or amount occurred in less than a year and-or was concentrated in one region of the body.

ergs, are an older unit for work in the **cgs** (centimeters, grams, and seconds) system of standardized measurements, and it may sometimes be mentioned in older literature, and 1 joule =10 million ergs = (1)(10^7) ergs. 1 erg is the work and-or energy used when a force of 1 dyne of force is applied to move an object 1 centimeter. This is about the energy needed to move a small dime sized coin its own distance. From: energy = work = (force)(distance) = (ma)(d) = fd = mad ,
1 dyne of force = (m)(a) = (1g)(1cm/s^2). **1 dyne** = (1)(10^-5) Newtons = 0.00001 N = 0.000010 N of force.

Seek medical attention if you or someone you know has been exposed to dangerous amounts of radiation. Keep others away from dangerous amounts of radiation. Inform authorities.

Some radioactive elements and-or materials have much more radioactivity than others. Obviously, the more mass of a specific radioactive material or element, there will be more atomic decays or changes, and therefore, more total radiation per second. **Anything with radioactivity needs to be treated seriously and with a high amount of caution, and it is best to shield any amounts of it in thick lead containers having a label (often with a skull and cross-bones image indicating a serious health concern) as to what elements are contained within, source, date, use, etc.** When radioactive elements were first noticed and-or purified, they were prized as both novelties due to light and-or energy without electricity, and scientific advancements, and little was known of their penetrating and life damaging radiation danger, and particularly when the radioactive substance is close to the body and is therefore higher in energy intensity, breathed in as dust, and-or ingested (ie., swallowed). If someone is not allergic to iodine, and if available at the time of need, **potassium-Iodide** (molecules) can help prevent the body from storing radioactive iodine particles, especially in the thyroid gland which naturally absorbs and requires (non-radioactive) iodine for body health. There has been a suggested dosage per day is about 130mg per 154lb adult person. After division by the numerator or denominator by the other, this fraction has the equivalents of: (1mg / 1.185lbs) = (0.844mg / 1lb) , and a dosage for a specific person and their corresponding weight can be calculated as:

Dosage according to the weight of a per person / day = (weight in pounds) (0.844mg / pound) , for example, if a person weighed 100 pounds = 45.3592 kg, their daily dose per day based on their weight is:

$$\text{Dosage per day, by weight} = (100\text{ lb})\left(\frac{0.844\text{mg}}{1\text{ lb}}\right) = (100)\,(0.844\text{mg}) = 84.4\text{mg}$$

For each radioactive element, it will have a certain half-life time for its (decreasing, decaying) radioactivity intensity, and will produce less nucleus decays because the radioactive substance or source is becoming reduced in (radioactive) mass, and is being changed to another (lighter weight) element, and therefore producing less radiation. There is an example in this book about calculating half-life time, etc. Nuclear radiation is dangerous at high (Bq) levels which increase the chance of that radiation to ionize or break apart atoms and-or molecules, and therefore causing more destruction within cell structures of life. In a living body, cells that compose it naturally die and are replaced, however if too many cells are damaged at once, such as by radiation, the health risks are much greater and even life threatening. This radiation and ionization concept, applied with the careful guidance of scientists and doctors is sometimes used as one of the methods to help stop cancer cells from growing further, but sometimes these types of methods to treat cancer may produce other side-effects and-or problems.

The main types of radiation, and in increasing strengths, are called: **alpha** (relatively large in size, atomic particles of matter, lower energy and-or speed protons and neutrons, and can be blocked by some thin materials like paper, a few inches of air, or surface of skin, and are dangerous over time if ingested (swallowed into the stomach and-or inhaled into the lungs) and not removed from the body), **beta** (high speed protons [beta+ radiation] or free electrons [beta- radiation], atomic particles of matter, can penetrate deeper into the body than alpha particles), and **gamma** (very high frequency, high energy electromagnetic RF = radio frequency energy like light is, high penetration, high danger, ex. an x-ray) radiation. Gamma radiation can travel a great distance through much matter. To significantly reduce gamma radiation to low levels, a thickness of about 1 foot of lead, or 7 feet of concrete, or 14 feet of water is needed. The denser the element and-or the thicker the shield is, the greater it will absorb and block radiation from traveling further. Generally, using just a few inches of these materials and-or an inch of steel will reduce gamma radiation by half. Combinations of materials and-or dirt, such as below the ground level, will also provide shielding from gamma radiation. It is also of note that high speed electrons striking metal can produce x-ray radiation which is a high frequency RF energy and-or radiation. There are many radiation detectors which are known commonly and-or generally as "(Hans) Geiger counters". A geiger counter can detect alpha, beta, and gamma radiation. These are more formally called "**Geiger-Muller** counters (~ 1928)".to detect electromagnetic radiation and-or particles of energy. They generally work by detecting (secondary) ionizing radiation (usually free electrons) produced in the air or some other gas, and which has a high voltage (ie., high energy, V=J/C) and can produce a brief pulse of electric current, however some other types may have a crystal which when struck by the radiation will then produce a small amount of light (ie., a photon) which is then greatly amplified by an electronic photo-multiplier (ie., photon or light multiplier - a type of free electron creation and chain reaction [ie., for more electrons created] circuit) so as to determine if radiation (usually gamma) was present. The pre-geiger tube technology is credited to **John Sealy Townsend,** (1868-1957) , from Britain, in about 1900, and who studied the electrical conduction of gasses.

Ernest Rutherford (1871-1937), from New Zealand and a British-kingdom scientist, discovered the proton in 1911 by observing hydrogen ions which is just a single proton of a hydrogen atom and without an electron. Note that a hydrogen atom does not even have a neutron counterpart of its proton, hence a hydrogen atom without an electron is a positive ion and that it is composed of just a single proton. He also classified and named the alpha and beta types of radiation, and conceived the half-life formula for radiation decay and intensity. Rutherford also discovered the gas and natural element of radon after experimenting with radium. Rutherford found that a radioactive element can change and-or decay into another element such as radon gas produced from radium.

1. Just as with common light or radio energy radiation, the farther a person is from the source of nuclear radiation, the less energy received per unit of area, and-or, the less intense it gets according to the inverse square law of electromagnetic transmission and reception. The intensity of radiation at a certain distance from the source can be indirectly measured by the intensity of the ionized radiation or particles produced by that radiation, such as what happens within the tube (ie., the radiation sensor) of a (Hans) Geiger (radiation) meter or counter. A received (ionizing) pulse or instance of radiation will then produce or create some free electrons which is technically a small current of charge or electricity, and which can then be greatly amplified to produce a more useful amount of current or pulse of electricity through a meters and-or a signaling light or audio speaker.

Directed energy beams such as a laser bean do not follow the inverse square law concept of energy radiation, and the intensity of the beam does not diminish or reduce by a great extent as it travels further from its source. This is very helpful for outer-space communications where the signal power is often relatively small and the distances are great. "Pulsed" laser or radio wave beams is a way to transmit a very brief and circuit safe amount of (intense or concentrated) energy, and of which can travel and be received even much further than a standard laser beam. As a simple example, consider: Power = energy / time , with units of watts. 1 watt = 1 Joule / 1s , but if that same amount of available energy can be released in a quicker (ie., shorter, less of a duration) or faster amount of time, perhaps in one-thousandth of a second = 1s / 1000 = 0.001s, the pulsed output would be equivalent to a much more powerful: 1 Joule / 0.001s = 1000w = 1000J / 1s for a brief, but effective moment of time. High power lasers, with many used for cutting metals, use this concept of having a high available and useful amount of power for a brief (ie., "pulses") amounts of time.

Some long distance spacecraft, such as the one that went to Pluto, used a radioactive substance as part of an electricity generator, and since being far from the Sun, there isn't much sunlight energy to power all the equipment on it such as the camera, computer, and radio-data communication system by using just typical sized solar panels. In general, these "atomic batteries" or "nuclear batteries" will convert the heat generated during radioactive decay into electricity by using many semiconductor PN junctions in series and-or parallel electrical connections and-or configurations near the heat source. Some small power capable nuclear batteries can use the emitted nuclear radiation directly rather than the thermal radiation (ie., heat, molecular energy) so as to create electricity.

A Cloud Chamber

A mentioned above, cosmic rays are from stars and other astronimical events such as collisions, and these rays will mostly be composed of particles such as protons. These protons will usually strike an oxygen atom or other gas atoms in the air in the atmophere and cause a secondary emission of radiation.

A **cloud chamber** is a device made of glass, and containng a gas - usually alcohol molecule vapor, and of which when a particle collides with a molecule of it, it will leave a visual indication, and the result is a visible trace line ("streak") or curve of the collision(s). This cloud chamber can therefore detect the presence of ionizing radiation or partilces, and-or it can be used to study the behaviour of those particles, hence it became a tool or device to study (essentially invisible) particle physics with. The types of particles that can be deteced are: protons, electrons, alpha rays, beta rays and muons.

The cloud chamber was invented by **Charles Wilson** (1869-1959), from Scotland-England, in 1911. Wilson used water vapor instead of alcohol vapor. These vapors are very small condensed gas particles (ie., atoms, molecules) forming a larger particlces, and of which are still seen as very small particles to the observer. If this gas particles is struck by a cosmic ray for example, the gas particle will loose an electron and become ionized (ie., having a net positive charge) and attract other gas molecules and essentially form a visible line, essentially by having several gas molecules nearer to each other in succession.

Others people have improved Wilsons cloud chamber and-or created other systems to see particles, and some use alcohol vapor instead of water vapor..

The following discussions are optional to the reader of this book. These discussions contain common knowledge about flight and modern technology so that the reader may have a basic awareness and understanding of them, and some examples of how having some math and science knowledge is very useful in many fields of study and-or work.

How Balloons And Planes Can Fly, And The History Of Flight

This book topic is mainly used as a practical example of the progressive advances in science and technology - usually aided with some amount of math along the way. The reader may skip over this till a later time since its not needed for further use in this book. If a person has interest in these or other similar topics, it soon becomes clear that also knowing some math will be useful. The selected discussions are relatively brief and to the point so as to keep the style of this book, and if you are further interested, you can research each topic elsewhere, such as by visiting your nearby bookstores for specific books about each topic(s).

Since ancient times, it was well known that warm and-or hot air rose upward or higher in the air and sky. For example, this can be felt as warm air rising up and away from a candle. The warmest air of a house would often be located in an upper room and especially near the room's ceiling if it was not vented or released outward. Warm and-or hot water or liquid also rises upward and resides on the surface of the cooler liquid below it. A practical question would be how does this actually happen, and the following discussion(s) will help answer this question. A related topic and question is why does oil always rise upward and-or float on water, and even when they are both at the same temperature. The quick and short answer to much of these questions has to do with the density of the substance(s) or object, and the pressure or forces acting upon it.

First, a brief discussion on the topic of gasses and pressure so as to help bring some understanding to the technical issues of flight.

Joseph Priestley (1733-1804), from England,, discovered and published in 1774 the findings of a substance we know today as **oxygen**. Just a few years before this, **Carl Scheel** (1742-1786), from Sweeden, made a similar, but published later, discovery of a "fire gas" or some substance in air (a mixture of gases that we breath) that helps combustion (ie., fire, burning) occur or happen. Scheel is also generally given some credit for the discovery of some other elements such as barium, chlorine, manganese, molybdenum, and tungsten. Priestley's friend and contemporary **Antoine Lavoisier,** (1743-1794), from France, determined this gas to be a unique (chemical and fundamental) element and called it **oxygen** which is a word based on the Greek words for "acid (strong or sharp)" and "gene" (that which creates or produces, "genesis", "generator", etc). Later discoveries by others showed that the element **hydrogen** (formally discovered by **Henry Cavendish** (1731-1810), from England, in 1766 and named by Lavoisier in relation to the word water (hydro) where the gas is part of the water and oxygen molecule: H2O) rather than oxygen, is actually the main substance or element for creating acids. **Robert Boyle**, from Ireland, previously noticed this gas being produced as bubbles during a certain experiment (iron in an acid solution) and resulting chemical reaction in 1671. Hydrogen is the most abundant element in the universe, and is particularly found as a major element of stars. Lavoisier then also made advances in the knowledge of oxidation and combustion. Priestley also discovered some other gas compounds, particularly some nitrogen gas compounds. Nitrogen gas was discovered in 1772 by **Daniel Rutherford**, (1749-1819), from Scotland. Nitrogen is a useful "inert gas" meaning it does not generally cause any chemical reactions with other elements and-or molecules, and is non-flammable and non-combustible.

Henry Cavendish determined that water is a compound of hydrogen gas and oxygen gas, and after combusting the gas mixture and noticing water drops. Shortly after **Alessandro Volta,** from Italy**,** created the first battery in 1799-1800 which permitted a portable, reliable, and steady (direct) current flow and rate, and at a desired voltage, the concept of **electrolysis** (using electricity to cause chemical reactions by using electricity to reduce or break apart matter, and-or bind matter such as for electroplating one metal onto another) or electro-chemistry was discovered in 1800. Electrolysis will separate a water molecule (ie. a compound of two or more atoms) into its atom parts and therefore create hydrogen gas (at the cathode or negative terminal or electrode), and oxygen gas (at the anode or positive terminal or electrode) from it when a voltage (about 1.23V (ie., 1.23 joules of energy / coulomb of charge) minimum, and any excess power may be wasteful if not designed correctly) is applied in and across the water with two metal electrode surfaces. Plain or pure water does not conduct electric current (ie., electrons and-or net positive atoms called ions) very well, and therefore some "electrolyte" (such as a small amount of salt, an acid or base) substance or particles are added into the water so as to create a (ion, solution, positive particles able to move) solution that can conduct electric current much better than pure or plain water. The electrolyte solution should also not conduct very well like a standard conductor or wire because that would then effectively "short circuit" the power, particularly the voltage difference and electric forces needed to propel particles needed for the electrolysis action on or from the metal or graphite electrodes. During electrolysis, electrons flowing (ie., the electric current) will add or remove electrons to or from ions and atoms in the electrodes (including objects used as an electrode(s)) and-or the electrolyte between the electrodes.

Hydrogen is flammable and is used in some safely designed "high heat micro-torches" and "fuel boosters", otherwise, hydrogen gas is dangerously explosive (highly, fast, combustible, resulting in much energy being released in a short amount of time, hence high power, explosive) in the presence of oxygen and when ignited ("lit", initiated, started, initial necessary energy input) by a flame, and this gas mixture is often called "Brown's gas" or "HHO" such as created during the electrolysis of water. Brown's gas is usually made only when immediately needed, and using short tubing, flame-back arrest or prevention filters, and a lack of pockets or regions where the gas can dangerously accumulate and cause a larger explosion. Often, the produced gasses are sent through a water-bubbler system as part of the flame-back prevention and safety system. By using some type of separator wall and-or collectors at the electrolysis process area, it will keep the hydrogen and oxygen gases separate, and they can be used for various purposes and-or storage, such as hydrogen balloons and breathing oxygen. The minimum voltage for this electrolysis is 1.23v (ie. 1.23 Joules / 1 Coulomb of charge), but 2v to 5v is more typical. Higher voltages can be used, but it can be a waste of energy and-or cause "thermal runaway" where the temperature increases conductivity and eventually leading to electrical problems. The amount of current drawn depends on the plate area, concentration or amount of electrolyte in the water, and it also depends on the temperature.

Electroplating uses the basic concepts of electrolysis for when a metal object is given a thin coating of another metal, atom by atom by using electricity through a conductive solution with the two metals also being used as the electrodes or terminals. This may be done to put a protective layer on another metal such as gold which is a metallic element that is highly unreactive to the presence of other substance and therefore has very low tarnishing or oxidation, and is therefore highly useful for electrical components and-or physical contact surfaces or joints. Often metals are coated with the relatively cheap metal zinc to prevent rusting (oxidation). Electroplating is also used for decoration and-or crafting needs. There has been some speculation if the ancient, possible crude or basic battery looking device modernly called the "Bahgdad battery" was used for some electroplating and-or novelty use, after all, several of any battery in series connection will increase the available energy or voltage, and any battery's in parallel connection will increase the current. There is no historical record or knowledge of any battery being manufactured and available for use to the general public, unless it was privileged knowledge and being kept secret, or simply too limited or insignificant to record. Much valuable knowledge is said to have been destroyed in the fire of the library of Alexandria (Egypt) historical incident and loss in 48BC.

Michael Faraday is often credited to the formal or scientific understanding of electrolysis, and created Faraday's Laws of Electrolysis, but there has been some limited use of it before then, but it wasn't understood and practical until the invention of the electric battery ("voltaic pile) by Volta in about 1800. Shortly thereafter, experimenters discovered electrolysis. Electrolysis has lead to the isolation (from rocks or "ores" containing the element(s) in practical quantities) and discovery of several elements such as the metallic elements: sodium, calcium, gallium, boron, lithium, barium, magnesium and potassium. **Humphry Davy** (1778-1829), of England, discovered several of these elements (sodium and potassium) by using electrolysis on substances at about the year 1807, and so as to break apart and refine substances such as compounds and oxides of elements into their more pure or elemental parts. This is a fine example of how technology can effectively improve, enhance and-or lead to other discoveries and technology since it was just a few years after the invention of Volta's battery which made the study of electricity more available and practical to many. Another similar leap in technology was with Geissler and Crooke's Tubes, and then later, the vacuum-tube and transistor electronic amplifiers. Michael Faraday initially worked for Humphry Davy. Davy invented the "trough battery" for his experiments, and where the two different metal plates (such as zinc and copper) were rather placed horizontally in series, rather than vertically in series like Volta's pile, and fully submerged in the (stronger, here diluted sulfuric acid) electrolyte solution.

Some of his battery's were also electrically (with wire or metal bars) connected in series (like a chain) so as to create a very high voltage (electric potential energy and-or force, and-or available energy difference to cause current to flow). With his large voltage supply, he also created the carbon arc (electric discharge through air, creating light) lamp that had carbon electrodes separated by a short distance in the air, and which then created a very bright light when an electric current was flowing through the air from one electrode to the other due to the high voltage applied. This was technically, the first (semi-practical) electric lamp (ie., that which can produce visible light energy by using electric energy) created before Thomas Edison made his study and discoveries so as to make a much lower voltage necessary, more practical (for the average person and household use) electric lamp about 70 years later in 1880. The light seen from Humphry's arc lamp is similar to that seen when welding (ie., gluing or joining) metal parts together with a molten metal which will soon becomes solid and rigid (strong) when the high energy and temperature is no longer applied.

The elements discovered by Humphry Davy using electrolysis are: Sodium, potassium, calcium, magnesium, boron, barium, strontium, and he also verified chlorine (a gas) as an element.

It is of note that some elements such as sodium are very reactive with some other elements (such as water) and are therefore not found in a pure metallic form in nature, and are rather found in ionic form and-or a (metal) salt form. Davy used the electrolysis of sodium hydroxide (NaOH) and found sodium metal, but modernly the electrolysis of molten sodium-chloride (ie., NaCl table salt) is used. Sodium metal cannot be stored in water (moisture) and-or air, and is stored in oil, and like some other elements such as mercury and the radioactive elements, it is generally illegal to have unless a permit for a specific use is granted.

Three ways to inflate a balloon:

1. Less dense, energized hot air. 2. More dense, compressed air. 3. A lighter than air, gas

Heated gas such as air molecules will acquire kinetic (moving) energy and move faster, and when these high speed, moving particles within a container strike its inner surface or wall, this will cause an expandable container to expand, "inflate", "balloon outward" and increase in volume size. If a (rigid) container cannot expand, the gas will retain its higher pressure state in its is more limited volume or space until it is somehow cooled and decreased in energy. Each "excited" or energized (increased in energy, such as kinetic energy) and moving atom or molecule of a gas has kinetic energy that can then apply a force or pressure on the inner surface of which it is in. This is how a hot-air balloon is inflated, and so as to have a larger volume, but containing less dense air, and therefore less air weight than the common cooler air at standard atmospheric pressure. As the kinetic energy of the moving particles of air is relatively, slowly reduced and transferred to the cooler balloon surface, and then to the air around the balloon, the balloon will decrease in internal pressure and will slowly deflate. If a hole develops in the balloon, and particularly near its top which has the hotter air and most pressure, it will deflate much quicker.

A key to remember when the word pressure is mentioned, is to always remember that it is caused by a force which is the application of energy. A ridged (strong, non-expandable) container may have a gas or liquid having a high pressure (and potential energy) within it. It took energy to compress that gas or liquid to have a high pressure, and it is stored much like a metal spring that was compressed, but here, the spring is made of a gas or liquid particles. This energy if not used, is then stored energy and-or "potential energy" that can be potentially (possibly, probably) used when needed.

As for inflating a rubber party balloon with cool air, this is done with air that is compressed and therefore it is more dense. Compressed air inside a rigid cylindrical tank can be purchased, or it can be made by a person blowing and forcing more and more air into a balloon until it becomes compressed within it. To keep the internal pressure and pressurized air inside the balloon, the balloon is tied closed, otherwise the compressed air will effectively will be forced out by that higher internal pressure, and it will travel into a lower pressure region, and the balloon will then deflate or decrease in volume and have the same air pressure in it as upon it, hence a pressure differential or relative pressure of 0 psi. When more air is forced into the balloon, it will cause the air within it to be pressurized (ie., greater than 14.7 psi, normal sea level air pressure) with the force upon it and the moving air molecules will compress closer together like a compressed spring. This effective "spring" of compressed ("pressurized") air will try to release its stored (potential) energy and apply a force upon the inside surface of the balloon which causes the balloon surface to expand outward. When a balloon rise into higher, less dense, less pressurized air (ie., < 14.7 psi) it will expand if the internal pressure is greater than the outside air pressure upon the surface of the balloon. If the air pressure is half, the volume of the balloon will double. According to the **gas pressure law** which considers the relationships between volume, temperature, and pressure of a gas:
$P1\ V1 = P2\ V2 = k$ = a constant value. Mathematically: $P1 / P2 = V2 / V1$ and these are reverse (or inverse) ratios, since the corresponding values of pressure and volume are inversely related. As the gas volume of a balloon increases when it expands into a lower pressure upon it, the internal pressure will decrease unless it is maintained, such as by heating it up to give it kinetic energy.

The air pressure of an deflated (non-inflated, expanded) elastic party balloon that is to filled by a person blowing into it will initially be at standard air pressure of 14.7 pounds per square inch (psi) on both its external and internal surfaces. To inflate (expand it internally) the balloon with a persons breath pressure, the air pressure upon its insider surface must be greater than 14.7psi for that balloon to expand into the now effectively lower air pressure of 14.7psi. This balloon will not rise upward vertically in the surrounding air since it now contains compressed air that is greater than 14.7psi, and is therefore denser and heavier in weight per unit volume than the surrounding air per unit of volume, and that type of air will actually "sink" (decrease vertically) in the normal air. **If the balloon is inflated and has less dense, high energy air in it, it will rise vertically such as like a bubble rising upward in water that is more dense and heavier per unit volume. More dense per unit volume, higher pressurized water will sink beneath the bubble area and will force the bubble upwards.**

Heating a gas(s) such as air will also make it less dense (ie., in amount) per unit volume, when the atoms or molecules of the material with an increased kinetic energy are moving faster and expanding outward into a larger volume or shape.

That air is then said to be "more lite" or "not as heavy" in weight per unit volume. Since ancient times, people knew that hot air, such as heated air from a fire, rose or lifted in a upward or vertical direction. Why does hot air rise upward? Heated air is less dense (per unit volume) than unheated air. This will effectively make it rise upward to a lower or equivalent pressure region as denser and heavier cooler air moves sideways and downward around it due to the constant force of gravity upon it and takes (ie., displaces) or "fills in" the balloons older position as the balloon moves into and displaces any denser air above it if the balloon does not have much weight, and this will be discussed further ahead.

It was just a matter of time from the first fires made by nature and ancient mankind until a small, lightweight hot air balloon type of structure called a Chinese Lantern was invented and which was made out of lite-weight paper material. These devices were sometimes used in the night as a signal for an event. Because they use a small flame for the energy or power source to make heated, less dense air, they are a potential fire hazard.

Matter that is said as being "lighter" is due to that it is, on average, less dense per unit volume of that matter or mass (the measure of matter). Less dense means it has less matter per unit volume, and less matter means it will also have less weight (force due to gravity acting on or applied that matter). Denser things have more mass per unit volume and therefore will correspondingly (and proportionally) weigh more per unit volume, and are said as being heavy or heavier in weight. This weight or force of the air up in the sky will cause a pressure upon the matter below it. The denser (weight, more force, more pressure) and more heavier air will effectively "sink" around and cause the less dense and less weight matter per unit of volume to be forced out (here upward) or "displaced" from its position, and cause it to move upwards towards the less dense air.

If the air pressure within a balloon or bubble remains the same as it rises upward, the size or volume of that balloon or bubble will actually increase due to the decreasing pressure upon its outer surface as it rises into a less pressure region.

When water freezes when being equal to or below 32°F = 0°C, it is one of the few substances that expands slightly when it is frozen to be a solid and no longer a liquid. This happens because these molecules that are loosing energy and joining together to form a rigid crystal structure with a slightly larger volume than that of the water. Ice will therefore actually be less dense (and "lighter") per unit volume than liquid water. Ice (ie., solidified water) is much harder than liquid water, but it is slightly less dense. If a piece of ice is placed in liquid water, the ice will effectively rise upwards (vertically), much like a less dense hot-air balloon would in the air, or a bubble of air in the water. By the force of gravity that applies some energy and induces motion, colder, more dense air or water will then sink to a lower level than less dense, warmer air and water. That which is less heavy in weight on average will be naturally forced via the pressure (from the weight, force) upon it to essentially move upward, as the more dense and heavy substance takes its position. This can be conceived as exchanging positions due to density, weight and pressure. Ice will float on water, and the relatively small amount, or percentage, of ice that is above the surface of the water is due to that ice has weight and is only slightly less dense than water. A unit and-or given volume of water will expand by about 5% in volume after it freezes. Now consider removing that 5% amount of volume, and we see that a unit of volume of ice then weighs about 5% less than the same volume of water. Since ice is much more dense than air, the ice will not be caused (by a net force due to a pressure difference) to move and rise upward and into the air to a lower air pressure region like a hot-air balloon would.

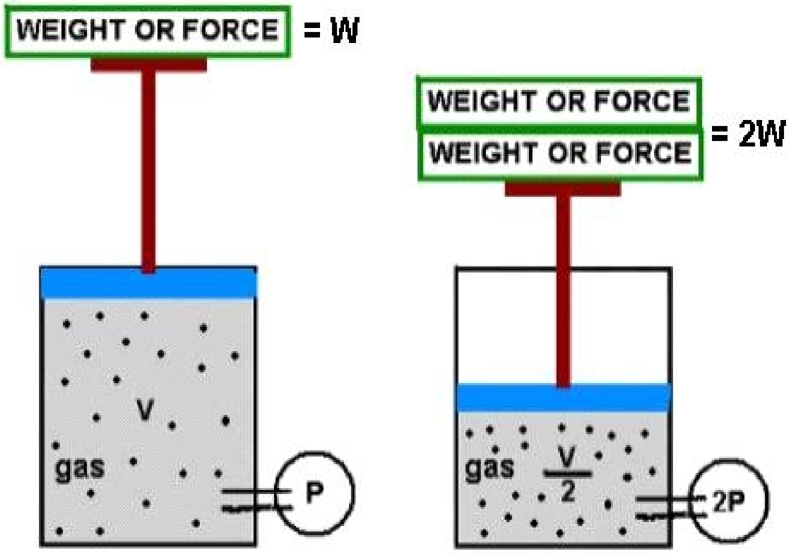
Air or any other gas that is twice as hot in temperature will have twice the kinetic energy, and therefore it will have twice the pressure or force upon the inside surface of a balloon to inflate or expand it. If the container is solid, rigid, non-expandable, then volume will not increase, but the pressure of the internal gas and its inner container wall or surface will increase when its temperature is increased. Excessive high pressure within a container can potentially cause a container to burst open abruptly and cause damage and-or injury. A lesson is to check how much maximum internal pressure a container is rated for before it is filled and-or (possibly) heated.

For a balloon filled with heated gas that is energized and expands in all directions, it could be said that the volume (**and not the mass and-or its weight**) of the gas has doubled when the temperature doubles. The space between the atoms or molecule of the heated gas has increased. If the container cannot expand, and is rigid, then the pressure of the gas will increase when its temperature is increased.

For a balloon, when the heated gas looses energy and looses temperature, the pressure upon the inside surface of the balloon will decrease, and the balloon will get deflated. For a balloon that was inflated with compressed air, it will generally remain inflated to the same volume for much longer and when the (internal, external) temperature difference is minimal and-or held constant. The volume of an inflated balloon can change if the outside, external air pressure on it increases or decreases, and-or the temperature changes such the temperature and pressure of the gas in the balloon changes. If an air filled balloon is placed in water, the internal volume of that air will decrease as it goes deeper into the water where more water pressure is upon the surface of that balloon or "bubble". The air in that balloon will get more compressed the deeper it goes in the increasingly pressurized water.

For a balloon with heated gas such as air, the density (mass per unit volume) of the gas will be less, and this will effectively cause the balloon to rise upward when the higher pressure, more dense air takes moves in to its place or "displaces it" with force. The higher air pressure at the bottom of the balloon will also force the less dense balloon upward into a lower pressure region. Technically, the air near the top of the balloon is slightly less dense and at a lower pressure than the air just beneath the balloon. For the balloon to rise, the upward pressure or force acting upon a balloon must be greater than the downward weight, force and pressure upon the balloon. At sea level, the air pressure per square inch is about 14.7 pounds per square inch = 14.7psi = 14.7lb / 1 in^2. Air is compressed more near the surface of the Earth and where the height and weight of the above "column" of air above it is the largest. Likewise, in a reverse way, the higher up into the sky, the less air pressure and density. The weight or force of this column of air or water can move into and displace less dense (per volume) objects (such as a bubble in water or a balloon to go up in the air) upward into a lower pressure and density region. It is also said that an object displaces (ie., occupies, replaces) the substance around it, and for example, it may be expressed in tons of weight of water displaced, rather than the volume of water displaced by a ship. The weight or pressure of the water displaced by a ship will causes the less dense on average ship (even if metal) to effectively remain floating on the top of the water rather than sink. The weight of just the metal parts of the ship are still denser and heavier than water, and will cause the lower portion of that ship to be submerged below the waters natural level until it **displaces a volume of water having an equivalent weight (or force) as that entire weight (or force) of the ship**. Since the weights are equal in value, the masses involved are then also equal in value.

For a strong or rigid container containing a gas, if the volume within that container can be compressed to be half, then the volume of the gas is also halved, but the gas pressure is doubled, and if the temperature of the gas is controlled to be the same. The gas is then said to be (more) pressurized or compressed. Raising the temperature of the gas will also raise the internal pressure of that gas, even if the container volume is rigid and remains the same value and does not expand in volume. Much of these concepts are often noted as being discovered by **Robert Boyle** (1627-1691) from Ireland, and later, in England in 1662, and is called **Boyle's Law** or the **Boyle-Mariotte Law**. This law states that pressure (P) and volume (V) of a gas are inversely proportional to each other. See [FIG 242].



If the container is not rigid (strong, unchangeable) and can expand in volume, an increase in temperature of a gas inside will cause an increase in pressure of that gas and it will expand the volume of the container. The expansion or movement will stop if the temperature does not increase further because the internal pressure will then not increase further.

The above figure shows that when twice the weight, force or pressure is applied to a gas such as on the right side, that the volume of it will be half because the gas molecules are compressed or pressurized closer together. A pressure gauge will display twice the pressure. In a reverse manner, when a volume of a gas is doubled and still having the same mass (ie., amount, weight), the internal pressure of it will be half. This relationship is true when the temperature of the gas is constant (ie., the same). Hotter gas has higher kinetic energy, hence it exerts more pressure upon itself (internal pressure) and the inside surface of its holding container.

(Jacques) **Charles's Law** published in about 1802 in France states that when the pressure (or weight as shown in the above figure) of a gas is constant, that its volume is determined by the temperature of that gas. A heated gas will have more kinetic energy and will want to expand the volume of the container it is in. Charles's and the **Robert brothers** also developed the first hydrogen gas, manned balloon in 1783. Hot air will expand the volume of a balloon. The pressure of the gas in the balloon is at the same pressure as the air pressure (14.7psi), and even if it has an opening at its bottom of it to let the hot air gas rise up into it.

Boyle's Law and Charles's law are two fundamental **Gas Laws** that consider volume, pressure, and temperature, and of which can affect the others two values unless one is held constant. This book briefly discusses these laws here, so as to have a practical, minimal understanding for chemistry, and for hot air balloon and-or airplane flight.

According to Boyle's Law, the product of pressure = (p) and volume = (v) is a constant (k), and for a specific type of gas (which has a certain density) used, and at a constant temperature. Though (k) is a constant, it rather has a specific and constant value for each specific system. For a certain gas (and its natural density) at a certain or constant temperature, and at or under (ie., subjected to) two different pressures and volumes, the equation is:

(p1)(v1) = k = (p2)(v2) : **Boyle's Law** , p = pressure , v = volume, and when the temperature is constant
Note for ex.: v2 = (p1 / p2) v1 : if p2 > p1 , their ratio is <1 , and then v2 < v1

Since the product of each side is a constant of (k), and if one factor of a side of the equation increases, the other will decrease by the same factor. Therefore, the factors of (p) and its corresponding value of (v) are inversely related.

Also note from this equation, mathematically and in reality, the "inverse ratios" of both pressures (p), and both corresponding volumes (v) of a gas:

$$\frac{p1}{p2} = \frac{v2}{v1}$$

: for these values, please consider a non-expandable, rigid container having a constant volume and holding a certain amount or volume of the substance such as a gas within it.

If one ratio (ex., p2/p1) went up by a factor 2, the other corresponding ratio (ex., v2/v1) will decreased by a factor of 2. If pressure doubled (increased by a factor of 2), the corresponding volume was halved (decreased by a factor of 2).

For the volume and pressure of a substance in a rigid container with a constant volume: At standard pressure (14.7psi, at sea level) and temperature (72°F) or STP conditions, air will exert a pressure of 14.7psi any place on a surface, including a container of any constant volume that is then sealed, and the air within it will still have the same pressure of 14.7psi. This rigid container and-or volume can have more air placed within it such as due to a pressure such as from an external air compressor forcing more compressed air inside, and while using a one-way ball valve so that the internal, pressurized (ie., having higher pressure) air cannot flow back out and then decrease the internal air pressure. In this type of situation with a rigid, constant container volume, both the internal air pressure and the internal volume or amount of the air gas matter will increase, but the volume of the rigid container will not. If the internal pressure (force/area) doubled, perhaps as displayed on a pressure gauge, the volume or amount of the internal gas has doubled. This volume or amount of gas per volume is called the density of the substance or gas, and is calculated as: density = mass / unit volume = mass / volume . For a compressible substance such as a gas, pressure and density are directly related. For example, if the pressure increases by a factor of 2, the density of that gas will increase by that same factor of 2. Another consideration is that for non-gas substances such as many liquids and metals, they can have a large pressure applied, and yet their density does not change by much or at all, and these substances still have the same density = mass/volume. The reason for this is that gas particles (atoms, and or molecules) have much more space between them than liquids and solids do, and when a pressure is applied to a quantity or volume of this gas, those particles will be forced to move closer together, and which results in more mass per unit of volume. Liquids and solids have particles that are closer together and held by positive and negative electro-static forces due to electron sharing at close distances, particularly with a metals that have more of a dense, closely packed and uniformly arranged atomic structure which is often called a crystal. Liquids are often said as being held together, particularly at its surface, by "surface tension (forces)". If a liquid is cooled enough, it will become a solid, hence denser. An exception to this is that when water freezes to a solid and becomes ice, its crystal structure actually expands larger than the container volume, hence its density actually decreases. density = mass / volume. If the volume of the substance increases, its density will decrease. This is why ice will rise up in water and then float, except that only about the upper $9.08\underline{7}\%$ of the ice structure is above the water due to that the density of ice is almost the same as that of water, except that ice is slightly less dense than that of water by about $9.08\underline{7}\%$ =~ 9.1% = roughly 9%. Liquid water at standard temperature and pressure is defined having a density of 1g/1cc = 1g/1mL. Ice has a density of 0.9167g/1cc = 0.9167g/1 mL . (1g/cc) / (0.9167g/cc) =~ 1.090869423

The molecules or atoms of a gas can be compressed closer together so as to have a compressed gas. The density (mass / volume = mass / unit volume) of a gas is directly related to the pressure on it. If the pressure doubles, the density of that gas will double, and vice-versa mathematically. (density / pressure) = a constant for a given gas , hence:

$$\frac{d}{p} = \frac{(\text{density})}{(\text{pressure})} = \frac{(n)(\text{density})}{(n)(\text{pressure})}$$ = equivalent ratios or fractions, = a constant value = k for a certain or given gas. : **when the gas pressure increase by (n), its density will increase by (n)**

For the physical and mathematical relationship between the volume and temperature of a gas:

$$\frac{v1}{T1} = k = \frac{v2}{T2}$$: **Charles's Law** , v = volume , T = temperature

The ratio of v to T is a constant (k) for a certain gas,
and when the pressure (force/area) is held constant.
Note for ex.: v2 = (T2 / T1) v1 , If (T2 > T1) , then (v2 > v1)

The Gay-Lussac's Law (1808) is that when the volume of a gas is constant, that the pressure of that gas is directly related to the temperature of that gas:

$$\frac{p1}{T1} = k = \frac{p2}{T2}$$: **Gay-Lussac's Law** , p = pressure , T = temperature

The ratio of p to T is a constant (k) for a certain gas, and
when the volume is held constant
Note for ex.: p2 = (T2 / T1) p1 , If (T2 > T1) , then (p2 > p1)

Air can be compressed to have a high "compression ratio" of the initial or total volume of air to the final or compressed volume of that same air. For a gasoline fueled combustion engine, the compression ratio is about 12 to 1 = 12:1, and for a diesel fueled combustion engine the (air, volume) compression ratio must be higher at about 20:1. Because of this, the air is more concentrated or dense and the fuel mixture becomes more combustible due to the denser structure of the air (specifically the oxygen atoms which promote combustion) atoms, and **Diesel engines** are said as being more efficient and need less fuel per mile of travel or for use in other machines, and mainly because diesel fuel has a higher energy density than gasoline. Things that compress air to a higher pressure will also force the water vapor (ie., steam, humidity) or moisture in that air to condense together into water droplets or "moisture" of which can be an issue to take into consideration.

When a gas is under a higher pressure (think of compressing or squeezing a balloon filled with air into a smaller volume or space, and the pressure of the air inside increases), there is also more atomic collisions among the (moving) gas atoms and the sides of its container, and the temperature of the gas will increase proportional (ie., by the same mathematical factor) to the pressure applied to that gas. In short, the pressure and temperature of a mass of gas in a fixed volume are directly related and proportional. This concept is called the: (gas and temperature) **Pressure Law**. The density of a compressed gas will increase, and if the heat is removed,it is possible to make a (dense) liquid form of that gas.

Here is the **ideal gas law = PV = nRT** **:**a practical generality only **,** P=pressure in atm , V=volume in liters , n=number of particles = amount of substance in moles , T=temperature in Kelvin. R=ideal or universal gas constant = about (0.08201 (atm)(L/(mol K) = **(**Avogadro's Number**)** **(**Boltzmann's Constant = particle energy /°K**)** = 6.02214076 (10^23) (1.380649)(10^-23 J/°K) =~ 8.3144626182 J / (°K mol) , hence **R = the total energy of 1 mol of the particles /°K**

If n=1mole of gas, and P = 1atm , V = 22.4L and T = 32°F = 273.15°K , R = PV / T =~ 0.08201
22.4L = 0.0224 cubic meters =~ 0.791 cubic feet =~ 1367 in^3
Setting up a proportion type of equation composed of equivalent fractions so as to find other amounts of mols:
For ex: 1 mol / 22.4L as= x mol / 1L , we find x mol = 0.044643857 , hence: 0.044642857 mol / 1L

There is a derivation in this book of: **(Pressure)(Volume)** = **PV = nRT = Energy in Joules units**
This **ideal gas law** is also called the "**combined gas law**" and the "**generalized gas law**" due to it being based on the equations and-or laws of Boyle, Charles and Gay-Lussac. For a given temperature, P and V are inversely proportional in value, and if one increases by a factor of (n), the other will decrease by that same factor of (n).

There is an example of using the gas laws in the Extras And Late Entries section of this book.

The compression piston in a Diesel type of combustion engine for vehicles briefly compresses the (fine mist) air and fuel mixture (previously created in the carburetor) to a very high pressure, and therefore, its temperature rises to a very high value and automatically ignites the air-fuel mixture without the need for an electric spark, or (electric, hot) "glow plug". At the core of a **Diesel** engine , created in about 1893, is a concept based on a very old and amazing method to light or start a fire which is often called a "fire piston". This fire starting concept was invented around 3500 years ago in the southeast Asian island areas such as the Philippines. With this device, a volume of air in a cylindrical container is compressed by a hand powered piston or plunger, and the air becomes heated to a high temperature by that high pressure. This hot, self igniting and combusting air is used to create a nearby hot glowing ember particle in a small piece of cloth or fiber that can then be used to create a fire to do beneficial things. This ancient concept was used and adapted in about 1893 by **Rudolph Diesel** (1858-1913), from Germany, when he made his combustion engine. The fuel this combustion engine used was refined (ie., filtered, processed) petroleum (ie., crude, unrefined oil from beneath the ground) based, but using various plant based oils is also possible. It could be said that the combustion engine is one of the results, derivative or product due to the "**industrial revolution**" phase of the world where much science, technology and communication assisted each other and they all began to increase exponentially, and until this day in 2022. The steam engine machine is considered as starting the "industrial revolution" in the 1700's. The steam engines of James Watt and previously builders had less than 5% efficiency. Modern steam engines and systems can be 40% efficient or more. Efficiency = Power Out / Power In , and with values being less than 1.

Fueled powered combustion engines could then be used for vehicles and machinery, and inspired the transportation revolution with automobiles ("cars" , ie., carrier, carriage, cart, and a form of chair) and paved (flat, hard), vehicle efficient roadways for quick and low cost, practical transportation to locations not easily or possibly accessible by other methods of transportation. This combustion engine replaced many of the smaller steam engines, however most trains would still use a very powerful (boiling water, high pressure, high energy and power) steam engine for many years into the future. For his automobile, Diesel also used some of the concepts of steam engines such as the piston, rod, valves, and the rotating wheels of a steam engine. Both steam and combustion engines convert pressure energy into mechanical energy such as for the rotation of a wheel or gear. There have been some crude attempts of internal combustion engines shortly after the year 1800, such as in 1807 by **Joseph Nicephore Niepce** (1765-1833) and his brother Claude from France, but it was not practical due to the type of plant based powdered fuel used which was not a liquid hydrocarbon, petroleum based fuel which contains much energy potential. Still, the engine showed a great concept of using (slow, pulsed) combustion to then give a propulsion or movement such as for a small boat. Niepce is most often historically credited to the **first photograph** and the basic photographic creation concepts in about 1825. These images were crude by today's standards, however this is how modern (analog, true, "film") photography (image or picture recording) and ("film") movies started, and which now includes very practical, inexpensive digital (a close approximation of the analog) images. Before Niepce, some others in the 1700's have experimented with light sensitive chemicals, such as various silver based solutions, and made crude outline images of various objects. Though it is possible to use a simple convex magnifying lens in a telescope or camera, a practical, less problematic glass lens was first used in a camera in 1832. **John William Draper,** from England, is one of the earliest pioneers or creators (ie., photographers) of quality photography in about 1839, but before this, a pinhole was usually used as a type of lens for great depth of field and high sharpness (low image distortion, no chromatic and spherical aberration) or clarity, and this lens which only allows a small amount of light into the camera and onto the photographic paper which at those times required a much longer exposure of light onto the photo sensitive material, and a very steady (still, not moving) subject to photograph, otherwise, a (visual) image "blurring" (distortion) of the resulting image of the subject recorded onto the photograph would occur. Since the pinhole opening is not an actual glass lens with spherical (ie., causing focus plane issues, out of focus areas) and chromatic (ie., for color ray divergence issues) aberrations, the depth of field is said to be infinite. It is of note that a pinhole was used since antiquity to study light and-or its conceived rays reflected from the subject and through the pinhole onto a surface of which can be adjusted in distance from that pinhole, and hence adjust the magnification of the image. The dark area for viewing the image created was often called something like the "**camera obscura**" [ie., a small room without illumination or light], and in here, the image can be viewed and-or traced onto bright paper. With photography, the image is rather recorded onto light sensitive paper. With a pinhole or simple lens, the image is rotated or "flipped" 180°, both horizontally and vertically, and this can be easily verified by following the rays of light from the subject and through the pinhole. It is of note that by using a light source and object, such as your hand, that the image outline defied by the shadow (ie., shaded, unlit portion) or shadow-image can also be traced onto paper and-or magnified by adjusting its distance from that light source. Before "fixed" or permanent images were made into film, **Johann Schulze** (1687-1744), from Germany, made a light sensitive solution nitric acid and silver (ie., silver nitrate) and which would temporarily record images via a chemical reaction using the light energy, and surely, this must of inspired Niepce who would later find a way to make the recorded image (ie., photograph) more permanent. When light shined on the solution, it became darker. It is of note that the recorded image is then naturally created and-or stored as a negative or ("reverse brightness") image where a bright object is recorded as being dark, and a dark object is stored as being as bright. If you were to then photograph this negative image, you could then obtain the positive or true image.

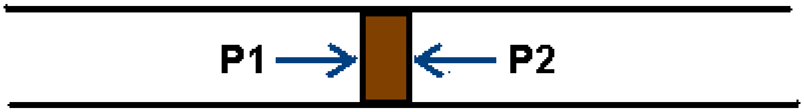
Carl Benz (1844-1929), from Germany, created the first practical automobile (ie., "horseless carriage" or simply a "car") for the public in 1885. It used gasoline fuel and worked well, but it was relatively crude when compared to **Henry Ford**'s "user friendly" Model-T car designed later 1908. Ford's was surely inspired by the Benz car. Carl was the husband to **Bertha Benz** who is credited to making the first long distance (about 60 miles in total length or distance) car ride in 1888. This distance and relative ease of travel was incredible for those times when a horse and carriage form of transportation was still very popular, and it brought the car into the minds and "wish-list" (hopes and desires) of many. She is also credited to some practical improvements to the design of the practical car. Relatively few could afford and properly maintain a horse, even till this day as of 2025. There is also a sanitation issue when a large number of horses are used within a city. Some of the modern "horse rides" for amusement in a city can probably be replaced by low cost Model-T replica cars, and so as to create a more nostalgic city theme.

To help understand how velocity can increase as pressure decreases consider this. If there is a difference in pressure (ie., force) in two containers of water, the water will be forced to flow in a pipe from the higher pressure container to the lower pressure container. The net difference in force or pressures upon the water will allow the slow water at the region of the pipe opening to gain kinetic energy and move, hence its speed will increased through that pipe and into the lower pressure region.

Here is another helpful description of the inverse relationship between the speed and pressure of a liquid or gas in a pipe:

Why is pressure inversely related the speed of the liquid or gas in a pipe?

One way to understand this is to consider a pipe that you are blowing into, and it has a sealed end. The air will get forced into it and get compressed or pressurized, and it will apply that pressure to the sides of the pipe as like trying to inflate it like a balloon shape, but not much change in volume will happen because the pipe is rigid (strong) and requires much more force or pressure to change its shape. If an opening of any size is then put into that pipe, such as a hole opening at its end, the pressurized air will force the air to the lower pressure region outside that pipe through the opening and where it is traveling at a higher velocity (possibly through another pipe) in that less pressure region. The compressed air in the original container or pipe will become more and more decompressed or depressurized and will no longer have energy to apply a force or pressure so as to move air, and the air in that pipe will eventually be at the same pressure as the outside air beyond the opening of the pipe or container. [FIG 243]



In above figure, when the pressures identified as P1 and P2 are equal, the object in the pipe will have no movement, hence no velocity. The net force applied to the object is 0 and its net velocity is 0. If P2 is now less pressure, there will be a net pressure or force upon the object in the pipe due to P1 being greater than P2. This net pressure or force due to the (remaining) difference in pressure will cause the object to move rightward in the pipe and to the less pressure region. If the difference in pressure is small, the velocity of the object will be small. If the difference in pressure gets larger, such as even when P2 gets even lower in pressure, the velocity of the object through the lower pressure region of the pipe will increase. For an analogy to the above pipe and pressure system, consider a lever or "balance-beam", perhaps for a scale, that has the same weight (ie., force) on both sides of the pivot, bearing or center point of rotational movement, and therefore, the beam or lever does not move (here rotate) in any direction (up or down, vertically) since there is no difference in the weight or force on either side of the balance point so as to create a force difference or imbalance to apply energy and induce motion. With an imbalance or difference in the forces, the greater it is, the greater the net force and the resulting velocity of movement.

Generally, the pressure in a container is evenly distributed and acting upon the entire inside surface of the container, and with that pressure trying to expand it, and the pressure trying to compress the material in it. If the container surface has a "weak point" that is not as rigid or strong at the majority of the container, it is possible that a hole will develop in that region and the internal pressure will then decrease due to the loss of the pressure and-or the pressurizing substance within it. A common example of this is when the inner tube of a bicycle wheel is punctured and all the compressed air within it, for example having 20 to 50 psi (pounds per square inch), is released to the outside air that is at a lower pressure, typically 14.7psi standard air pressure at sea level.

Ex. A weight or force of 10 was applied in one direction, and 10 in the other direction such as either left or right horizontally, or in the clockwise or counter-clockwise direction of rotation. We can assign a positive sign (+) to values for one direction, and the negative sign (-) to values for the other or opposite direction. Using a subtraction or difference operation so as to find the difference in these two (vector or component forces, and with direction) forces:

Net force upon the mass that can move = algebraic sum of those forces = difference in those force

Ex: (+10) + (-10) = +10 (+) -10 = +10 -10 = 0 = a net force, or difference of 0

Ex: If P1 = 3 and P2 = 10 : : ex. 3psi and 10 psi respectively

(P1) + (-P2) = 3 (+) -10 = 3 -10 = -7 = a net force or difference of -7, and the object in the above pipe will have a net, effective, resultant or useful force of 7 applied to it, and the negative sign indicates that the direction that the object will move will be in the left direction which is the same direction that the net force is being applied to it.

The difference between pressure and force

From: **pressure = P = (force / area) = F / A , force = F = PA Pressure can be considered as like the average force per unit of area, actual or a conceived distributed force on an surface area, and force can be considered as the total sum or multiple of the (same) pressure(s) applied to the entire area.** Higher effective pressure upon and in the water per unit area will also apply more force to the water at that area and pipe, and this potential or pressure energy will transfer more kinetic energy to that water at the output pipe at the bottom of the tank and its velocity will increase and flow faster into and in the region of lower pressure due to a pressure imbalance which could be thought of as a force or energy imbalance, or potential or static pressure energy difference. This could be thought of as that the energy stored in the compressed or pressurized water is now converted to water with an increase in momentum and-or kinetic energy and is now not as compressed when subjected to a high pressure, but now is decompressed and with a lower pressure and faster speed.

Though pressure applies a force and (potential) energy to the sides of a pipe or container, there is no transfer of (actual) energy to the side of the container if it is rigid and does not expand. If it did expand, some this could be imagined as expanding a spring which also requires energy, but then stores the energy applied. A expandable container could also possibly burst open and release (ie., transfer) that internal pressure energy to the outside, lower pressure region. If a container does expand, its volume will increase and the internal pressure will decrease.

Faster moving liquid or gas has more (kinetic) energy per volume of it because its kinetic energy (KE=mv^2 / 2) is more. An increase of applied **force (a measure of the application and-or transfer of energy)** causes an increase in pressure which causes an increase in the momentum (p = mv = momentum = (mass)(velocity)) of the gas or liquid if it is able to move from that higher pressure region.

The velocity of the gas or liquid is inversely related to the cross sectional area of the pipe. If the cross-sectional area of a pipe segment changes by a factor of (n), the velocity of the gas or liquid will change by (1/n), or in other words, the velocity of the gas or liquid will decrease by (n). For example, if the pipe area (A1) decreases by a factor of 2, n = (1/2) = 0.5 and A2 = (A1 / 2) = 0.5A1 = n A1, the velocity of the substance will increase by (1/n) = (1/0.5) = 2, and the kinetic energy of the substance will increase by 4 since KE = mv^2 / 2 = m(2v)^2 / 2 = 4 mv^2/2 = 4 KE

Faster moving gas or liquid has more of its energy stored in its velocity and motional ability (momentum = p = mv), rather than as a compressed gas or liquid storing (potential) energy, and therefore, for a moving liquid in the output pipe, there is less ("static") pressure applied to the inner sides of that pipe. This is the reason why the pressure is reduced if the velocity of the gas or liquid increases.

An airplane wing has less air pressure on its upper surface when there is fast moving air flowing over it. This concept is formally called **Bernoulli's Principle or Bernoulli's Law** and was discovered many years before the invention of the airplane. For the airplane, when fast air passes upon the upper surface of that wing, there is then less air pressure (force/area) and-or force upon the upper surface of the wing than on the lower surface, and the net difference in these two forces or pressure on each side of the airplane wing is the net or effective force applied in the upward (perpendicular to the direction of planes travel) direction to wing of which is attached to the plane and also transfers its upward force (ie., [upward, vertical] lift or lifting force) to it If the wing is tilted slightly upward, some compressed or higher pressure air beneath the wing also improves the lift force, but the increase of the cross sectional area of the wing in the direction of the plane movement also increase the "drag" or resistance to forward motion of the plane and causes it to collide with the air and loose some kinetic energy, speed and fuel efficiency (distance/Volume). A plane can use smaller adjustable wings called **"flaps" or ailerons** to change (horizontal and or vertical) directions due to the created forces such as drag, and this is much like how a **rudder** of a boat in water is used to change direction or steer the boat. The drag on one side of the boat will slow that side of the boat more than the other, and will effectively cause a turning or (usually partial) rotation of the boat about that slowed, lower (angle) velocity side closer to the center of rotation if the rudder is fixed into a position or angle and not reset (to 0 drag) to the desired, straight direction of travel. Setting the ailersons at a certain angle can also help provide some extra **compression lift** forces during the relatively slow speed during the take-off (ie., "lift off") from the runway to flight. This lift is somewhat like a plane going up a ramp that directs and-or forces it upward.

Faster moving liquid or gas has more energy per volume of it because its kinetic energy ($KE=mv^2 / 2$) is more. An increase of applied force causes an increase in pressure which causes an increase in velocity and momentum ($p = mv$ = momentum = (mass)(velocity)) of the gas or liquid. Faster moving liquid or gas means a high flow rate or volume of it per unit time being transferred from one location to another. **Flow Rate** = (accumulated amount of substance) / time
Flow Rate = volume / time , or mass / t. For a pipe, it is reasonably obvious that the amount of fluid input into the pipe equals the amount of fluid output of the pipe, and that the flow rate in equals the flow rate out, even if there is a restriction or constriction in the pipe, such as a smaller diameter section of pipe where the velocity of the fluid will increase and which therefore has or maintains the same flow rate as the input and output.

Flow Rate In = Flow Rate Out or: Flow Rate In = Flow Rate Out : "conservation of flow"
volume in / time = volume out / time mass in / time = mass out / time

If a pipe is then restricted, and so as to have the same flow rate and-or volume rate at the input and output, the velocity of the gas or liquid substance is naturally or automatically increased, and this will then result in the same volume of the substance flowing per unit of time at that point in the pipe, hence the same flow rate.

A pipe constriction, smaller diameter or cross-sectional area pipe is often called a **Venturi tube**. A common example for the use of a Venturi tube and its effect is found in the carburetor (or "fuel vaporizor", "atomizer") device of a gas or fluid combustion engine, and so as to provide a low pressure region of which the gas stored in a tank (a container, a volume) can be naturally forced up into by normal and effective higher air pressure upon it in the tank, and then it is turned into or converted to a fine mist mixture of fuel and air created by the high velocity force of the incoming air, and so as to promote a more powerful and efficient fuel combustion in the engine. A Venturi tube section of a pipe, such as on an airplane, can be used to determine or measure the pressure difference of which also determines the velocity of the substance (here air) flowing in it which is equal to the velocity of the airplane.

For an analogy to a Venturi tube, a two gear system can be considered, and with a larger input gear than the output gear. The smaller output gear will turn at a faster rate (angle or rotation / time) and store energy as kinetic energy of a smaller mass but at a higher velocity, and this is analogous to the higher velocity or speed of the substance in the Venturi tube section of a pipe. Since the input energy and-or power, must equal the output energy and-or power, there is a reduction in torque (ie., a force) in the output gear, and this is analogous to the reduction in pressure (= force / area) of the fluid in a Venturi tube. A decrease in cross-sectional area of the pipe will cause both an increase in velocity so as to maintain the flow rate, and a decrease in the (local) pressure in that location.

Due to the force of gravity, fluids can naturally flow "down hill" (at an angle below the horizontal level) in the less dense atmosphere, and-or through a pipe without any extra power needed. If the liquid, such as water, is deep, such as in a deep storage container placed at a height above ground (ie., an altitude of 0), the water at the bottom of that container is at a higher (static) pressure (ie., force) and it will be accelerated to a fast velocity in a pipe due to that pressure or force. As the water drains or moves away or out from the container and is less deep, there will be less pressure at the bottom of that container and into the pipe.

Another formula for flow rate in terms of velocity is: **Flow Rate = Av : (Area) (velocity)**

$$Q = \text{Flow Rate} = \frac{(\text{Volume})}{t} = Av = (\text{Area})(\text{velocity})$$

: Q for "Quantity rate".
This can be verified from:

$$\text{Distance} = \text{Length} = L = \frac{\text{Volume}}{\text{Area}} = \frac{L^3}{L^2} = L^1 = L = v\,t$$

, mathematically:

From: $\frac{\text{Volume}}{t}$ = A v , we have: $\frac{\text{Vol.}}{A}$ = vt = L , as shown above

Another related equation is: Flow Rate = pAv and this is derived here:

Qv = Flow Rate = V / t = "volume-metric flow rate" , or also, Qm = "mass flow rate" = m / t

density = p = m / V , therefore: m = pV : V = Volume , here, p = density and not momentum

Qm = m / t = pV / t = pL^3 / t = $\frac{pL^2\ (L^1)}{(\ t\ )}$ = pAv = (density of substance)(travel Area)(velocity of substance)

At two locations in a pipe with different cross-sectional areas, pressures, and velocities, the flow rate is still the same constant value, and Q1 = Q2. The density of the substance is also the same.

Q1 = Q2 : Q = flow rate

(p)(A1)(v1) = (p)(A2)(v2) : flow rate of a substance in a pipe with different cross sectional areas
Dividing out the common factor of (p=density) from each side:

(A1)(v1) = (A2)(v2) Due to Q being constant, A and v at a given location are inversely related and are not generally reciprocals of each other.

Since the flow rate Q remains constant in a pipe, if the cross-sectional area (A) changes by a factor of (n), the corresponding change in velocity (v) will be the reciprocal of this (n) value, and which is therefore: (1/n) :

Av = (n)(A) (v/n) or= (A/n) (nv) : the product of Av is constant for a constant flow rate

$$Av = \frac{n}{n}\ (Av) = nA\,\frac{v}{n} = \frac{A}{n}\ nv$$

If the known flow rate in a pipe has changed, and usually to a lower value, then there is a restriction or blockage in it, and-or an opening, "hole" or "leak [leakage]" at some place along its length which changes the internal pressure(s) on the pipe and within the moving substance, and this will indicate a leakage of some sort.

If there is compressed air in a container, and having a high pressure, and it is used to fill a balloon, that compressed air which had 0 speed, as like a liquid at 0 speed since it is not moving or flowing, will get decompressed as it moves out of that container and toward a lower pressure region. Once an (expandable material, stretchable) balloon starts to inflate, the air in it will begin to get compressed and pressurized so as to apply pressure to the inner side surface of that balloon and will cause it to expand (in volume) or inflate as it stretches outward from the internal pressure. The expansion will continue until that internal pressure equals the input pressure and there is no net difference in pressure to permit a flow of the input air, or the possible output air from the balloon such as if it had a greater pressure.

If you were to blow air into a rigid or strong container that does not expand, the pressure of the air within the container will increase up to the pressure of the air input, and that increasing pressure will reduce the speed of the air being input into the container until that input air speed falls to 0. If an opening was then put into that container, the velocity of the air being forced out will be initially high due to that internal pressure, and then the higher (than atmospheric) pressure within the container will decline to the value of the pressure on the outside of the container, such as the standard air pressure at sea level (14.7 psi).

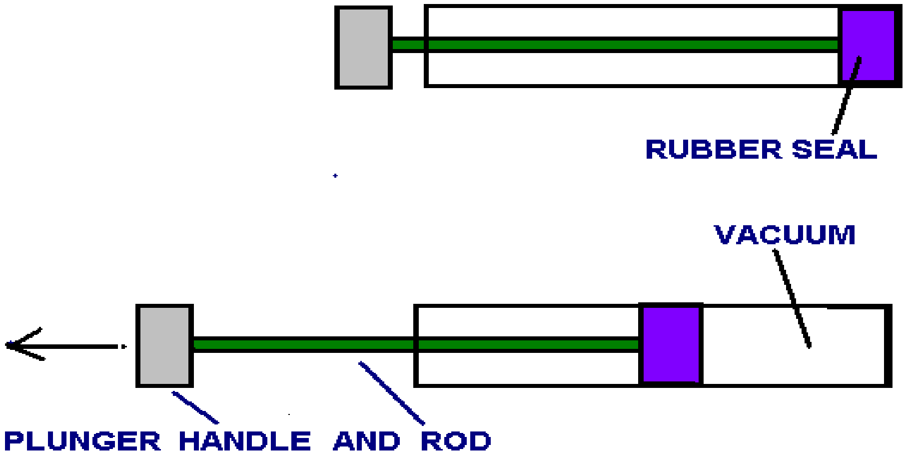
Considering **density = mass / volume**. Compressed air is "packed or squeezed", more dense air, and hot air is less dense and lower weight air and is therefore like decompressed air having less pressure. What keeps the hot air balloon inflated or expanded is the high kinetic energy of the air that is in the balloon as it applies pressure to the inner sides of the balloon. Though the denser air will inflate a balloon, it will not allow the balloon to rise upward since it is actually heavier in weight air than the air outside the balloon. Heated air is less dense, and therefore has less weight and is forced to rise upward like a bubble in water due to the downward and surrounding pressure of the water it is displacing. For the balloon, it will rise upward as the more dense, heavier and higher pressure air moves in and takes its place or "displaces it", effectively forcing it upward to a lower pressure region. Hydrogen gas can be used to inflate a balloon, however this gas is not heated because it is combustible, but simply is a low density, low weight gas that is put into the balloon as a compressed gas, much like how a person can inflate a balloon with their breath of compressed air. If a balloon is inflated with cool, regular compressed air and then sealed , it is possible to heat that mass and volume of air from within.

As a hot air balloon rises into the air, the pressure on the outside of the surface of the balloon becomes less, and that pressure within the balloon will then cause that balloon to expand even further if the temperature and pressure of the hot air inside remains the same and didn't cool down to a lower temperature as it rose upward into the cooler atmosphere.

While on this topic of pressures, and before more discussion about balloon flight history, a related topic to pressure is about a **vacuum**. The word "vacuum" is based on the word and meaning of "vacate", "evacuate", or "vacated" which means the lack or absence of something in it such as a gas (often air) and its pressure. If it helps your understanding and analysis, a vacuum can be considered a like a region of low pressure, and of which a high pressure region or substance will try to enter. A "vacuum-cleaner" is a machine that people can use to clean up debris on a floor surface by creating a low pressure (vacuum) region in the device of which the outside air (at normal pressure) and debris will be forced into that region as if the machine itself pulled, forced, "sucked" (inward, towards itself) or drawn it in. The debris will be captured and-or collected by a filter system that allows air to easily flow and pass through it, but not dust and-or other larger debris. This air flow is necessary so as to maintain air and debris movement into the machine, otherwise the machine would not function as a vacuum if there is a "clog" or blockage impeding air and debris flow or movement. The air pressure created by a vacuum machine is less than that of the normal air pressure of 14.7psi. A pure or complete vacuum has no gas or liquid substance in it, and therefore it can not possibly have any gas pressure from within it. The pressure within a ("pure", "perfect", "real", "true") vacuum is said to be 0psi, but for a home-use machine or vacuum, it only needs to be somewhat less than 14.7psi. The outside air pressure applied upon a vacuum container is still 14.7psi, and it will collapse due to that outside pressure if it is not a rigid structure that cannot bend and-or be compressed easily inward,, and it will take much more pressure and-or force for that to happen. Outer-space is generally considered as a perfect vacuum with some light and radio wave energy, and possibly some debris, constantly passing through it and which are not subjected to an external gas or liquid pressure. There are many uses for vacuum environments, such as for canning or jarring certain foods, or for manufacturing certain products where air would cause a contamination or more difficult process, such as in vacuum tube devices such as amplifiers.

A person using a straw to suck up a fluid from a cup, so as to have a drink of it, is essentially creating a low pressure region (less than 14.7psi) when they suck on the end of the straw, and the air or fluid is pushed (ie., forced) by the normal air pressure (14.7psi) upon and in the fluid to move upward into the straw and towards the lower pressure region in a persons mouth. When a person breathes inward and-or outward, it is due to the pressure differences created in the lungs and body.

Here is a basic form of a vacuum device or machine: [FIG 244]



In the above figure of a plunger (ie., a compressor) and-or suction (ie., a vacuum, decompressor) device when the handle is pulled out of it, a vacuum and larger volume with a lack of air or very little air is created. The little bit of air that was initially there, at say 14.7psi, is now all within a much larger volume, less compressed, and therefore under less pressure on itself and the side walls of the device in the vacuum region. The rubber seal is expandable and expands or pushes tight enough against the wall of the container so as to maintain a vacuum or compression (such as when making a compressed air or substance) forces. After pulling the plunger out a little into the normal air pressure region it becomes apparent that it requires more force to do this (besides any friction and-or compression forces of the rubber seal). The required force by the user is due to that the normal air pressure (or force) of 14.7psi must initially be overcome with an equal amount of force, otherwise the normal air pressure will force this plunger end to move back into the plunger device because the vacuum that was created there is at a lower pressure. If the plunger had an opening, tube and-or pipe on the right side of the image shown, it could be used as a vacuum device so as to effectively suction up or "draw" a gas or liquid into a low pressure vacuum region (volume) when the plunger is pulled outward from the device in the leftward direction.

The vacuum created with the above device is a "high vacuum" with a very low amount of material remaining in it such as some air atoms that may have been put into it when initially putting the plunger into it. An opening or an out-only, one-way ball valve on the right side of the plunger container above will allow the plunger to be easily pushed into the container since there will no compressed or pressurized air causing a resistance to its motion and the full seating of the plunger. This opening can then plugged so as to use the device as a vacuum, and with a ball valve, this will happen automatically as the plunger is pulled out of the container.

The device is also very similar to that of a medical, fluid injector or remover called a syringe or "needle" that is often used by a doctor or nurse so as to give a patient some medicine. The medicine dose (the prescribed amount) needed plus a little extra is drawn into the vacuum area by the aid of the plunger, and then the plunger is tipped vertically and physically tapped so as to allow any possible air bubble to rise to the top of the liquid so as to be ejected out of the plunger and through a thin, hollow needle (essentially a rigid metal tube with a sharp point at one end) with an inner hole along its length. The slight waste of medicine is acceptable due to the dangers involved. When the plunger is forced in, the fluid or gas will get pressurized and compressed slightly (ie., reduced in volume, denser, and more so for gasses than liquids) in size, and if there is an outlet (opening) to a lower pressure region having less force acting upon that gas or fluid, then that fluid or gas will move (via the applied force, pressure [compressing the material together] and some kinetic energy given to that fluid or gas) into that lower pressure region and become depressurized and be at the same pressure as that of which it was sent out into. The above device is also the basis of a mechanical air pressure gauge to measure the internal air pressure of vehicle's tires or inner tubes.

When a person breathes in, their diaphragm muscle pulls upon their lungs and expands or increases their volume while creating a lower pressure, partial vacuum region in the lungs, and then the higher, normal outside air pressure will then move into and fill in to occupy. When we "breath in" or "inhale" air; a process called "inspiration", that air in our lungs will get pressurized until it is at normal air pressure. When we "breath out" or "exhale" air; a process called "expiration", our muscles begin to compress and deflate the volume of our lungs. This increases the pressure of the air within them of which then has (kinetic) energy to travel towards the (relatively) lower pressure region of normal air pressure (14.7psi) outside our bodies.

The above device shown in the figure, when used in a reverse manner as a compressor or "pump", is how inner-tubes, tires, balls and various floats are inflated and expanded in volume. Tires and-or inner tubes of a tire are inflated to a safe and effective rated psi (pounds (of pressure) per square inch) value for assisting (avoiding friction and wasted energy) the movement and momentum (p=mv) ability of a vehicle. This will help the tires avoid much friction and the resulting wasted energy - usually as heat, into the road surface and tire. Tubes and-or tires, etc., will have a one-way valve that is much like a ball-valve with a pressure spring upon it so as to keep the pressurized air within the tube once it is put in using that same valve. **Over-inflating** a tire and-or tube, or anything else being inflated, can apply a high pressure above its safe rated value on its inner surface and damage the tube or tire, and-or cause a **dangerous, outward explosion**. Please check the literature and-or the side of the tire and-or inner-tube for the recommended, minimum and maximum air pressure.

If the above device is used without general modification as a compressor, so as to compress the internal air when the plunger is pushed in, the pressure of the internal air or other substance will increase. This compression will "squash" the air together into a smaller volume and therefore, it will create more air per unit volume, hence the air density (mass / volume) increases. The pressure or force compresses the air closer together and there will be more air atom collisions (especially since its now denser air) and the temperature of that air will increase. This is how a fire piston device works so as to heat a small piece of material to make an (combusting, glowing) ember so as to make a useful fire. The internal heat energy will eventually dissipate or be transferred through the wall of the container if the surrounding air or other material is cooler. During this process, the internal volume will not increase from the increase in temperature if its a rigid or strong container. If the container could expand like a hot air balloon, the heated air would expand the volume, and then the internal pressure will decrease in this process. If the heater internal air cools to that of the surrounding air, the balloon will be deflated.

A small air compressor can fill a huge tank with compressed gas but it will take a long time, depending on its volume much like filling a large container ("tank") of water with a small pipe and low flow rate. It does this by compressing a small volume of the air or other gas into an even smaller volume of gas having a high pressure. This pressurized gas is directed through a hose or pipe and into a rigid tank being pressurized. At someplace within this compressor system, there is a "one-way" valve(s) that allows the pressurized gas to flow in only one direction such as into the tank and prevents the pressurized air withing the tank or container from cumming back out, and will be there when needed. As mentioned previously, one type of valve for this is called a "ball valve". A can of "spray paint", that allows the spray of a fine mist of paint onto a surface, has an internal gas and paint contained and at a high internal pressure, and this paint and gas material can come out when a valve is pressed, releasing and decreasing its internal pressure into the lower, normal air pressure of 14.7 psi. As an average value, a can of spray paint may initially have an internal pressure of 75 psi.

To see a very easy and practical demonstration of air pressure, water pressure and vacuum, take a plastic bottle that has a screw type lid on it and put a very small hole near its bottom area using a metal pin. Fill (at the normal dispenser opening) the bottle with some water and then put the top on or cover that opening with your hand. If the outside air pressure is greater than or equal to the water pressure at the pin hole, no water will leave through that hole. If you remove the top or your hand, the air pressure will fill or displace any (low pressure) vacuum created and apply more pressure to the water in that bottle and force it out through the pin hole. Some containers are deliberately constructed so as to have a small (air pressure, inlet) hole near its top so as to prevent a vacuum from forming at the top of a liquid and preventing it from flowing well out from it. Some non-fluid barometers (for air pressure) or general pressure scales are construct so as the small movement or distance produced by changes in pressure is magnified by a long lite-weight lever so as to be more visible have more precision ("preciseness" of measurement).

A **siphon** is a device and-or concept that can help raise a liquid or fluid in a container and into a pipe or tube and raise it to a height above that fluids surface level, and then direct it to an outlet at another location that is physically below the supply or input liquid height. The siphon is first "primed" (ie., to prepare, such as the tube or pipe filled) by filling it with the source liquid, either by suction (ie., a vacuum with lower pressure region) or by filling the (closed outlet end) pipe with liquid. Once primed, opening the outlet end so as the liquid will move out from it due to its weight and gravity will create a lower pressure region in and at the pipe or tube opening in the supply fluid container and causing more fluid to be naturally pushed (if it is already at some pressure) or sucked into the pipe, fluid or tube region that is at a lower pressure. A siphon is a good method to irrigate (to apply water) farms when possible and needed. This type of siphon functions much like a hand operated or motorized water pump. The word "sip" is a derivative or form of the word "siphon", and a common use of it is to take a sip of a drink from or through a straw (a small tube used to assist some people when drinking fluids). A siphon will create a low pressure region, and therefore, it will cause a pressure difference upon a substance such as air or water pipe. This pressure difference will cause the (higher pressure) water to move toward the lower pressure of the siphon which could be a water pump. This water pump has a limited amount of power available to create the siphon, and it will be useful on level surfaces when moving water rather than trying to move it upward or vertically which will require more energy. The more water to be moved, the more massive and heavier it is and more energy and-or power will be required to do this, and this will usually result in a larger, more powerful water pump or siphon. It takes less energy to pump a unit volume water on a level surface than upward or vertically. If the energy is limited and-or a smaller pump is used, a smaller volume of water, and which has a corresponding small amount of mass and its resulting weight per cubic volume, per second (ie., the flow rate = volume / time) can be used, and the pipe and-or hose can be thinner in cross sectional (ie., diameter) area. How much wight of water or other fluid can a person siphon vertically? It depends upon the amount of "siphon power" (ie., input energy to cause the pressure difference and-or resulting application of it, hence to induce a [proportonal amount of] force upon the water so as to move it) they can create. A "self or free running" siphon requires no additional energy once initiated to function, but it can only lift 14.7 pounds of water per square inch of cross-sectional area of pipe due to the natural 14.7 psi of the atmosphere or air pressure at sea level and upon the opening of the pipe and-or the water there. It take a difference in pressure to cause the water to move, and even if the water has a certain amount of weight and-or pressure and kinetic energy already associated with it.

A calibrated **barometer** ("baro" means weight or pressure, hence a pressure meter) can sense and indicate any changes in its local air pressure value and displays the current air pressure. In short, a barometer is a (air) pressure gauge for measuring the natural air pressure due to the above air column. A mercury (column or filled) barometer is sometimes called (Evangelista) **Torrricelli** (ie., units of tor=mm of height, units) barometer because he invented it in 1643 in Italy. He was a student of Galileo. This barometer uses a rigid glass tube sealed at the upper, top end and is filled with liquid mercury (Hg) metal. Mercury, with a higher density per volume and weight than water, is used since if water as used, the device would need to be much taller (about 33.8 feet = 10.3m, and this is derived in the topic of Air Pressure And Barometer Values Derivation, further ahead in this book) since water has less density, and therefore, less weight and less pressure (at the bottom, deepest part) per unit area of a (vertical) column of it. The tube is then tilted vertically (ie., "upside down") and will drain slightly into a bowl filled with mercury which can be used as a sensor and be affected by the air pressure upon it. The mercury will drain into the bowl until there is no difference in the force (ie. weight) or pressure (psi) of the column of mercury and the air pressure (that is on average, 14.7psi) upon the mercury in the bowl. When the pressure of the column of mercury equals the air pressure, say 14.7psi at sea level, then the pressures will be in balance and no further movement or flow of that column of mercury will take place and reduce the height of it. There will be a slight vacuum (without air or other substance) of space created near the sealed, top or upper end of the tube. This space helps the mercury have some room to move upwards. If the local air pressure increases, it will push down on the pool of mercury and cause it to apply more pressure to the mercury in the glass tube and cause it to raise upward in height, or decrease height if the local air pressure decreases.

With a barometer, it is possible to calibrate it and use it as an altitude sensor and altitude (height) indicator since air pressure (or "air weight", or "air density") decreases with altitude, and this was discovered in 1646 by **Blaise Pascal** (1623-1662) from France. Other liquids, such as water, can be used to make a homemade barometer, but then that barometer needs to be larger (especially higher) in size and is therefore impractical. Normal air pressure is defined as 14.7psi = 1atm = 1013.25 millibars (mb) = 101.325 kPa , or a height of 760mm = 76cm = 29.92in. =~ 2.5ft. =~ 30in of mercury (Hg). This pressure is when there is 760tor = 760mmHg =~30inHg of a column of mercury (Hg). 1mb = 0.01451 psi. 1 psi = 68.93mb. 1 in. of Hg = 33.86mb During stormy weather, the height of the mercury may reduce by 1 inch or so, and this indicates a lower air pressure, and during a hot and dry day, the height may increase by an inch or so, and this indicates a higher air pressure. Surly, hot, less dense air which can expand a balloon, is at a higher pressure due to its excited or energized state or condition with its atoms having a higher thermal (kinetic, motional) energy and can apply more force to the inside surface of the balloon. pressure = force / area = weight / area. Since pressure is expressed as a ratio, if the numerator and denominator are multiplied or divided by the same value or factor, it creates an equivalent fraction, and yet the pressure rating is still the same. Due to this reason, the column of mercury can have any cross sectional area, such as for example, 3mm, and it is rather the density of the liquid used and the height of it which determines the pressure:

P = pressure = (force / area) = (mass)(acceleration) / (area) = (weight / area) : units of **Pascals** = Pa
$1Pa = 1N / m^2 = kg / m s^2$

P = pgh = pressure of a vertical column of an element = (element density)(gravitational acceleration)(height) =

P = (mass / volume) (g) (h) = $(mass / L^3)$ (g) (L^1) = $(mass / L^2)$ (g) = (mass / area) (g) = **(weight / area)**

work = (force)(distance) = (ma)(h) = (mg)(h) = **mgh** = Kinetic Energy joules , to raise an object in gravity = KE
KE = work = $\mathbf{mv^2 / 2}$ **= Fd = mad = mgh = (weight)(h)**
Here, KE = GPE , joules

P = pgh = (density)(g)(height) = (m / Vol)(g)(h) = $\frac{mgh}{Vol}$ = $\frac{\textbf{stored or potential energy}}{\textbf{Volume}}$: joules / volume mathematically:

PV = pghV = **mgh** = joules of potential or stored energy : stored or potential energy in a vertical column of fluid
Extra: For a given amount of energy, and PV being two factors of it, and if one changes by a factor of (n), the other will change by the factor of (1/n).

Blood Pressure Values

Normal and-or average human blood pressure is usually noted as: **120 / 80** (often said as "120 over 80"). When expressed more technically with units, it is actually: 120 mmHg / 80 mmHg relative to standard pressure, hence these are the increased, change or greater values than standard air pressure. mmHg means millimeters of height of a mercury barometer or pressure gauge or meter (here meaning a measuring device and not a distance). In terms of PSI, this corresponds to: 2.32 psig / 1.55 psig , and where psig means pounds per square inch greater than atmospheric pressure, hence its a relative pressure. This is because our bodies are always being compressed by the typical 14.7psi of the atmosphere. The numerator, upper or top value is called the systolic (or systole, an old Greek word having a meaning such as "contraction") pressure (P=F/A) on the artery walls when the heart is pumping or "beating" (ie., heart muscle contraction), and the denominator, lower or bottom value is called the diastolic (or diastole) pressure when the heart is at rest, not pumping or moving blood throughout the body, and is actually refilling with blood fluid for the next pumping cycle. In general, a person is said to have some high blood pressure if the systolic pressure is greater than 120 and the diastolic pressure is greater than 80. If the systolic pressure is greater than or equal to 180, that person has a dangerously high blood pressure and should seek medical assistance. Blood pressure is also mentioned at other locations in this book.

Extra: A (water) **ram pump** is a purely mechanical (ie., non-electric) pump that can operate using the kinetic energy (KE) of the fluid such as water being pumped. A stored mass of water above a reference height has stored energy called gravitational potential energy (GPE = mgh). Moving or flowing water has movement or kinetic energy: $KE=mv^2 / 2$, and which increases as it fall downward under the constant force of gravity (g) constantly acting upon its motion and accelerating its velocity (ie., speed) Since energy is conserved, except for some system losses, we ideally have: energy out = energy in, and so as KE increases, GPE decreases. Total energy = GPE + KE. The more mass and velocity of the flowing water per second of time, the more power (watts = joules of energy / second) that flowing water will have. Since this device is a pump, it can force (application and transfer of energy) and move (ie., lift) water up to a height above itself, but not higher than the distant, initial source of that water such as a stream of flowing water - weather a natural and-or artificial source and flow from a dam (essentially a pool or reservoir) of water.

If you were to take a container filled with water, and a hose connected to the bottom of it, and then bend the end of that hose upward in height, the flowing water will stop flowing at the surface level height of that source of that water, and therefore not any higher. A water surface at sea level on Earth has a (air) pressure (P = F/A , and F = PA) upon its surface, and at 14.7psi.

The (automatic) ram pump is also called a **hydraulic pump**, and it was invented in 1796 by by **Joseph Montgolfier.** Montgolfier and his brother are also celebrated as for creating the first manned flights in hot air balloons. The ram pump has an input for the flowing water, and output of flowing water. It has two internal valves where one is called waste value (ie., wasted, non-pumped water, but can otherwise be used for something), and the other valve is called the (water) delivery value or output valve. These valves periodically (ie.,cyclically) open and close one after the other. The system is "primed" or stated by allowing some water out of the waste valve, and then shutting it, and there will then be a higher water pressure in the input pipe due to the kinetic energy of it then having a value of 0 Joules. This higher pressure and stored energy will then open the delivery value. Higher pressure water has more energy, and the flow of the output water can go higher than the height of the source of that water. Usually the output pipe or tube usually has a smaller diameter than the input pipe or tube, and so as to pump the water even higher since it there will be less weight to force and move given available (temporary, pulse of) energy applied to it. Once the output water pressure cannot keep the output value open, it will close, and the water pumping cycle automatically repeats. A ram pump essentially functions due to the "water hammer" effect of quickly stopping the flow of water by using a (flow, movement) valve, and then hearing and-or seeing the mechanical stress it induces with that pipe.

Flight With Hot-Air Filled Balloons

Before parachutes, gliders (ie., like a kite - an air-plane without an engine) and air-planes with motors, the first form of "human flight" or transportation through the air was made possible using hot-air filled balloons.

Hot-air balloons are capable of lifting a gondola, vessel or container having some reasonable (heavier than air) weight and-or travelers in it, and upward into the sky, and may even drift (move without any needed balloon power) and travel with the aid of the forces of the wind upon the balloon surface. Wind is a movement or flow of air gas and its composing atoms of mostly nitrogen and oxygen, hence that air has kinetic energy which can apply a force and transfer (kinetic) its energy to other objects such as a "wind generator" that can make electricity. Most of these balloons will have an on-board heat source so as to produce any needed heated to heat the air within the balloon and make it less dense and less heavier air which will effectively allow the balloon to rise further upward. It is the heated air in the balloon which gives it its expanded and-or round shape due to the pressure upon its inner surface. When the heated air in the balloon looses energy and cools down, the balloon will start to "sink" or move downward in altitude (height), and more heat will be needed again to heat the internal air so as to maintain a desired altitude in the sky and-or to keep traveling further.

Though a hot-air balloon may have a few (lite-weight) metal parts in its entirety or whole volume, a hot air balloon structure, on average, is still less dense per unit volume of air, and therefore it also has less weight per volume than the surrounding air, and this will effectively cause the balloon to rise upward into a less dense region above it as the denser, heavier, more pressurized air forces it upward like a bubble in water. For a balloon to lift a weight or object upward, it must supply the conditions necessary for an effective upward lift force to be greater than that weight of that object. More technically, the (heavier than air) vessel or weight is suspended or held by the balloon, and it is rather the pressures and-or forces acting upon the hollow, less dense balloon volume that initially causes it to move upward and which with then will pull (ie., a tension force) the suspended weight upward with it.

The **Montgolfier brothers** worked by making paper materials for people, and noticed that when it was constructed to be a shape of a hollow lightweight bag (essentially an open-ended, 5-sided box-like shaped container made of fabric and-or paper cloth and glue), it would float upwards when heated air was allowed into the bottom opening. This is very similar to how the small, lite-weight, low power, ancient Chinese sky (floating upward, "flying") lanterns functioned, however, there is no knowledge or public record of them being large and practical enough so as to carry people by the time of the Montgolfier flights. We can still ask today: "Were the Montgolfier brothers inspired by the (ancient) developed Chinese sky lanterns?", and the answer would be "probably", but occasionally, things have been discovered independently and in such a way that it both verifies and increases the total known and useful body of knowledge about it. The first recorded account of a kite (a plane-like surface lifted into the air by the wind, and then held stable by a person holding a string attached to it) is in China, and is generally considered to have been created and flown there at about 500BC. Both kites and balloons have shown that various types of flight are possible. Since ancient times, ships or "sail-boats" have been using fabric (cloth) sails so as to collect the wind's (moving air) kinetic energy and transfer it to the forward movement and-or kinetic energy of the boat. A sail can be considered as a type of pre-kite since antiquity (for many thousands of years). The word "kite" is rooted in the words: "bird", "flight" and "sail". The word "sail" is rooted in the words "sea" (ocean, water) and "veil" (cloth).

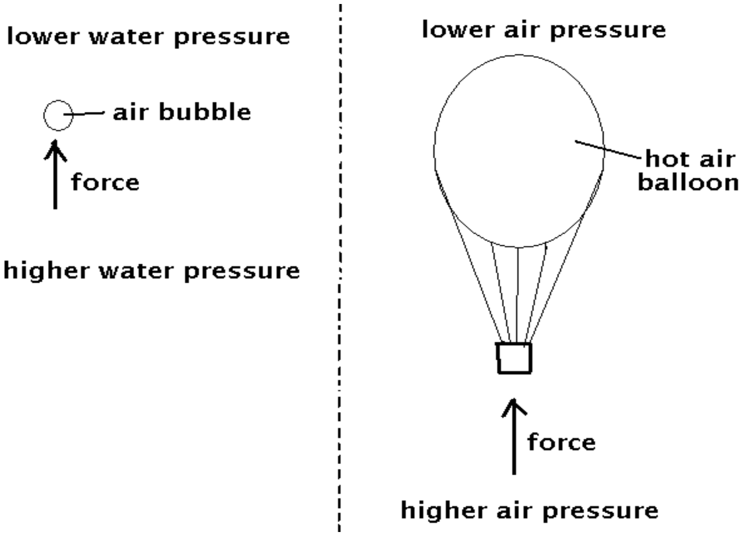
The first travelers on a large enough hot air balloon were a sheep, duck and rooster. These hot-air balloons, capable of lifting a substantial weight, such as for a one or two people, were first developed and tested by the **(Joseph-Michael, and Jacques-Etienne) Montgolfier** brothers in France in the year 1783. This was an surely an incredible event, and had peoples minds filled with joy, inspiration, and the wonder of science and the things yet to come, and which eventually lead to other flying objects and vehicles such as gliders, airplanes, rockets, satellites, and the Moon landings 186 years later.

The word "flight", "flying" or "to fly" is the common description of how a bird, bug (ex. a fly), creature or object such as a balloon is seen moving ("flys", or is "flying") in and through the air. "Flown" is the past tense of the word and meaning of "to fly" or "flying". Even the word "flown" can be associated with the word "flow" (movement) of a current of water.

After the initial discoveries and tests, the next logical step for the Montgolfier brothers was to just increase the balloon's size (ie., it's internal volume) and strength so as to have enough air displaced so as to essentially allow a larger, upward and more practical (ie., more useful) upward force to carry or lift some objects, animals, and people. These balloons would be made from a lite-weight cotton cloth material with paper glued over it so as to seal it from air leaks which would eventually release the internal hot air and its pressure and that will deflate the balloon and reduce its altitude.

The famous United States of America (U.S.A) statesman, inventor and one among the first electric pioneer's, **Ben Franklin** witnessed the first manned (by **Jean-Francois-Pilatre De Rozier**, and **Francois Laurent d'Arlandes**) balloon flight while in France on November 21, 1783, and then some of the other initial balloon flights later, and with some filled with hydrogen gas which is even less dense and lighter than heated air and will effectively allow a greater upward force (lift) than just hot air alone, and it can therefore lift more weight per (same) volume of gas, and without the need to have an on-board air heater. Some of these flights went several thousands of feet high and traveled more than 10 miles away. People who knew of these balloon flights (and even later, such as with the first airplane and rocket flights) were amazed and considered them as a wonderful technological discovery and advancement for mankind. Ben Franklin soon told **George Washington**, the President of the country of United States Of America, and in 10 years later, George Washington became privileged to witness the first manned balloon flight launched in United States, and this was on January 10, 1793 at Philadelphia city in the state of Pennsylvania (PA). The balloon landed eastward in the state of New Jersey. The pilot was Jean-Pierre Blanchard, and who previously was the first person to cross the English Channel on January 7, 1785 via a balloon, and while delivering the first air-mail from England to France. Many practical applications or uses for balloons were soon found such as: travel, mail, package or cargo delivery, observation, photography, signaling (communication - visual [lights] or radio), recreation, and high altitude research of which eventually lead to space flight research.

A lighter than air balloon rises upward due to a similar process that happens with an air bubble in water, or warm water that is less dense than cooler water, and it rises upward to the lower pressure water surface. Another example is when the less dense than water, piece of ice rises vertically (upward) in water. The simple answer is that the air bubble is less dense and-or lighter than water around it. The internal pressure of the water bubble, due to its "water column" and weight above it and-or at its sides will move (due to its pressure or force) into (ie. displace, by force, to take the place of) the position of the less dense, less weight bubble, and replace (opposite of displace) or fill its current location, and the bubble will be moved or forced to a less dense, less pressure region above it. [Fig 245]



Though a balloon's construction material is heavier than air, its volume displaces (resides in its original place and-or volume ["space"]) the air around it like how an air bubble in water displaces the water around it. Regular air in the balloon will not let it go upwards, and it needs to be filled with something lighter (less dense and weight) than the surrounding air and the air pressure upon it. The hot air, hydrogen (a very dangerous, flammable or explosive gas) or helium gas in a balloon is lighter than the cooler, denser (due to air pressure) air around it. The word "lighter" here means of less dense, having a lower density, and therefore it weighs less per unit of volume, and is said as being "light-weight" (or "lite-weight" to distinguish it from visible light) which is the opposite of something that is said to be a "heavy-weight" (heavy-in-weight).

Being less dense or lighter in weight, such as oil that rises upward and floats on water, may not a sufficient or full explanation as for how something like the bubble or balloon would move upward. When a bubble of air is below the surface of the water, there is water pressure (ie., a force) on that bubble, and is generally the same value all around that bubble when the dimensions of that bubble or other container is not vertically large in volume where the pressure would be greater on a deeper part of it. The deeper that bubble is, the more water pressure and force on it since there is more water above it like a heavier stone (vertical) column on a piece of foam, sponge, wood or a weight scale. The bubble displaces water and there is now the pressure due to this water displacement upon it. Since there is nearly the same force in every direction upon the bubble, the bubble should not move, but it does, and where to? Rather than being forced to a deeper depth where water is more compressed and dense, and with greater water pressure upon it, the bubble is rather forced upwards and moves into an area of lower water pressure or force since it is essentially the "easiest" natural place and direction it can be moved to with less resistance (due to less pressure and-or force) to its movement. Even a hollow metal, such as steel (ie., many times denser and heavier than water) ball can rise upward like a bubble and float near the surface if the total average density and-or weight of it is less than that of the volume of water that it displaces. It can also be said that the volume of water that was displaced by that hollow metal ball was heavier than that hollow metal ball, and so the hollow metal ball rises upward, rather than downward, and at the same time, water of higher pressure or weight (under the constantly applied force of gravity promoting movement) flows around it to fill its previous place at the same time that it rises upward with some gained kinetic energy and displaces water again and so on. This process repeats until the ball is at the waters surface and ceases movement upward because its average density and average weight is too much for it to rise up any further, such as up into the much less dense air.

A less dense substance will rise upward, and-or be forced upward, in a more dense substance. A common example of this is oil that will rise up to the surface of water because the oil is less dense than water. The weight of oil is also slightly less than that of water, and water will essentially sink around it and displace the oil and cause it to move upward.

Objects that rise upward in water or air are said to be **buoyant** (pronounced correctly as "boo-yent", and more commonly as "boy-ant") and-or have buoyancy. A buoy ("boo-ee") is a floating structure in water that is usually held in position by an anchor or heavy weight at the ground beneath the water, and so as to visually help guide or direct boats as they travel near the shore or other structures in the water that are a collision and-or boat grounding hazard due to a low water depth. The total amount of upwards force or "lift" (ie., lifting force) upon a balloon or bubble can be increased by using a gas with less density and-or by increasing the size or volume of that balloon(s) or bubble(s). In a very similar way, a heavier than water boat can float on water due to the total effective water pressure or force on the bottom of that boat. Due to the weight of the boat, the bottom of a boat will go into the water to some depth until the total upward force of the water pressure equals the entire downward weight of that boat. The hollow shape of the bottom of the boat structure gives buoyancy (floating ability) to the boat portion that is beneath the water as that boat portion essentially has less density per unit volume than that of the water it went into and displaced or "pushed aside". In general, and as mentioned previously, a hollow metal ball, and a solid metal ball of equal size will displace an equivalent volume of water, but the solid ball will sink in water since the effective (ie., average) density, and therefore its weight, is greater than that of the water it displaced, and the force of gravity and resulting weight (ie.,force or pressure) of the ball upon the water below it will be greater than the upward buoyant (water pressure) force upon it, and that ball will sink or move vertically downward. The hollow metal ball or boat shape will rise upward and float if the weight of it is less than the weight (ie., a force, a pressure, the buoyant force) of that of the displaced water, and this is similar to the average or resulting density of the volume of material (here a volume consisting of a hollow metal sphere and air) being less than that of the density of water it displaces.

The buoyant force upon an object is rather due to the water volume displaced and the average density of the object, and not its weight. The effective buoyant force acting upon a submerged object , or its effective weight in the water will be the value of: **effective weight of a object submerged in water = (objects weight - buoyant force)** , if the buoyant force is more, the object will rise and have a negative weight or upward force.

One of the greatest scientist of antiquity, **Archimedes** from the city of Syracuse in Italy, in about 250BC, discovered that the upward force called the buoyant force upon an object in water is equal to the weight of the volume of water that the object displaced (ie.,is in place of and-or pushed aside). If an object, such as a hollow plastic ball is above the surface, and you slowly push it under water, you can feel this **buoyant force** or buoyant pressure increase as the object is caused to push back against your hand in an equal and opposite force. **There is a formula for the calculation for the amount**

of buoyant force for a given volume and-or object in the Extras And Late Entries section of this book. This buoyant force is due to the weight and pressure (force / area) of the water surrounding the ball. More accurately, it is due to the water pressure difference on the upper portion and lower portion of the object. The weight of a cubic foot of water displaced by an object having a volume of 1 cubic foot (7.48 gallons) is 62.43 pounds (lbs) of weight. The weight of a liter of water = 1L = 1000g (gram weight, of 1000cc = 1000 ml of water) = 1kg = 2.205lbs =~ 10N. If you had a lite-weight and rigid box structure with 1 cubic foot =~ 28.317L of empty volume in it, it would take about 62.43 pounds =~ 278 N of downward force so as to make it submerge below the water surface level. Due to this upward (buoyant) force, this also means that an object submerged in water will feel less heavy (ie., weigh [the downward force due to force] less) by an amount equal to the weight of the volume of water it displaces and-or the (upward) buoyant force. In short, the water pressure is essentially forcing the object upward to a region of lower pressure, hence against the downward pull of gravity, and the object will then effectively weigh less in the water, but still have the same amount of mass. It is also as if the force of gravity was less upon it. With the known values shown above, you can use a proportional type of equivalent fraction equation to solve for the buoyant force or volume. Ex. 1ft^3 / 62.43 lbs = 2 ft^3 / x lbs, after solving: x = 124.86 lbs

The concept of displaced water is also a very effective way to calculate the volume of an object by measuring the equivalent volume of water it displaces, which can be determined by the difference of the height levels of the water that it is placed into - such as a calibrated measuring container. The (mass, rather than weight) density (p) of the object can be found by dividing the mass of the object by its volume. p = m / V . Note: weight = effective force = (mass) x (acceleration) = mg, and therefore, mass = weight / g. Therefore, **density = p = m / V = weight / g V** . Note that: **weight = mg = Vpg**. On Earth's gravity, (pg) is a constant for a given substance. Knowing the density (density = mass / volume) of the object can also be used to determine the specific element that the object is composed of, such as determining if a king's crown is composed (ie., containing, consisting) of pure gold which has a certain known density of matter and-or weight (= mg) per unit of volume. Many modern scales will automatically convert the weight of an object to its equivalent mass value, and then display that amount of mass.

Ex. For 1L of water displaced, the weight of it, and the resulting total buoyancy for a structure of equivalent volume:
(pg) = (1kg / 1L) (9.8m/s^2) = (9.8 kg-m / L s^2) , and since L was used for volume instead of m^3:
Vpg = L (9.8 kg-m / L s^2) = 9.8 kg m/s^2 = 9.8 Newtons = 2.205 lbs = Force = ma = Weight

Due to being capable of displacing a large amount of water that is relatively heavy in weight, underwater balloons with a suspended basket or rope beneath it are very practical for helping lift heavy weighted objects to be propelled (ie., forced) to near the surface of the water for retrieval. For this to happen more easily, a deflated balloon must first be taken beneath the water to the object's location and then filled and expanded with a volume of air so as to displace water. The larger the volume of the air filled balloon beneath the surface of the water, and it displacing a larger volume of water and its equivalent weight, the more total effective buoyant force or actual "lift" force it can produce. This process mentioned can also be achieved by using several smaller sized balloons connected to the object, and the total lift or buoyant force will be sum of the lift or buoyant forces from each individual balloon used.

A research submarine can remain at a certain depth of water, and without naturally rising upward into a less depth of water, or naturally moving downward to a deeper depth of water. If need be, it can remain at a depth by placing enough water into its (water) ballast (ie., additional weight used for some stability and control) tanks or pipes to where the average density of the submarine structure has the density of the surrounding water - about 1g/cc = 1kg/1L. In other words, the submarine will have the same weight of the water it displaced. If it weighed more, it would sink, and if it weighed less, it will rise upward. To make the submarine rise up to the surface, the water in the ballast tanks is simply replaced with low density and weight air, and via a pump. Likewise, to submerge to a certain depth, a certain amount of water is let into the ballast tanks so as to make the submarine heavier and denser per unit of volume, and therefore reduce the effective buoyant force upon it.

A hot-air balloon may use some ballast weight such as sandbags (bags filled with sand or dirt) to help set a maximum altitude, or to possibly give it some extra altitude if needed by discarding some of it. Note that a balloon will not keep rising upward like a bubble in water will. This is due to the fact that the density and pressure of the air is getting much lower at higher altitudes, and the buoyancy force, here equivalent to the weight of the displaced air, will not be enough to move the balloon and its corresponding weight further upwards unless it can displace more air by increasing its volume, and which is generally unlikely. Due to this, high altitude balloons will require a larger volume balloon, and where the pressure of the balloons internal gas will cause it to expand and displace more ("thin", low density) air.

The amount of the upward buoyant force or "effective lift" is due to the amount of displaced water and-or the difference in water pressure on the upper and lower surfaces of the object. Due to this, even at great depths and pressures, the buoyant force on an object remains the same since the difference in pressure upon its surfaces is still the same as that of when it is in water not as deep, and where the water pressure is lower. There is an article for calculating the amount of the buoyant force upon an object in water in the Extras And Late Entries section of this book.

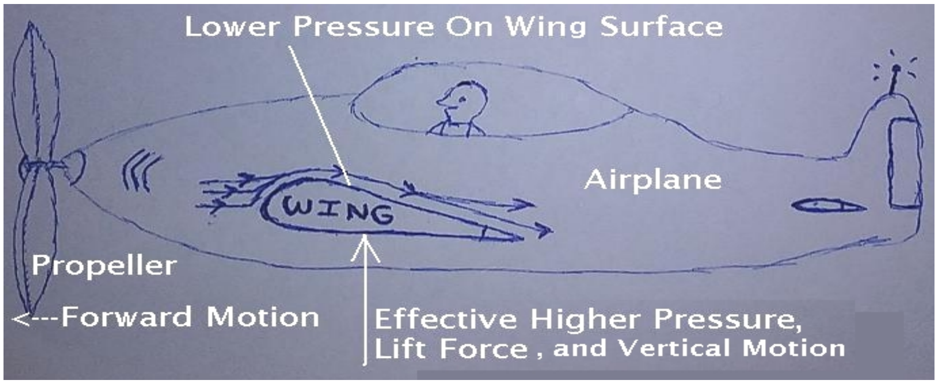
By the second half of the 1800's, experiments of machine powered balloons ("airships") were beginning to be made by several people, and first using steam powered (paddle wheel, shaped) propeller (for speed and-or various directions) in 1852, by **Jules Henri Giffard** in Paris city, France. An electric motor was first used in 1883 by **Albert and Gaston Tissandier**. In 1884, in Paris city of France, **Charles Renard** flew the first practical and controllable, electrically powered airship. **Alberto Santos Dumont** (1873-1932), from Brazil, made the first practical balloon with a gas powered engine and tested it in Paris city of France in 1898, and this balloon was propelled forward by using a spinning propeller which effectively pulled this airship forward. He was also an early and significant pioneer in airplane flight soon after the success of the **Wright brothers** first combustion ("gasoline", "petrol") engine powered, controllable (ie., steerable) and sustained airplane flights. Dumont is generally credited with making the first plane with wheels (rather than curved wooded skids or ski's) to assist with take-off and landing of the plane. The Wright brothers initial flights used a weighted catapult mechanism so as to give the airplane some initial kinetic energy and-or power, particularly some initial speed, and wheels would of been useless in the soft sands at Kittyhawk located near the Atlantic ocean shore in the state of North Carolina. Wheels offer low friction, and therefore low energy losses, and practicality on a hard surface such as hard dirt and-or a paved runway of hard material such as asphalt and-or cement.

In 1848, **John Stringfellow** (1799-1883), from England, created a steam powered, unmanned airplane, but it was relatively crude, under-powered and very limited in the amount of time available for sustained manned flights. It essentially made short "hops" or distances rather than have a sustained flight, but it did indicate and helped inspire the possibilities of future advancements and powered manned flights. Stringfellow was inspired by the earlier, in 1842, "aerial steam carriage" idea or concept created by **William Henson**, also from England. Henson and Stringfellow received a patent for a steam powered airplane design. Both dreamed of a future with transportation of passengers using airplanes. It is of note that balloon knowledge and flight was already in existence since the 1780's, and surely the concept of a large kite (ie., a glider) carrying a person began to be considered, and that an engine of some sort for power would be helpful. Their airplane was under-powered and could not sustain (upward, vertical) lift due it to being under-powered, low speed and not having a proper and adequate wing design or curvature so as to more easily create a lift force for sustained flight. Still, it was a promising starting point for other inventors to continue their research on machine powered flight. Between 1848 and 1932, there were many attempts at a steam powered airplane for this was the generally the era before a lite-weight and powerful combustion engine could be manufactured. By 1933, about 30 years after the Wright brothers first practical flights, the **Besler brothers**, from America, were the first to create a steam powered airplane capable of sustained flight. Their airplane consisted of a modified airplane with its combustion engine replaced with a steam engine.

Samuel Langley (1834-1906), an American scientist, demonstrated the first (steam) powered, heavier than air, unmanned flying machine (airplane) in 1896, but it could only travel relatively short distances (or "hops") of a few thousand feet due to a lack of sustained power of the design of the on-board, lite-weight steam engine. Nonetheless, it was a great technological achievement for the time, and it pointed directly to a high possibility of future manned flights, and must have been some inspiration to the Wright brothers and their airplane soon to come a few years later. In 1903, he created a manned, piloted version with a combustion engine of high power for those times, but the flights were unsuccessful - probably from not having a long enough runway to develop a sufficient initial airspeed and the resulting lift force. His airplanes also had limited steering, landing and reuse capabilities. Previously, in 1891, Langley invented the **bolometer.** A bolometer is very sensitive light or energy meter, and is made from a sensor [usually a seimi-conductor] that is sensitive to various RF and thermal radiation, and of which will increase its temperature and change its resistance. This can be sensed when the sensor is part of an electronic "bridge curcuit". This meter could measure very small or minute changes in temperature, infrared (ie.. "heat" energy) light (electromagnetic energy) and other forms of (energy) radiation (ie., transmission). Changes of the input light, radiation level or intensity can likewise also be sensed and measured. The word "bole" is from an ancient Greek word for a ray of light, energy and-or a thrown object. Langley also established an accurate **(railway) time standard** for the United States eastern railroads, cities, etc., and this was based on the position of stars as Earth rotates on its axis per day. The exact time was communicated via using the (fast, electric) telegraph system. Some places in Europe were already doing this at this time, such as in telesscope observatories. Many locations and facilities are named in honor of Langley, such as the NASA Langley Research Center, and Langley Air Force Base.

The inevitable march toward manned flight finally culminated on December 17, 1903 at the windy and relatively soft sandy hills near Kitty Hawk city in North Carolina state of the United States of America (USA). **Orville and Wilbur Wright,** commonly identified today as the "**Wright Brothers**" from Dayton city in the state of Ohio, brought to, and flown the first-ever manned (as the pilot and passenger), practical, self-contained (on-board) powered flying machine or "**airplane**" capable of sustained flight using the power from the on-board engine. They also experimented, designed and built this powered aircraft and since they were already crafty with fixing, modifying and improving bicycles before this time. The bicycle at these times was already becoming very similar to the modern designs and practicality. In geometry, a plane is essentially defined as an endless (ie., infinite), thin and flat (ie., no thickness) surface. This airplane machine essentially created and relied (like a balloon and glider does) upon a difference in air pressure, but now applied to the "wing" surface as the airplane moves forward, so as to create a net pressure difference and resulting net force beneath the wings so as to lift the plane and pilot (driver, controller) upward (vertically), albeit, even if just at a low incline angle above and with respect to the horizontal or level flight line considered as 0°.

To make the Wright Brothers flight more possible, a lightweight (here, mostly aluminum metal) liquid fuel ("gas") combustion engine was built by their machine shop employee **Charlie Taylor**, and was necessary to give this airplane power for forward movement so as to essentially have sufficient air flow of higher speed and lower air pressure along the upper surface area of the wings. It needs to be noted that the air effectively and relatively travels faster over the upper surface of the wing due to the entire airplane propelling itself and going at a fast velocity. A wing that is tilted or angled slightly upward from the forward direction of motion will also have some increased air pressure on the bottom surface of the wing, and it helps to improves lift, but this then also begins to increase drag and therefore reduce efficiency and a compromise angle for that plane needs to be found for the best fuel and efficiency. This wing tilt or angle with respect to a horizontal line at its lowest point on it is called the "**angle of attack**" [or (wing) "attack angle", into the forward motion, into the wind]. The net or resulting difference in air pressure or force upon the upper and lower surfaces of the wings is naturally called a (vertical) **lifting ("lift") force** (applied to the bottom surface of the wing) so as the entire plane can be forced or lifted vertically (upward in height) and-or perpendicular to the direction of flight. After their airplane flew or worked, the Wrights constantly improved their airplane design and made it more controllable (steerable), powerful, and efficient. The Wright brothers sister, Katherine, helped her brothers promote aviation and became a worker at the Wright Company which made airplanes at Dayton, Ohio. In 1909, Wilbur Wright, as the pilot, dazzled the spectators as he flew his airplane around the New York city area and Statue Of Liberty. Wilbur, born in 1867, died in 1912 from illness, and Orville, born in 1871, continued onward with things about airplanes and the business of aviation. It is interesting to note that the propeller and forward motion of the plane will effectively supply a current or flow of air across the wings so as to create a lift force due to the air having a higher velocity and lower pressure on the upper surface of the curved wing. The propeller is essentially collecting some air in front of it and pushing it back towards the wings at a high velocity. This will also cause an equal and opposite force in the opposite direction, and which will then cause the plane to move forward with the same force of the wind it is pushing back towards plane and its wings. [FIG 246]



A noted good attempt, similar to **Samuel Langley's** attempt of creating and flying an airplane at about the same time frame as the Wright brothers, was from **Richard Pearce** of New Zealand. With some more assistance and resources, he could of made a plane that was practical enough to be publicly and repeatedly demonstrated. Some of his knowledge and ideas were important and eventually became helpful to other airplane makers, but his claims were generally not publicly documented by him at the time. Even the Wright brothers did many of their test flights in secluded locations so as to help keep them private from potential competitors. One concept Pearce used tor his crude and under-powered airplane was that of using the previously known concept of ailerons used for balloon airships. Ailerons ("flaps") are small movable wing extensions or segments of the wing itself, so as to help control the direction and-or stability of a flying vehicle. His flying machine and concepts are considered as a very good attempt of powered flight, but his airplane didn't have a sustained flight capability since it could only be flown in "hops" (short distances). He later acknowledge the Wright brothers first practical and independent flying achievements which include a special curved wing shape to effectively create a lifting force which is due to the difference in air pressure (a force) upon the upper and lower wing surfaces, and with the higher force (ie. usually, normal air pressure) being applied to the bottom of the wing and forcing the wing and plane vertically.

In 1916, the first airplane manufacturing company was created by the Wright brothers and was called the Wright Company. It briefly joined together with their rival, the Glen L. Martin Company, so as to improve new airplanes. Later, the Wright Company became known as Wright Aeronautical and focused on the manufacture of more powerful airplane engines, and specifically, improved engines based on the original 1901, high power, **Manly-Balzer radial engine** created for Langley's failed experimental aircraft just before the Wright brothers success. This company later joined with the (Glen) Curtiss airplane company and became the Curtiss-Wright corporation. In 1916, the Boeing company started making seaplanes that could take-off and land on water, and this helped to overcome the problem of the limited number of airplane runways (long "take off" or launch surfaces where enough speed and lift is first developed) available at the time, and especially near more remote destinations in need of supplies and where no runway could possibly be built. Boeing currently builds many of the large passenger airplanes with jet engines such as the 737 airliner. The word of "jet" is a short form of several old French words, mainly the verb word of "jettison" which means to toss out, or to force out and away (ie., "thrust"). "To jet about" is a phrase that means to move quickly. A jet is also a word modernly used for an airplane that has a jet engine. A liquid under high pressure will jet outward from an opening. As of the year 2022, the Curtiss-Wright company is still in operation and making various technology products. After the business relationship with the Wright Company, the Glen L. Martin Company continued onward and would manufacture both airplanes and rockets, and later, this company joined with the Lockheed company and became known as Lockheed-Martin.

The first human to walk on the Moon was **Neil Armstrong**. He was born in 1930 in Ohio state (where the Wright brothers are from) and was already flying an airplane in 1946 before he had a car (automobile) license. Orville Wright lived long enough, up to Jan 30, 1948, to know of jet powered airplanes, and the increasing dreams and possibilities of advanced airplanes and rocketry. Because Neil was good at flying planes such as a high speed, high altitude rocket plane to the edge of space, and of which requires a pressurized space-suit, he was chosen to be an astronaut along with several other airplane pilots trained for space flight. Neil took some small samples of the Wright brothers first airplane to the Moon and back in honor of the Wright brothers and their achievement for all of mankind. Neil mentioned that he never met Orville in person and that the Moon landing was made possible due to all the teamwork and cooperation of many people. Neil mentioned to the effect that he was just in the next available job position, chance and luck, location and time so as to make the first human footstep on the Moon, and of which represented all of mankind landing on the Moon with him.

Lift or lifting force is due to a difference of force due to the difference of air pressure upon an object such as an airplane wing, and can be easily demonstrated by blowing fast moving air directly above and past a flat strip of paper about 1 inch wide and several inches long on top of your hand, and held by thumb and index finger. The paper and its surface where the moving air is applied to should move in a perpendicular (ie., 90 degrees) direction to that of the moving air, and in the direction away or opposite from the opposite side of that paper where the air pressure is (naturally and-or commonly: 14.7psi) slightly greater than that of the faster moving air on the top of the paper. On the top of the paper the air pressure will become less than 14.7psi. This net or total difference in air pressure (force/area) effectively places an upward net force on the bottom wing surface. For example if the bottom air pressure on the paper is 14.7ps, and the top air pressure is 10psi due to the fast moving air over it, there is a net air pressure or force of (14.7psi - 10psi) = 4.7psi on the bottom side of the paper. This force which causes the plane to be lifted vertically (higher) in the air is naturally called a "lift force", or simply called "lift". The faster the plane moves horizontally in the forward direction, the faster the air moves over its surface and the lower the air pressure on it, and the more lift force created since the net difference in force upon the wing (top and bottom) surfaces is now larger. Planes with a low speed will therefore take longer to move higher and to be at a certain altitude (height). When the lift or upward force created can no longer be greater than the (downward) weight (a force) of the plane, such as when the plane has a low speed, and-or the air density is low due to a high altitude, the plane cannot go any higher. This happens when the airplane is at an altitude where the air is "thinner" or less dense, and-or due to a low speed of the airplane not creating enough lift force. In this condition, at level or horizontal flight, any instantaneous gain in altitude due to a small amount of lift, is then lost by the equivalent instantaneous drop in altitude due to gravity. To maintain level flight, the upward lift force created at and upon the wings must equal the downward force of gravity, and which is the weight of the plane and anyone or anything else on-board.

The net difference in air pressure, and which creates the lift force, upon the upper and lower wing surfaces is generally not much in value, say only 0.1lb psi, but if the wing surface is large enough, the total lift force will become larger than the weight of the plane and allow it to move vertically upward. As a reminder: **Pressure = Force / Area and F = P A**

Effective lift force = (total lift force on the wings) - (total weight of the plane, passengers, etc.) : 1 ft^2 = 144 in^2
Effective lift force = (pressure difference in psi) (area of the wings in in^2) - (weight of the plane and passengers)

Ex. Effective lift force = (0.1 lb psi)(3ft x 20ft) - (500 lbs)
Effective lift force = (0.1 lb / in^2) (36 in x 240 in) - (500 lbs) = (0.1 lb / in^2) (8640 in^2) - (500 lbs) =
Effective lift force = 864 lbs - 500 lbs = 364 lbs

As indicated previously, any object, whether a lite-weight balloon or a fast and heavy plane will require some amount of energy to maintain its altitude because Earth's gravity and force is always acting upon it and causing it to accelerate and move towards the Earth at: a = g = 9.81m/s^2, hence the object will go lower in altitude, and even if maintaining a constant horizontal velocity. Heavier objects with more mass and weight will require more energy to both arrive to and maintain their altitude or (horizontal) level flight. To overcome the effect of gravity and maintain level flight, the lift force must provide an upward acceleration of the object by the same value as that of gravity, hence 9.81 m/s^2. For a balloon, the buoyant force of the atmospheric pressure will provide the lift force on the (average and low density) "lighter than air" balloon. Heavier objects with more weight will require a larger amount of lift force so as to obtain an upward acceleration of 9.81 m/s^2. Planes with longer and-or larger wings, and-or being faster will generate a higher amount of lift force upon its wing surfaces. If this lift force is constantly applied as the plane drops by only a very small amount of height or altitude distance per fraction of a second, the corresponding amount of energy required to move the mass of the plane this short distance upward or vertically will be relatively small: Work = Energy = (Force) (distance). As a plane takes off from the ground, much energy is initially needed and-or used to lift it to that height or altitude of flight. It must be remembered that the drag force upon a plane also slows the airplane's velocity and is a waste of fuel energy, and this must also then be replaced by using some fuel and its energy so as to maintain velocity and-or altitude. In general, the upward lift force must be equal to the weight of the object or plane so as to maintain level flight or the same altitude. Relatively slow moving solar or bicycle powered, and-or other experimental planes, usually have a very long and lite-weight wingspan so as obtain the necessary lift force.

As a object such as a ball is thrown horizontally, the force of gravity is always acting upon it, even when it is rising upward, and pulling it vertically downward. Its velocity (v = d / t) or rate of the change in distance with respect to the change in time will then not be a constant value. As the ball rises vertically, it will be constantly decreasing in the amount of its vertical velocity due to gravity. When the ball has reached its highest altitude or height and appears to briefly stop in motion, the force of gravity will still keep acting upon the ball and accelerate it to have a higher velocity, and it will then move quicker and quicker towards the ground (ie., in the vertical direction) since the force of gravity is constantly acting upon it. If the ball was also thrown with some initial horizontal velocity, its flight path or trajectory will be that of like a curved arc, and is in fact a **parabolic shape or arc** of which a parabolic or quadratic equation (similar to: height = y = - at^2 = - gt^2) can be used to mathematically represent and study an objects motion through a gravitational field. In a vacuum with no air resistance to reduce the kinetic energy of the balls motion, the maximum height of the ball will occur halfway between its starting point and ending point on a horizontal or .evel surface.

Seemingly "weightless" spacecraft or satellites orbiting the Earth are sill in the nearby presence or gravitational field of Earths gravity force which causes a constant gravitational acceleration (of the amount of: a=g = 9.81 m/s^2 at the surface and-or low (radius distance) orbit heights above of the Earth and-or from its center point). The (apparent) "weightless effect" is due to that the observer and other objects are all falling at the same speed, and it then appears as everything is not moving faster or slower than the observer or vice-versa, hence as if those items are motionless and-or weightless.

Another fairly common example of where movement can be commonly observed due to pressure differences is by aiming the wind from a fan across the surface of a movable door. This will create a low pressure region on that surface and will cause that door to be pushed or moved in a direction that is perpendicular to its surface and toward the lower pressure wind direction on its surface.

Aviation Discoveries Before The Wright Brothers First Manned Airplane Flight

The glider (unpowered, no engine, manned (piloted) airplanes, somewhat like a kite) makers, and later, the Wright brothers naturally based some of their work on the previous knowledge of others. Scientists and-or inventors have no need or desire to reinvent the wheel, so to speak, but rather try to understand it more and-or to improve it. The Wright brothers also used their own imagination and observational discoveries noticed in nature, such as with the flight ability of bird wings and their movement, various "propeller" seeds of trees, flying insects, various types of fish (ie. their tail-fin being the "rudder"), boat sails, windmills, hot-air balloons, ("box") kites (ie,, with wing surfaces), and (non-machine powered) gliders (essentially large kites, capable of a lifting a pilot and sustaining a reasonably long horizontal movement and direction, particularly in the direction of any oncoming wind). Before the first self-powered airplane flight, the Wright brothers made and experimented with manned gliders beginning in 1900 at Kitty Hawk in North Carolina state, and it would only be a matter of time and experiments such as with new wing designs and their increased lift efficiency found with the aid of a small wind tunnel they had built. A **wind-tunnel** is structure that consists of a powered fan blowing (ie., moving) a fast and controllable, steady current of air (ie., wind) at a known speed and into and through a long rectangular box and expelling it over the wing models and-or airplane shapes and surfaces. The amount of lift can then be measured. Thin streams of colored smoke over the wing surfaces can help visualize the air movement and-or turbulence with that specific wing shape and-or angles it is set to. The wind-tunnel was first created in 1871 in England by **Francis Wenham** and **John Browning**. The Wright brothers used patience, persistence, calculations and technology (such as the engine itself) until that first successful airplane could be made and then flown. Unlike a balloon at the mercy of the near random windspeed and direction of the wind, the airplane allows people to fly in any direction needed, and to any practical landing location (ie., a designated flat, "runway" surface). The Wright brothers first airplane had a similar design to the 1896 biplane (bi-wing or 2 main wing surfaces. so as to slightly (about 20%) increase the total lift force) glider made by **Octave Chanute and Augustus Herring** from the United States of America, however the Wrights used a wing shape with its upper surfaces deliberately made slightly curved (sometimes called "camber") since it was first noticed by **George Cayley** who, many years previously, made the first scientific study of how things could possibly fly, and of a specially curved wing surface shape called an "**airfoil**" (see FIG 246) that improved lift. Cayley is also further discussed below in this book. The Wright brothers eventually perfected their glider to the point that it was practically a controllable airplane without an engine to sustain longer flight. Chanute and his knowledge also provided some help to the Wright Brothers before their first flight. Many modern **windmill** wings or blades for the generation of electricity also use an airfoil shape so as to help increase the efficiency of the energy collection and conversion of the available wind power to available electric power. In brief and without consideration of the airfoil shape, for a windmill ("wind generator") blade to collect the wind and its kinetic energy, it cannot be flat or at a 0° angle because it would collect no wind energy, and it also cannot be perpendicular or 90° to the wind for its force would be simply pushing the blades in the direction of the wind, and rather than rotating them. A compromise blade angle must be found by experiment, and obviously a 45° angle is a reasonable place to start, but it will usually be lower than that. The best angle will produce the most output power for a given windspeed. If the blade is at a too low of an angle, then the input energy collected will be low, and some of its energy will be lost when it is deflected or diverted at an angle. If the blade is at too much of an angle, then the wind force applied will not rotate the blade as much, and the drag (air resistance, friction) caused by the side of the blade colliding with the air as it rotates at a high number or revolutions per time will also reduce the speed of the blade and the power output. The **Betz Limit** is a theoretical, **59.3% =~ 60%** maximum limit to the amount of the input wind energy collection possible by all the windmill blades of a wind turbine. Due to other losses in the wind-energy system such as mechanical friction and electrical resistance, the final output power of the wind turbine, wind energy collection system will usually be less than the Betz's limit, and at about **30% on average**.

After the first successful airplane flight, the knowledge of flying, airplanes and their manufacture expanded quickly and greatly all over the world, and with many people still being naturally skeptical and unconvinced of the manned-flight news until they have personally seen photos of an airplane in flight, and-or actually seen an airplane flying nearby. By the end of just the first year of airplane flight, the Wright brothers were flying for several miles of distance in their airplane at a relatively low altitude since their plane had a very low amount of lift force available. By as early as 1910, some planes such as the Wright Brothers popular "Model-B" plane were already capable of flying up to and over a mile (5280 feet) high (altitude) in the sky. The study of flight, airplane design and efficiency has continued ever since their first flight in 1903.

The first practical, flown manned gliders were developed by the **(Otto and Gustav) Lilienthal brothers** from Germany, in about 1891, and which was only a few years prior to the Wright brothers first airplane flight. Nonetheless, gliders were very important for (mechanical powered) airplane development, and are a fun way to fly. In modern times, some highly experienced skydivers at a high mountain location, or jumping out of an high airplane, put on a suit called a "wing-suit" that has a wing-like shape and some gliding capability which gives them an incredible fast, bird-like flying sensation and view of which is often recorded for others to experience later such as via a video. At some point with sufficient altitude left in their journey, these fast moving skydiving pilots will deploying a parachute so as to slow them down and land safely.

About 100 years prior to the Lilienthal gliders, **George Cayley** (1773-1857), from England, in about the year 1799, made many of the fundamental discoveries of ((effectively) "lighter than air") airplane flight by using various wing designs including the necessary "airfoil" shape of the wing(s) that the Wright brothers would also use later for their gliders and first airplane. He recognized lift (upward force) upon that airfoil or airplane wing shape. Cayley also recognized thrust (the force that provides forward propulsion or motion) and drag (the effective force in the opposite direction to the forward thrust direction, and due to air collision and air movement resistance on a surface, particularly the front forward edge of the wing and plane shape). A larger surface area in the direction of flight will create more air particle collisions and this increases the net air resistance to fly through, and reduces the maximum possible (such as if there was no drag) forward thrust or force, and therefore reducing the airplane speed, wasting time and energy (available or stored in the fuel source). Cayley probably got some incentive to do his aeronautical studies after the first manned balloon flights 15 years earlier. Even if the air is not moving, it is as if it was and has kinetic energy and collision force relative to the motion of the airplane. This collision force is called a drag force or sometimes as a reduction or an opposite (direction) force.

For the airplane to have any upward vertical movement, the total effective lift force generated and available must be greater than the weight (a downward force due to gravity force and its acceleration upon a mass) of the plane. If the lift force equals the weight of the plane, the plane can maintain and have a constant altitude (height) in the sky. Reducing the lift forces, such as when the plane is slowed down, will make the plane descend such as to make a landing. A plane can change its horizontal direction of travel by using a rudder (a "flap" [flying, planar], surface) in a similar way that a rudder of a boat is used to change its forward direction. Cayley also made some simple or basic constructed experimental gliders to help verify his fundamental discoveries and ideas. Cayley discovered that the upward lift force was directly related to the square of the (relative) speed (ie. velocity^2) of the wind and-or the surface (ie. the plane wing) it flew over.

Due to his significant contributions, Cayley is considered as the founder of modern aerodynamics or aeronautical engineering. Before Cayley's study and discoveries of flight and lift, **Isaac Newton** discovered that the drag (ie., the effective resistance force opposed to forward movement) force upon an object, such as a rectangular plate placed in a stream of flowing water, was directly related to its area size and the square of the speed of the fluid, air or object. Upward "lift" or force on a flat plate or plane surface is also related to the square of the speed (v) of the fluid or air (sometimes considered as a low density fluid) over the wing surface. A pointed shape has less drag force upon it since the force is not then perpendicular to its surface, but rather at an angle to it, and is then also spread out over a larger area. P = F / A. This area still needs to be as thin and small as possible and practical, and the ideal ("bow", "nose" or "forward") shape of the moving structure in air or water is a compromise shape of which can be described as that of a combination of a flat plane, a cone and a sphere, and it is actually an "airfoil" shape that is used for airplanes. Boats, automobiles and objects are also designed to have a low drag resistance when needed. If you hold a flat object in moving water or a air, you will see that when you hold it perpendicular to the wind or water, that the (resistance, drag, collision) force is the greatest amount possible, and that it is best used for things like water-wheels to power grain milling and other machinery, and for water turbines (somewhat like a large geared wheel) that can collect and transfer as much mechanical energy as possible so as to make electrical energy (electricity) from a (rotating, coil and magnet, electric) generator. The amount of drag to expect for a given shape has been experimented with and the resistance force measured due to the air or water. From this force value, another value is calculated so as to then have a comparative, relative rating called a "**drag coefficient** (c)" for each wing shape. As you can imagine, a flat, perpendicular surface will have a high (c) rating of about 1.0, and a thin planar, level surface has a rating of about 0. A semi-sphere shape has a rating of about 0.45, and an airfoil has a rating of about 0.05 which is very low. Formally, the drag force (Fd) is mathematically defined and-or calculated as:
Fd = c p A v^2 / 2 , where: c = drag coefficient , p = fluid, or "medium" (substance) density , A = cross sectional area of resistance, v = flow or relative velocity with respect to the objects motion. Doubling (2) the velocity of the object or fluid, and-or the effective relative velocity change will increase the drag force by 4.

The faster the plane goes, the faster the air across the upper surface of the wings and the air pressure upon it will decrease, and the pressure difference on the lower and upper wing surfaces will be more, and of which results in a greater lift force. A common formula used for understanding and calculating the (generated or created) lift is:

$$\textbf{Lift Force} = \frac{(\text{coefficient of lift})\,(\text{air density})\,(\text{relative velocity}^2)\,(\text{upper surface area of wings})}{2} = \frac{(Cl)\,(p)\,(v^2)\,(As)}{2}$$

The coefficient of lift (Cl) number is mostly determined by the **attack angle** (ie., upward tilt with respect to the horizontal line) of the wings, and the wing curve and-or shape. The generated or created lift force produced must be greater than the total weight of the plane system so as to provide a net or resulting vertical lifting force applied to the plane. The above equation for lift force does not include a pressure or pressure difference variable upon the wing surfaces for the calculation effectively includes it via the other variables used. Depending on speed, an attack angle up to about 15° at low speed might be employed to increase the air pressure on the lower wing surface, otherwise if greater, it increases the drag forces. As indicated previously:

Effective lift force = (Total lift force created) - (Total weight of the airplane, passengers and any other loads)

The lift force due to the attack angle or angle of attack is sometimes called the **compression lift** force, and where its angle naturally causes the plane to go upwards and toward a lower pressure region, much like a propeller (ex. windmill, plane) does after wind strikes it and slightly compresses it and imparts some kinetic energy into the propeller or blade to then move and-or rotate. Modern propellers or the blades on large windmill, wind electric generators may be designed to provide a lift force so as to help reduce the drag (ie., air friction) force as it rotates.

A **glider** is a plane without any engine, and it is launched from a high location such as on a steep mountain, or it is towed by another (engine powered) plane to a high altitude and released. A lightweight glider (or "glider plane") can stay aloft in the air for a reasonable long time (ex. 20 min. typical, up to about 1 hour if the conditions are more favorable) as it slowly descends to the ground and-or is given some new lift force and a increase in altitude by some wind over the wings, or "thermals" that are updrafts or currents of warm air rising upward from the ground region to under the plane body and wings. An nice idea is to have a small light weight rocket or jet engine that could assist a glider gain speed and-or altitude, and-or to help travel a further distance to the runway landing zone if needed.

An **ultra-light aircraft** is usually a relatively inexpensive airplane of cheaper (lite-weight) construction where the pilot is often not fully enclosed within an aircraft body ("shell", container, insulator) which would provide more comfort from the elements (wind, cold, rain, etc.). By law, there is a maximum weight limit to these types of planes which can often be flown without a license and-or much training. This weight limit could reduce construction, comfort and-or safety measures, and perhaps the maximum engine power and-or speed should rather help decide the weight limit.

A **paramotor** (a parachute type wing shape, and motor) is a backpack-like, portable, lite-weight combustion or electric engine powered flying paraglider which is essentially a parachute-glider that uses its cloth-like fabric wing, somewhat similar to a parachute, to enable the lift process. Paramotors are generally not very fast, but can travel reasonably far and at reasonably high altitudes. Paramotors require only a very short runway, perhaps less than 30ft, and can safely land in a clearing (absent of trees, brush, fences, wires, stones, water, etc) at the on the top of a mountain after a few minutes of flight from the ground level. A paramotor is generally much less expensive than a regular airplane and-or ultralight aircraft. Having an airplane pilot license is sometimes not required, but pre-flight training by a certified paramotor flight instructor is recommended and-or required by local (ie., location of flight) laws. Due to that there may be other planes in the sky, there are further laws, rules and-or recommendations to follow, such as what altitudes to fly at, and-or not to fly at, etc..

Today, experiencing a form of flight and-or being a pilot is relatively cheap with modern remote controlled (RC) small electric engine(s) helicopters (non-passenger "**drones**") having an on-board, live radio-wave ("wireless") video for steering, location, and-or "filming" (image recording) capability via a small and lightweight camera. This is a virtual ("nearly", "as if", virtually, simulated) flying experience. Being small helicopters, they require no runway and can be launched almost anyplace and at anytime after charging up its power battery. These pilots and planes often need to observe any local laws created in regard to their use, and to fly fair and safe. I would personally recommend blade protectors or guards ("standoffs") to help prevent device damage and-or injuries to others. These devices are also used for many practical and valuable applications such as for search and rescue, movie making, aerial photography, data acquisition and map making.

Several human powered lite-weight airplanes have been designed and successfully flown at low altitude (less than 100 feet high due to having only a low "air speed" and-or forward movement, hence a low lift force). These would of made the Wright brothers proud since they use human leg power, much like riding a bicycle, and so as to turn a long propeller. The drawback is that a very long wing surface (about 112 feet) is then needed to create enough lift force. The longest verified flight as of the year 2020 was about 71.5 miles of distance in about 4 hours of time. The average speed of this flight was therefore: From distance = (speed)(time). speed = (distance / time) ~= 71.5 miles / 4 hours ~= 17.<u>9</u> ~= 18 miles per hour. The pilot and human leg force power for the airplane flight and record was **Kanellos Kanellopoulos** from Greece in 1988. He flew the plane from and between two islands: Crete to Santorini Island of Greece in the Mediterranean ocean, and for a continuous distance of **118km =~ 73 miles**. He was previously a cyclist in the 1984 Summer Olympics sports events, and so he had a good physical condition, strength and duration to achieve this. With comparative reasoning, a person of typical or average physical health could probalby fly this same plane a few miles.

Several solar-electric powered and piloted airplanes have also been designed and successfully flown and they require wings longer than most small commuter airplanes that have a combustion engine. These planes are therefore rare, costly, and impractical, but it is still good to know that it has been tried, possible and accomplished.

Before extreme high altitude airplanes, jets or "rocket-planes" were made, the only way to test peoples (mankind's, pilots) abilities in very high altitude flight near the edge of space was with high altitude balloon flights. The data from all these high altitude flights was, and still is, very useful for all the future manned high altitude rocket-planes and spaceflights. Amazingly, as early as 1800, the year Volta invented the "Voltaic pile" (ie., battery), balloon flights were already over 4 miles high and near the zone of where supplemental oxygen is typically needed for most trained high mountain climbers.

In 1932, in an internally air pressurized craft ("gondola", "capsule"), Swiss scientists **Auguste Piccard and Max Cosyns** were the first to reach 10 miles high (= 52800 ft). Piccard is also credited later to the creation of the **bathyscape** (strong container or vehicle for deep water, essentially a "**submarine**") which is used for exploring deep water, and with the inside occupants still at a normal air pressure for normal breathing. Piccard has therefore made many additions to the knowledge for survival in both low and high pressure environments. His son **Jacques Piccard**, and **Don Walsh**, from United States of America are among the few explorers to ever reach the deepest part of the ocean which is in the **Mariana Trench** region known as 'Challenger Deep' (named after a ship that discovered this very deep area) in 1960. This deep location is in the west Pacific Ocean near the island of Guam. While a typical space capsule or container only has to endure a relatively low (air) pressure, say 14.7psi, from the inside and upon its inner surface, the Trieste bathyscaphe ("deep-ship)", that is much like a specialized submarine vehicle, had to endure the extreme danger of thousands of pounds per square inch from the outside water pressure at the depth of about 35800 feet (6.78 miles deep). This depth is greater than the height of Mt. Everest (29032 ft ~= 5.5 mi high). The pilots were safely located in a thick steel sphere located on a submarine vehicle called the Triest which gets its name from an Italian city where part of the vehicle was made. A sphere shape can withstand much more pressure than other shapes because it helps distributes any outside forces over the entire surface and structure of that sphere. Its circular window was made from a transparent plastic material, and its thickness was cone shaped so as to give it high strength, and while held in and against the sphere wall as a support. Plastic has some ability to flex rather than crack or break like glass might when under high external (here, water) pressure. During the Apollo 11 mission in July 1969, Jacques Piccard and a group of other people studied the Gulf Stream current and ocean bottom in a current drifting submersible called the Ben Franklin while traveling along the eastern U.S.A. coast from Florida to Nova Scotia. Because of the extreme (inside and outside) pressure difference and danger at great depths, and the need for a strong (and heavy) vehicle, much fewer people have went to the deepest parts of the oceans than into outer space, and much of the oceans still need exploring, even if by using unmanned vehicles. The Gulf Stream current is a relatively fast moving current that typically moves at about 4 miles per hour =~ 6.44 km / hr .

By early June 1957, manned balloon flights were near the edge of space at a height of 100,000 feet (about 19 miles) as for Project ManHigh, and so as to know the feasibility of future manned space flights and the spacesuits that would be needed. The pilots of the two first and notable flights to about this altitude were **Joseph W. Kittinger**, and then **David Simons**. Their craft was like a miniature one-man modern space craft which was pressurized (to simulate Earth's normal 14.7psi atmospheric pressure at ground level) and contained: oxygen, heating, food and water, communication, flight instrumentation (data) displays, photographic systems, sensors, lighting and electrical systems. In 2012, **Felix Baumgartner** ascended to the highest manned balloon flight of 127851 feet (about 24 miles), and then he performed the highest parachute jump while wearing an insulated spacesuit having a "life-support" system such as oxygen to breath and some internal air pressure, hence much like a spacesuit for an astronaut.

A **parachute** (based on the words: "resist-falling") is much like just the top hemisphere or portion of a balloon made of strong cloth, and with the passenger and-or load suspended below it by strong fibers. Its large and curved surface provides much upward drag force against the downward pull of gravity as it descends in the air, and it will reduce the speed of the descent of the person or object to a relatively safe value.   The invention of the parachute is nearly intuitive and-or common sense based on the idea of an umbrella that prevents rain, wind and-or snow from landing upon an object or person, much like a small and portable roof, but it took till about the 1450 AD to be scientifically realized as being capable with a relatively heavy human passenger. **Leonardo DaVinci** is credited to a designing a more practical design in about 1485, and which was later improved and used by **Louis Lenormand**, from France, in 1783, and it was therefore, available for use for the hot-air balloons invented just a few years later in France, and later for the airplanes.

SPACE FLIGHT

Let us begin at some of the notable scientific concepts and discoveries for science, astronomy and space.

Robert Hooke (1635-1703), from England, theorized that the motions of the planets could be like that of a pendulum bob swinging or rotating about an imaginary center and force. This motion describes an ellipse (or possibly a circle - a special instance of an ellipse) shape, and that the same forces acting on the pendulum bob, object or weight must also be influencing the motion of the planets. One force was causing it to curve so as to stay in its circular motion and not fly away from its orbital motion. He later told **Isaac Newton** these things and it would later help Newton develop the value for Earth's gravitational acceleration (g) due to the constant force of gravity upon objects pulling them downward, and then later, to develop the force of gravitational attraction (Fg) of two masses.

In about 1660 Hooke made some observations and measurements and created an equation known as **Hooke's Law** that describes the amount of force needed to compress or stretch a spring, and of which temporarily deforms its atoms alignment, and it can store the input energy for later use as potential energy. For relatively short distances (x) of deformation and where it is linear, the amount of force (F) needed is linear in value and will be a multiple of the amount of distance moved. **F = kx** , and where k is a constant value, sometimes called the springs stiffness constant, that is determined by the spring's material (ie., what metal(s)), construction (ie., thickness, diameter, turns per inch) and then testing it with a known weight or force, and its units are force per unit distance: **k = F / 1x.** Note that even a flexible or bendable piece of metal or wood can also act as a spring. Note that stretching a spring too much will cause it to permanently deform and not function properly as expected, and the equation no longer applies unless that spring is somehow repaired. The distance moved by the spring is mathematically: **x = d = F / k**, and the more ridged or stiffer the spring, the higher its mechanical constant (k), and the less distance it will move when a given or certain amount of force is applied to it, and this spring may be described as being "stiff", and being harder to compress and-or to expand.

In 1665, Hooke was also the first to use a mid-power **microscope** (a device or instrument that magnifies the image seen of small objects) he designed and it had about 50 "power" or magnification and he could see very small creatures and large cells that are essentially invisible to the unaided human eye in terms of detail. He made up the word "**cell**" (ie., small room, area, container, chamber, body or region structure similar to closely spaced bee cells in a bee hive [dwelling, home, shelter]) as being the common or basic micro-structure of all organisms. The average diameter or length of a cell is **20um**. Shortly after this discovery, **Antoni Van Leeuwenhoek** (1632-1723), from Denmark, made high-power microscopes using a small melted sphere a few millimeters in diameter made of clear glass as the lens, and they had about 300 "power" or magnification, and he effectively created the field of micro-biology. He discovered bacteria, and that (microscopic) sperm (from male) and eggs (from female) are the basis of reproduction in many animals. The average length of a bacteria is **5 um**. Reproduction or growth by the division of plant cells into two identical cells was discovered in 1835 by **Hugo Von Mohl** (1805-1872), from Germany, while observing (plant-like) green algae. Before Leeuwenhoek, there was some (low-power, about 2 to 3 power) single lens, magnifier "glasses" or lenses since antiquity, perhaps inspired by the rounded shape of a drop of rain which can slightly magnify the object under it. Credit to inventing a modern type of microscope is generally and independently given to **Zacharias Janssen** and **Hans Lippershey** from the country of Netherlands (often called "Holland") during the years of about 1570 to 1590. Today, it is recommended that a microscope have a minimum of 400 power ("400 X") so as to identify and study cells effectively. To identify many bacteria species, it is recommended to use a 1000 power microscope, and in particular having a higher power objective lens, say of 40x, for greater initial detail rather than just a higher power eyepieces lens. Today's modern and high quality microscopes available are relatively inexpensive as compared to large and costly telescopes with the same optical power, and they are much more portable and useful to most others, such as to study blood samples for various problems or diseases that need medical attention. If you have a clear glass sphere and-or a clear glass "marble", you can use it as a crude microscope; perhaps 30 power, but it will have image distortion at the outer edges due to it being an out of focus area of the subject when it is not directly in line with the center or area of focus.

The first virus (a Latin and ancient word meaning "poisonous", hence dangerous, the spread of it is often noted as being "viral") as we know of today was noted in 1892 by the **Dmmitri Ivanovsky**, from Russia, while investigating what substance was causing a disease in some plants. **Martinus Beijerinck**, a biologist in Holland actually coined the word of "virus" in 1898. A virus is a complex (DNA and protein) molecule that can replicate and multiply within the infected host cell, and this will eventually damage that cell. To view a virus requires the high magnification of an electron microscope.

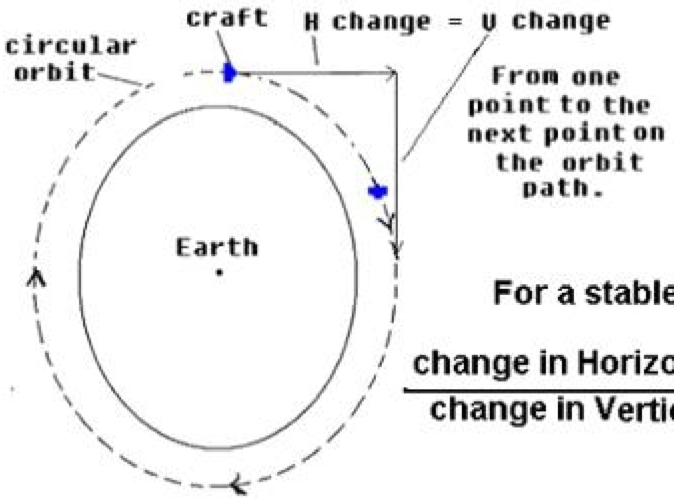
The world celebrated scientist, philosopher, and astronomer **Isaac Newton** was the first to conceive how masses such as the Moon can maintain a fixed orbit (travel around, go about) about another such as the Earth. He created a (logical) thought experiment, commonly called today as "Newton's Cannon" (ie., an imaginary cannon ball, fast projectile) in about the year 1687, and this hypothesis (something probable, and yet to be proven) states that if an object (such as a high speed cannon ball projectile) was made to go fast enough over the surface of the Earth, it would **orbit** (go completely around) the Earth. It would do this by effectively overcoming (but not actually cancel or stop) the constant downward gravitational (gravity) acceleration force of the Earth that causes it to decline in altitude, and then it will no longer orbit the Earth when it reaches the ground. At this orbit speed, it's vertical fall rate (height or distance per unit of time) towards the Earth would be equal to the downward (beyond and-or over the horizon) curvature, or decline rate (in height or distance per unit of time) of the Earth's surface that is below the craft or object.

For a simplified example of an orbit: If the craft was falling at 10 feet per second toward Earth, and the Earth curved downwards by 10 feet in that same amount of time, then the craft will effectively maintain a constant altitude and its orbit. For orbiting, the horizontal and vertical movements of the object or craft are constantly and instantaneously happening at the same time and rate, and the result is a smooth circular-like orbit or curved path of the craft or object about a central point such as the center of the Earth. For a simplified example to help comprehend all this, consider if the craft falls 1 foot due to gravity, and that the Earth's surface has curved downward by 1 foot during same amount of time, hence the orbit altitude is maintained a constant value.

The orbit mentioned above would be circular about the Earth's center point of gravity. If the craft or object does not have enough horizontal velocity for a specific altitude of orbit, the craft will not orbit the Earth indefinitely, but rater it will eventually be pulled downward in a normal or standard parabolic (ie., a quadratic or a squared variable equation, From: $g = 9.8 m/s^2$, $d=vt = (at)t = at^2 = gt^2$) motion by the force of gravity. If gravity was somehow stopped, an orbiting craft would no longer be pulled downward and be in its circular-like orbit, but it will continue in the direction that is tangent (ie., a tangent line, perpendicular, 90°) to that orbit and radius line to the center of the Earth.

To launch a spacecraft into orbit eventually requires a high, effective horizontal velocity so as to maintain orbit. Soon after a stationary rocket with the spacecraft (in and-or on it) is launched vertically, it will be steered to climb higher towards space at about a 45° angle with respect to the ground or horizon for much of the flight, and then later, to a lesser angle so as all of its remaining fuel energy is converted to mostly kinetic energy and velocity of the spacecraft in the horizontal direction (ie., parallel to Earth's surface), rather than the vertical or higher direction, and until the desired orbit altitude is reached.

The downward or vertical drop (downward distance) over (ie., below) the horizon (horizontal, level or straight line) of the Earth at its surface (ie., 4000 miles, the radius from the center of the Earth) is about 8 inches per mile. To orbit the Earth near its surface, a horizontally traveling object will need to likewise drop by the same value of 8 inches per mile. For higher altitudes of orbit, both the force of gravity and the curvature (ie., vertical drop per horizontal distance) of the Earth gets less from the center of Earth. At higher orbits, the gravitational acceleration caused by that amount of continually applied force of gravity is less. Here, in more distant or higher altitude orbit, the orbiting object will then fall (vertical drop distance) a lesser amount of distance per amount of time, perhaps just 1 inch per mile of travel in its orbit, and therefore, that object can and must actually go slower in the theoretical linear, horizontally direction so as to maintain its altitude of orbit. Below is an analysis of a circular orbit. [FIG 247]



For a stable orbit:

$$\frac{\text{change in Horizontal distance / time}}{\text{change in Vertical distance / time}} = 1 = \frac{dh}{dv}$$

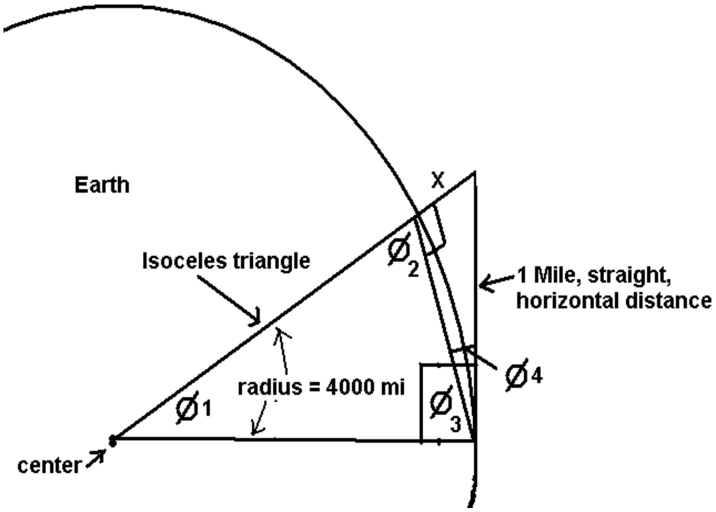
The amount of vertical drop per unit of time depends on the gravitational acceleration = (change in velocity / change in time) at that altitude.

From the above equation for a stable circular orbit: (change in horizontal distance) = (change in vertical distance)

At low Earth orbits, say less than 1000 miles, the gravitational acceleration due to the Earth is only slightly less than at ground level.

Another equation similar to that shown in the image above is:
(change in vertical distance / time) / (change or drop in the curvature of Earth directly below the horizontal / time) = 1

Here is a derivation of the 8 inches per mile drop in vertical height below a straight or level horizontal line located directly on the Earth's curved surface, and that the specific vertical drop from that line is due to the ideal (with no hills or valleys) amount of curvature (below Earth's level, straight horizon) of the Earth's surface at that radius (here, 4000mi from the center point of Earth). [FIG 248]



In the figure above which is not drawn to scale, but having exaggerated parts so as to view the concept better, (x) represents the distance of the drop below the straight horizon line. This vertical drop is due to the natural curve or curvature of the Earth away from and-or below the horizontal or tangent line. Though the Earth's surface appears to be flat on average to a person near the surface level, a true, level or horizontal distance of 1 mile away from any point, the Earth will have curved and-or dropped in elevation by 8 inches. In the above drawing, we will be solving for (x) which is equal to 8 inches.

The triangle construction shown on the left, within the Earth's circle, is an isosceles triangle with two equivalent sides equal to the radius (r) of the Earth, and two equivalent base angles of: ¢2 = ¢3. This inner isosceles triangle is also shown as part of a larger right-triangle construction where:

tan ¢1 = opp. / adj, = 1mi / 4000mi = 0.00025
¢1 = arctan (tan ¢1) = arctan (0.00025) = 0.014324°

Since the internal sum of angles of a triangle is 180°, for the isosceles triangle:

180° = 2 (¢2) + ¢1 , after solving for ¢2: ¢2 = ¢3 = 89.992838°

At the indicated larger right angle: 90° = ¢3 + ¢4 = 89.992838° + ¢4 , after solving for ¢4 , ¢4 = 0.007162°

At the smaller indicated right triangle: sin ¢4 = opp. / hyp. = x mi. / 1 mi mathematically:
x mi = sin ¢4 (1 mi.) = sin 0.007162 (1 mi) = 0.000125 mi

0.000125 mi = 7.92 inches ~= 8 inches = $0.66\underline{7}$ ft : only at earths surface, an altitude of 0ft, and a radius distance
= 20.32cm = 0.2032m of about 4000 miles from the center of Earth.

Extra: According to this 8 inch value, an observer looking along the horizon at ground level (and without any increase or decreases in the altitude of the object), the top of an object less than 8 inches in height at 1 mile away would not be visible. If the observer rose their eyes to 8 inches above the ground level, then that object would be fully visible.

A 12 inch = 1 ft. drop corresponds to 1.5 miles. At 10 miles distance, the drop from level is 6.67 feet.

If the spacecraft drops in altitude by (x) feet per second, and the Earth's curvature or surface directly below the spacecraft drops by (x) feet per second, it will be the same rate vertically, and without any difference in the rates, and the altitude of the orbiting object or spacecraft will effectively remain the same value.

The larger the distance or radius from the center, the greater the circumference, and for a given angle, the corresponding or subtending segment or arc of the circumference is longer but actually gets "flatter" (less of a curve) or more straight-like or more linear or line like. It could be said that the curvature at a farther radius value is less per degree, and therefore, there will be less effective drop below the horizontal line per mile at that radius or orbit distance, and the craft will not have to go as fast to effectively regain the altitude it lost due to gravity, and of which is actually less for farther radius orbits.

Extra: The **radius of the Earth** is about 4000 mi =~ 6537 km, and the **radius of the Moon** is about 1080mi =~ 1738 km. The ratio of the Moon's radius (Rm) to the Earth's radius (Re) is about: 4000mi / 1080mi =~ 3.7 Using the same calculation as above and using the Moons radius (Rm), the surface of the Moon will curve away, and horizontally below from a point or location at 2.4444 ft / mile =~ 29.3333 ft./mi. Hence nearly 2.5ft or about 30in per mile. The ratio of the surface declinations (D) per milie is about: 29.3333 in / 8in =~ 3.7 which is the same ratio as the radius values, but using (larger value / smaller value) or reverse ratio here, and this fact can also be used to simplify or estimate this value for say Mars. From this analysis, we find: Re / Rm = ~ 3.7 = Dm / De , and mathematically: Re De = Rm Dm

Due to that the force of gravity upon two objects or masses also depends on the distance between them, a higher altitude spacecraft will have less force of gravity constantly applied to it, and therefore, it will not accelerate as much downward or vertically, and the value of the gravitational acceleration at that orbit altitude will be less, such as shown here:

Note: Circular orbit distance or altitude from the center of the Earth = Radius of orbit = Ro =
Distance from the center to the Earth's surface (Ro) + The Altitude of orbit above the surface of the Earth (**Ae**)

Earth's radius , (Re) + **Ae** , (Altitude of orbit above the surface of Earth)
Ro = 4000mi + Ae : Ro = radius of orbit, from the center of orbit

Altitude (mi)	g (m/s^2)	Altitude (mi)	g (m/s^2)	: and Ro = Re + Altitude above Earth's Surface : Altitude (Ae) is the measured from Earth's surface
0	9.81	1000	6.25	: If: Ro=5000mi = 4000 mi , (radius) + 1000 mi , (Ae)
100	9.33	2000	4.33	
200	8.87	4000	2.426	: = 8000 mi = 4000 mi + 4000 mi, from (r) Earth's center.
300	8.47	8000	1.075	: = 12000 mi = 4000 mi + 8000 mi, from Earth's center
400	8.09	20000	0.268	: g = 26.8 cm/s^2 = 0.0268 m/s^2
500	7.73	25000	0.183	: r = 29000mi = 4000 mi + 25000 mi , g = 18.3 cm/s^2

Due to the inverse square law of forces, if the distance increases by a factor of (n), the result is a force value of: force / n^2. distance2 / distance1= n. At Ro = 4000 miles from the center of the Earth, g = 9.81m/s^2, and at twice this distance which is: Ro = 8000 miles from the center of the Earth which is 4000 miles above the ground level, n = Ro / Re = 8000mi/4000mi = 2, the value of (g) is: (g) = 9.81m/s^2 / n^2 = 9.81m/s^2 / 2^2 = 9.81m/s^2 /4 =~ 2.45 as shown in the table above. If the radius of orbit doubles, (g) decreases by 4 as expected for an inverse. square law.

(go) at a certain radius from the center of Earth = (g) at Earth's surface / ((orbit distance from center, mi) / 4000 mi)^2
go = (9.81m/s^2) / (Ro / Re)^2 : A formula for the gravitational acceleration at a given radius of orbit of Earth
go = (9.81m/s^2) / n^2 :n = ratio of actual orbit distance above Earth's surface to the center, to Earths radius
This is due to that the force of gravity is an inverse square law mathematically.

For an object to remain in a stable orbit, the force of gravity (Fg) upon an object (with mass = M2) must equal the centripetal force (Fc) upon that object. The inward or center-seeking force is called the **centripetal force** upon an object, and it can be thought of as being the equal and opposite force of the outward-force called the **centrifugal force** pushing the object away or outward from the center point. Centripetal force is due to the force of gravity. When these two forces (F = ma) are equal or "in balance" with no net difference, the object will not move closer to, or further away from the center of orbit, but will remain in a stable or constant (circular) orbit and altitude and-or distance. As noted previously, the force of gravity is less for higher orbits. If you were to attach a string to an object and move or "swing" it as if in an orbit about you, the inward (to and upon your hand) tension in the string keeping it from "flying off or away" due to centrifugal force, would be the centripetal force.

When: Fg = Fc : When the are equal: Fg - Fc = 0 : = no net difference = not net force

$$\frac{G\ M1\ M2}{r^2} = \frac{M2\ v^2}{r}$$

: G = universal gravitational constant, **M1 = mass of Earth** in kg
M2 = mass of orbiting object in kg, v = velocity of orbiting object in m/s^2 ,
r = radius of orbiting object from Earth's center, in meters
= radius of Earth + altitude of orbit
Re = 3959 mi = 6381 km =~4000 mi =~ 638000 meters
: If the forces are the same, the accelerations must be equal to (g) at that alt.
: F = ma = Fc = M v^2 / r , hence (a) = v^2 / r and (m/s)^2 / m = m / s^2
: v = sqrt [Fc (r) / M] = d / t = 2(pi)(r) / t = Ce / t

Solving for the velocity of this orbit in the previous, main equation:

$$vo = v = \sqrt{\frac{G\ \mathbf{M1}}{r}}$$

The av. Period (T) or time of each orbit can then be calculated as:

$$T = \frac{\text{Distance}}{\text{Speed}} = \frac{\text{Circumference or orbit length}}{\text{Average speed of the orbit}} \text{ , ex: } = \frac{2(pi)(Ro)}{v}$$

Other equations for centrifugal and centripetal force:

You may also wish to view the topic of **Orbital Motion Of Objects** given later in this book.

First: v = w r : (linear velocity) = (angular velocity) (radius) and (angular velocity) = (linear velocity) / (radius),
v^2 = w^2 r^2

Fcentrifugal = m a = **m w^2 r** and **Fcentripetal** = m a = **m v^2 / r** : such as for an natural orbiting object

From the above equations, we can equate: a = m^2 r = v^2 r , and from this and the a previous equation, we can find that:: v^2 / w^2 = r^2 and v / w = r and w = v / r

checking: a = v^2 / r = w^2 r^2 / r = w^2 r

The mass and-or weight of an orbiting object does not determine its needed or natural orbital velocity, however it does determine its kinetic energy and-or inertia (ie., resistance to changes in movement, hence a resistance to changing direction and-or speed, f=ma, a=f/m). All size of mass in an orbit at a certain altitude will fall towards the center of gravity (such as Earth's center), and at the same rate due to the same gravitational force at that altitude. Consider that objects of various mass and-or weight when dropped at the same height will reach the ground at the same time since the force due to gravity upon them is the same. Orbit velocity, and orbit altitude or height have an inverse type of mathematical relationship. The farther from the center of orbit, the lower (g) is and the lower the distance dropped (vertically) per degree of orbit and-or unit of time. Farther orbit distances of a mass have a larger orbital path (such as a circle, C=2(pi)(r)) to travel about the center of orbit, and therefore, it will take longer to orbit at a given speed, and especially at a lower speed. For a given angle about a center of orbit, such as the center of a circle, the (arc) distance traveled is directly related to the distance (r) from the center of orbit or reference, and it is also said that the "arc of curvature" (ie., or "departure from being straight") is inversely related to (r). For a very large circle or orbit, the "arc of curvature" is very low, and that orbit segment can appear to be practically a straight line with an imperceptible arc or curve about a central point, such as the center point of orbit. Note that arc of curvature is not the same concept as arc length which is a segment length of the circumference of a circle, and that this length depends on the angle and radius distance from the center.

In the equation above for orbital velocity , (G Me) is a constant = Ke, for Earth orbits, v = squareroot (Ke / r), and if (r) changes by a factor of (n), v = squareroot (Ke / nr) , and v will change by a factor of squareroot (1 / n). Ex. if n=2, the change in orbital velocity is squareroot (1/n = 1/2) =~ 0.707 =~ 70% of the first velocity.

The force due to gravity (g) at (r) is inversely related to (r). g2 = g1 / r^2

Obviously, it will take more energy and work to lift a larger mass to a larger height or altitude of its orbit:

Work = (force)(distance) = (ma)(distance) = (ma)(height) = (force)(altitude) = Joules of energy

It will also need enough momentum and-or kinetic energy (KE = mv^2 / 2) to maintain its ("free-fall" over the edge of the Earth) orbit, rather than just loose altitude due to gravity. Once an orbiting spacecraft has enough KE for orbit, it will also have enough velocity to maintain that orbit regardless of its mass, and without requiring more energy since the energy losses are very minimal, practically 0 while orbiting Earth. At low orbits, there is an increased chance of colliding with some gas atoms such as of air, and this is much like a very small friction force that will transfer a very small amount (ie., Joules) of the orbiting craft's kinetic energy to that air, and which causes the craft to loose a small amount of velocity and then orbit altitude, and if this keeps happening, eventually the craft will need to go back to its intended, higher orbit, and via a force or thrust, usually created by its on-board rocket engine(s).

The **International Space Station (ISS)**, as of the year 2021 has an altitude of about 250mi =~ 400km, and has an orbit velocity of about 4.76 mi/s = 7.66 km/s = (4.76 mi/s)(3600 s/h) = 17136 mi/h. Its velocity is often spoken as (roughly) 5 mi/s. (g) at this altitude is about 8.75 m/s^2 = 28.71 ft/s^2. It's orbit radius is about 4000mi + 236mi = 4236 mi, and the surface of the Earth drops below the imaginary horizon line (at this altitude and-or radius) at about 7.55in/mi, and this is a less rate than at the surface of the Earth as mentioned previously in this book, at about 8 in/mi. The arc of curvature is less at this radius distance, altitude and-or orbit. Its orbital period is about 1.5 hours which corresponds to 90 minutes. During 1 day = 24hrs, the number of orbits would be: (total time / time of each orbit) = 24hrs / (1.5 hrs / orbit) = 16 orbits. If each orbit is about: C=(2(pi)(r) = (6.28)(4200mi) = 26389mi, the total distance traveled per day is: (number of orbits per day)(distance per orbit) = (16 orbits / day)(26389 mi / orbit) = 422230 miles / day . Also, 422230 mi / day =
= 422230 mi / 24hr = 17593 mi / hr = 17593mi / 3600s = 4.887 mi / s = (distance / time) = v = velocity of the ISS orbit. The ISS has an orbit inclination of about 51.6 degree with respect to the equator. With this angle, much of the Earths surface will eventually be directly below it. The gravitational acceleration (ge) value in a low Earth (altitude) orbit, is slightly less than that at sea level of (9.81m/s^2), however since both the spacecraft, people and objects in it are falling at the same rate relative to each other, it then appears as if everything is weightless, non-moving, and unaffected by the actual force of gravity upon them. Skydivers jumping out of a plane, and before deploying or opening their parachute to slow down and land safely can also experience this weightlessness effect, except that the drag or friction forces due to the air on larger objects is greater and this effect is not a great as that in space.

Even when a spacecraft is in a low orbit about the Earth, which is called a "Low Earth Orbit (LEO)", for it to go to a high orbit, or even to the altitude of the Moon, it must still overcome the gravity of the Earth, and much energy will be needed. This energy is most often in the rocket fuel which will be combusted by the rocket engine so as to produce the propulsion or thrust force. Some special elliptical orbits about Earth, and also using "flyby gravity assist" of the Earth so as to increase the kinetic energy of the spacecraft can also be used to save fuel, but the time to reach the Moon would then take a longer distance and time.

If a spacecraft does not maintain its required orbit velocity, it will not maintain its current orbit. If the spacecraft slows down, perhaps by using a rocket engine to provide a force in the opposite direction to its forward travel, it will then not have enough (outward) centrifugal force (Fc) to balance (ie., 0 net force, 0 difference) the gravitational force Fg upon it and pulling it inward towards Earth. Fg will then be greater than Fc. The altitude of the spacecraft will decrease, and it will usually have some remaining horizontal velocity if it was not completely slowed down in horizontal motion to 0 mi/s. The spacecraft will then also have a downward vertical component to its motion and it will accelerate toward the Earth due to the net **e**ffective downward force (F**e**) of gravity (Fg) now acting upon it **:** (F**e** = Fg - Fc).
In order for the spacecraft to slow down and make a relatively soft landing at say 0mph, all of the high kinetic energy of its orbital kinetic energy must be expelled or removed, and much of this energy will be lost as friction (resistance to movement, and converted to heat) and-or pressure with Earths (air) atmosphere, all due to the high speed of the reentry flight. Some kinetic energy (particularly the velocity factor) will also be lost with a parachute's upward drag force or resistance with the air. Some spacecraft even have a rocket motor or engine to reduce its downward motion and kinetic energy during landing, and some spacecraft may deploy a type of "air bag" (ie., a type of strong material, inflated balloon) at the bottom area of the spacecraft so as to help it make a softer landing. A spacecraft could reside and travel in a lower orbit if it can be made to have the natural orbit condition of Fc = Fg, and at a lower orbit, the velocity needed for a given mass will be higher since the force of gravity (Fg) is higher at lower altitudes. A higher velocity means a higher Fc.

Since a high velocity spacecraft has a high amount of both kinetic and gravitational potential energy, the spacecraft needs a high temperature thermal shield due to the high temperatures created by friction with the air upon reentry and-or landing on Earth. This shield protects both the astronauts and spacecraft. When it lands, all of the energy (KE and GPE) it had in orbit will have mostly dissipated as heat, and reduced to 0 joules.

The longer that astronauts are in space, they will usually develop some slowly worsening health problems while there. On-board larger spacecraft such as a space station, there is often various exercise machines and-or routines. Due to the effect of feeling no gravity and some atrophy of muscles and bone mass, they can also develop problems such as standing and walking for awhile after they return back to Earth and its apparently (to the astronauts) much stronger force of gravity force. Over the next days and weeks, they will need to exercise slowly so as to develop a typical amount strength.

The famous author **Jules Verne** (1828-1905), from France, was probably fascinated by the more modern telescope views of the Moon, advances in technology, and considered Newton's theory of orbiting in about 1865 while writing his book called 'From Earth To The Moon', and then afterwards, writing another book called 'Around The Moon' in 1870. In 1902, before the first practical airplane was invented, and inspired by Verne, the first science fiction and outer-space type movie called 'A Trip To The Moon' was created in 1902 by **Georges Melies** (1861-1938). Melies also created several new technical, film processing (ie., editing, "special effects" such as appearing and disappearing things, etc.) and-or filming (ie., movie making) and movie concepts for the motion picture industry. Melies also made the movie called 'The Impossible Voyage'. These books and movies surely helped inspire the imaginations and creativity of people, and the future of science and flight. Shown in the movie, the passengers entered a large projectile and were launched out from within a large cannon (a propulsion and aiming tube for the projectile). This idea was most likely based on Verne's books which seems to consider the previously known (Isaac) "Newton's Cannon (or projectile)" theory about how to orbit the Earth. While returning from the Moon in the year 1969, Neil Armstrong (the first person on the Moon) mentioned Jules Verne. Verne's book had essentially and reasonably predicted some similar details of the actual ventures to outer space and the Moon. Verne also wrote many other highly popular science-fiction books, some of which were later made into popular movies such as: 'Around The World In Eighty Days', 'Journey To The Center Of The Earth' and 'Twenty-Thousand Leagues Under The Sea'. A contemporary to Vern was **Herbert George (H.G.) Wells** (1866-1946) who wrote books such as: 'The Time Machine' in 1895, 'The War Of The Worlds' in 1898, and 'The First Men In The Moon' in 1901. These writers took actual, known scientific explorations, discoveries and facts, and mixed them with their own "vision" (ideas about the future), imagination, dreams and fantasy into a "mixed literature" called science fiction (fictitious , meaning probably "fake", "made-up", "exaggerated" and often with some facts being real or true so as to make a known and believable connection with reality), and of which can even inspire real science, invention and research in an increasing, circular-like growing or continuous manner. Some of the earliest and significant science-fiction, outer-space adventure type of movie series were: Buck Rogers (literature by 1929, movies by 1930, TV by 1950), and Flash Gordon (literature by 1934, movies by 1936, TV by 1954). Some other popular, and relatively modern science fiction writers are: **Arthur C. Clarke**, **Isaac Asimov,** and **Robert A. Heinlein**. Arthur C Clarke who wrote books such as '2001 A Space Odyssey', was also an early visionary of man-made satellites for (re-transmission) relaying communications on Earth. **Robert A. Heinlein**, was a writer and visionary who included many science facts and social ideas in his science fiction writings. **Isaac Asimov**, a writer and visionary that promoted the concept that robots should only be made to help humanity. In late 1958, the military launched a large area communication satellite which was mainly for proof of the concept, and other experiments. About three years later, **Telstar-1** was the first public communication satellite, and it was launched on July 10, 1962, and which soon inspired a popular instrumental song called Telstar in late 1962. Telstar was placed in a relatively close to Earth, elliptical orbit, and therefore had to be tracked (ie., moved to aimed at) more by receiving antennas here on Earth, unlike some of the more modern communication satellites placed into a very high altitude, **geostationary orbit** (ie., has the same rotational or angular velocity as Earth's axial rotation) about Earth. The Telstar mission demonstrated that its technology was practical for public communications such as relaying some distant (wireless) TV (electronic TeleVision) and telephone (electrically transmitted) audio signals.

A modern large and heavy rocket can enter a high velocity (about 17100 mph =~ 4.75miles/s after starting out at 0 mph and then gaining more and more velocity when the rocket engines are providing force), low altitude (about 255 miles high, such as for the ISS - International Space Station) or low Earth orbit (LEO) in about 8 minutes to 9 minutes of time - hence an average of 8.5 minutes = (8.5min)(60s/min) = 520 seconds. It is sometimes mentioned how many seconds of rocket fuel and-or the resulting thrust (ie., forward force) was needed or used, and it can be about 9 minutes maximum = (9min)(60s/min) = 540 seconds (maximum). Once this fuel source reduces to 0, and-or is shut off from reaching the engine, the thrust force created and applied to the rocket will be 0, and the rocket will no longer accelerate and gain speed (ie., velocity). Note that for a rocket to orbit the Earth, it must enter orbit at parallel (ie., a 0° angle, level, horizontal) to the Earth's surface, and for much of the trip to space, the rocket travels at an average angle of about say 45° relative to the ground reference plane (ie., horizon). In a way, this is much like using a ramp or inclined plane so as less force is needed when the change in height or altitude is less per unit of time, but it will then take more time to reach the intended altitude. With a given thrust or force value, the rocket will gain more and more velocity as expected due to a constantly applied force creating the acceleration (ie. gain in speed, due to more energy being additive to the rocket) of its movement, but there is also an increase in acceleration (a = ch v / ch t) due to the very lower density, "thin" high atmosphere, and which effectively applies a lower friction, resistance or drag force in the opposite direction of the thrust and-or flight. As the amount of heavy rocket fuel and its corresponding mass and weight is significantly reduced, the thrust from the engines will apply its force to a smaller rocket mass. From F = thrust = ma, we get: a = F / m , and if the total mass (here of the rocket) decreases for a given or constant force (F) from the rocket engines, the acceleration of movement and-or velocity of the rocket increases.

If the velocity of an orbiting object increases, such as due to a temporary uses of its rocket engine(s), its orbit will then become an elliptical (like an egg or squashed circle) shaped orbit. If the velocity of the object increases too much and is greater than or equal to the "**escape velocity**" (the minimal velocity to escape from the attractive force of the local gravity and-or to leave orbit), it will break free from its natural gravity force held orbit and travel away from the Earth mass it was orbiting, and this is necessary to happen for the object to travel to the Moon or planet and possibly orbit and-or land there. The minimal velocity for this to happen is called the (gravitational field) escape velocity. The escape velocity for Earth is about 25000 miles per hour for low Earth orbits. The force of gravity, or gravitational attraction and acceleration, decreases the farther from the center of mass. Near the surface of Earth, the constant gravitational (g) force and acceleration rate of the Earth's mass is about 32 feet per 1s^2 = 9.81m/s^2 = "one G". At a higher altitude or orbit, the force of gravity is less and therefore, less orbital velocity is needed since the downward pull toward the Earth is less and objects will fall less distance in a given amount of time. Note that there is still significant (about 0.9g) gravity upon low orbiting (<1000 miles high) craft such as the ISS (International Space Station), however it only appears as 0 amount of force or a negligible (micro gravity) force due to the "free fall" effect. If this craft, people and things in it are falling at the same speed together and their relative velocity to each other is 0, and then things (mass) will generally appear as being not moving or falling, but rather appear as "weightless" or still (ie. not moving vertically) in motion. If a spacecraft slows down with force created in its rocket thrusters to reduce its forward motion or momentum, or encounters friction ("drag") due to the object or craft essentially colliding at high speed into some of Earths atmosphere (air) atoms, it will reduce its altitude and come out, or "fall out", of orbit and return to Earth since its horizontal speed is no longer enough to effectively regain (due to the downward curvature of the Earth) the loss in altitude and overcome the corresponding (gravitational, gravity) drop in vertical height per unit of time as it orbits the Earth.

If an object, such as a communication satellite is orbiting at the same angular velocity or rotational speed as that of the rotation of the Earth which is 360° per day = 15° per hour, it is said to be in a **geostationary orbit** when it is always orbiting above the equator plane of the Earth. The object will appear (if it was large enough to be seen) up in the sky as being steady or still, and it will always be positioned directly overhead at one point on Earth's surface, and-or at the same angle and direction in the sky as seen from other locations. This is ideal for satellite communication since the communication antennas can remain fixed and does not have to constantly track (follow) the satellite so as to move the communication antenna so as to keep aiming the antenna for the best or strongest communication signal. A fairly common example of this in many countries as of the year 2025 is for fixed in position and aiming, circular-like, parabolic satellite TV antennas-receivers seen on rooftops of homes and buildings. A **geosynchronous orbit** (ie., synchronized or "in sync" with Earth's rotation on its axis), perhaps at an angle relative to the equator line, is any orbit having the same angular velocity as that of Earth's axial rotation, and if it is at an angle with respect to the equator line, it will not then not actually be stationary above a constant location or point on the Earth's surface, and it will always appear as moving.

For a, and like any other stable orbit, and the centrifugal force upon the object equals the gravitational force upon the object. A geostationary orbit needs to be a circular, and not an elliptical orbit. A point, object or person on the circumference (about 25000 miles around) or surface of the Earth at the equator will go about the center point of Earth at an angular or rotational velocity of 15°/1h, and-or a corresponding linear velocity of (circumference / time) =
25000 miles / 24 hours = about 1042 miles per hour = 0.289352 miles per second = 1528 feet / second. As the latitude on Earth increases, this velocity will decreases. Technically, the Earth rotates once on its axis during a "solar day" or "**sidereal day**" which is almost 24h, and is actually 23h, 56m, 4s of time length. A natural geosynchronous orbit of 15°/1h angular or rotational speed about Earth is usually located at about 22236 miles = 35785 km above Earth's surface (or about 26236 mi =~ 43333 km from Earth's center, and of orbit) at the equator due to Earth's mass and gravity there, and the velocity to maintain it is about 1.86 miles per second which is much lower than that of low orbiting spacecrafts that are just a few hundred miles in altitude above Earth's surface. Since the Moon orbits the Earth, the Moon is actually in a "free fall" orbit about Earth due to the gravitational attraction between the Moon and the Earth, and it orbits the Earth about every 27.32 days. Note that due to Earths axial rotation and the Moons rotation about the Earth, it takes a longer time at about 29.5 days for each same phase (ex. full or new moon) of the Moon to be seen by a person at the same location on Earth. A helpful equivalent fraction: (Ce=25000 mi) / 360° = x mi / 15° , x mi =~ 1042 Here is an equation derived in

this book for the **average velocity of an orbit : vo = squareroot [(g at that radius distance) (radius of orbit)]** , and this value is about 1.91 miles / second =~ 6865 mi / hour for the geosynchronous orbit altitude mentioned. Notice that mass of the object is not used in the formula. The specific high altitude distance of the geosynchronous orbit is chosen so that the spacecraft or satellite will orbit the Earth at 15° per hour, hence 360°, and only once (1) per day = 24h unlike low orbit craft orbiting many times (about 16) per day at the required high orbit velocity. Each circular orbit has its own unique radius (r), a unique corresponding velocity, and therefore, it also has a unique corresponding time period (P) of orbit. As (r) increases, v and P decrease. There is only one circular orbit about Earth that has a natural period of 24 hours. At high altitude or radius orbits, the satellite can communicate to a very large area on Earth, and where any possible adjustments to its orbit will not require much distance, energy and time to correct.

A company recently created (about 2021) by **Elon Musk** (born 1971, in Africa) has currently manufactured a (stationary and-or portable) satellite transceiver system called **Starlink** which is for relaying and-or improving communication services such as for the popular Internet (electronic, digital data composed of "1's and 0's") communication system for undeveloped, difficult and-or distant regions on Earth. Though each Starlink satellite launched for this system is relatively expensive, the users transceiver system is relatively inexpensive and has a relatively low monthly fee for the many subscribers or users of which will eventually add up to pay for the system. He has helped employ many people, and with his earnings from other businesses, he has branched off into the exciting field of space and rocketry of which also employs many people, and so as to help benefit all the people of Earth in some way, either now or in the future. As of the year 2025, Musk is still creating more efficient and powerful rocket engines, and launching spacecraft with people into space, and many small communication satellites into a relatively low altitude orbit about Earth on his SpaceX company rockets. He is currently associated with several other popular companies such as Nasa, Paypal (for digital payments using the Internet communication system), Ebay (a popular selling store website on the Internet), the Boring Company (for tunnels), Tesla (for electric automobiles, and power storage systems such as electric batteries). In 2025, Musk began working as the director of a new U.S. Government agency created by President Donald J. Trump in the year 2025, and it is called DOGE (Department Of Government Efficiency).

Many of today's rockets to space use various types and combinations of solid and-or liquid fuels such as gasoline, nitrogen oxide, methane, liquid hydrogen and liquid oxygen. On March 16, 1926, the first successful liquid fueled rocket launch was made by **Dr. Robert Goddard,** (1882-1945) from the state of Massachusetts in America, and who was a scientist and teacher, and who theorized about rocket construction and space flight. His liquid rocket concepts began in about 1909, and his rocket fuel was gasoline and liquid oxygen that was then mixed together in the rocket engine during launch. Later, he would launch his rockets at a more practical and larger test range (ie., a large unused land area) site at Roswell, New Mexico. The best rockets he made did not go very high (about 2 miles high), but it was still enough to prove they had potential abilities such as high-altitude research, and perhaps, for space research. Using liquid fuel allows the fuel flow to be controlled with pumps and valves, whereas it is much more difficult to do this practically with a solid rocket fuel. Rocket engines need to produce a controlled ("controlled explosion") combustion of just some of the total amount of rocket fuel, and so as to produce a practical (non excessive) force in just the (forward, travel) direction of the rocket body or mass. Goddard is credited to the first modern methods of steering (guiding, guidance, aiming control, stability such as with gyroscopes) rockets, and creating the modernized concept of using multi-stage rockets that are essentially a rocket attached to the top of a another rocket. A heavy stage can be discarded once its internal fuel is used up, and this will significantly improve the thrust and efficiency of the remaining rocket engines since they rocket weight will be less. Goddard utilized the previously known concepts of liquid cooling, and made the first practical method to cool the rocket bell, nozzle or exhaust cone from being disintegrated by the very hot, high kinetic energy exhaust gas particles after being combusted. First he used water, and later he used the much colder rocket fuel being circulated in its nozzle structure before being used to create combustion and thrust force in the rocket engines. As a youth, and even before plane flying was proven to be practical in 1904, Goddard was highly interested in all forms of flight such as with birds, kites, and hot-air balloons. In 1908 Goddard thought that cameras could be sent to and back from the orbit of other planets. Goddard, in 1912, was also one of the first pioneers in vacuum tube construction and its uses at about the same time as its first certified original inventor - **Lee DeForest.** Goddard's rocket studies and discoveries would eventually lead to the development of rocket-engine powered airplanes ("jets"), jet airplanes with liquid fuel, and then rockets to outer-space. For a historical note, "**blackpowde**r" is a solid, granule fuel developed for small rockets and-or various projectiles and some machines was invented in **China** in the early 10th century AD, and today, it is used in some permit only (due to the potential dangers of fire and-or injury) "fireworks" which are colorful, decorative light and sound displays launched up into the sky during a celebration of a festive occasion(s).

The first hot gas, and here, particularly a primitive steam engine that could produce (here rotating) motion via the force and-or pressure of the hot (water steam) gas is credited to **Hero of Alexandria** in the first century AD. His (steam) engine is commonly known as the **aeolipile** which can be translated to English as "wind ball", "wind sphere", "wind spinner", and possibly a "wind engine". This engine eventually would eventually lead to things such as steam trains for transportation on rails (ie., metal rail roads), and turbines (ie., mechanical energy transfer blades, or energy transducers) for electricity generation. Rocketry is also a creative hobby, and some people joyfully build the available kits for purchase and launch them in relatively safe, open (no nearby man-made structures and-or dry flammable grasses) and permitted locations. Some of the rocket contemporaries to Goddard are **Hermann Oberth** (1894-1989) of Hungaria-Germany, and who liked the Jules Verne books, and he later wrote some of his own books about spaceflight and rocketry, **Konstantin Tsiolkovsky** (1857-1935) of Russia, and **Robert Pelterie** (1881-1957) of France were also pioneers of both theoretical rocketry and space flight which helped to motivate people and science in various ways. Oberth was also involved with the first (solid fuel) rocket plane tests in 1929, and was a mentor (ie., a teacher) to **Werhner Von Braun** (1912-1977), (aka, ["Verner"] "Von Brown" as an English language derivative or interpretation) of Germany. Braun and some other members of his rocket team became prisoners of the Americans (USA) and Russians (the Soviet Union at that time) in WW2 (1939-1945), and some of their rocket knowledge would become usable and cost saving for their space programs such as those of **NASA** (National Aeronautics and Space Administration, of the USA) who would create the large rocketry and spacecraft industry to take mankind to the Moon. Since his youth, Von Braun was a joyful and artistic visionary of the future of spaceflight, space research and exploration so as to benefit humanity. He was probably inspired by Jules Verne, Goddard, and the amazing leaps and exponential growth in science and technology of those times he was living in and so as to benefit humanity. With having some rocketry knowledge, he was like many young men, drafted (ie., ordered) into the military service for his country, and for him, so as to create new large, powerful and accurate rockets - some of whose infrastructure and manufacture were performed by "work details" that were assignments given to some Jewish civilian prisoners (many even Germany born citizens) during World War 2 (WW2, 1939-1945 Europe, 1942-1945 USA), and of which some were also scientists, etc. A few years before the war ended in May 1945 in Europe, and in August 1945 in Japan, some of the parts of these used rockets were eventually found in England, Germany, and France, and were then studied by scientists. A lesson learned from WW2 is that old tribal ways of ancient mankind may resurect themselves from time to time and that blame rather rests on humantiy itself, and that it needs to be aware of these possibilities so as to prevent them. Various cultures of humanity offer a healthy variety of sorts, often dictated by climate and local conditions, resources and infrasturcture, and they should be acknowledged, embraced and helped if need be.

The first practical **jet engine** for (jet) airplane, high speed propulsion is credited to **Frank Whittle** (1907-1996), from England, in 1930, and the planes with jet engines would eventually be simply called as "jets". The basic concept of a jet engine is to use a highly combustible fuel mixed with compressed (ie., high density) air so as to created a high combustion, semi-explosion of hot gasses having high kinetic energy which then produces the resulting forward or thrust force upon the plane. In 1941 Frank hoped his recently built jet plane would be able to shorten WW2, and meanwhile, the Germans were already testing and using a recently built (solid fuel, not liquid) rocket engine (and not a jet engine) plane. One rocket plane was briefly tested in 1929 with **Fritz Opel** as the pilot, and it had a modern-like design based on the primitive rocket car and rocket plane flights by others. Opel also tested a liquid fueled rocket plane in 1929. Another significant pioneer in Germany's and Austria's early, pre-war rocket programs was **Max Valier** (1895-1930), from Austria, and who was one of the founders of the Society For Space Travel in 1927, and of which Wernher Von Braun would join. **Pedro Paulet** (1874-1945) from Peru tinkered with rocket fireworks and conceived of, and possibly built an unverified, primitive liquid rocket engine in the late 1890's. He then also conceived of a rocket plane as early as 1902, but it was never built, and that any practical, self-powered airplane flight of any type had not even been achieved yet. In August 1941 the American **JPL** (**J**et **P**ropulsion **L**aboratory) were first to use small solid fuel rockets attached to the airplane so as to assist and shorten the take off length needed, and this is termed as **JATO** or "(rocket) Jet Assisted Take Off" **John Whiteside Parsons (aka, Jack Parsons),** (1914-1952), from America, was the leading chemist and a founding member, along with a few others, such as **Frank Malina**, of JPL, and then later with the **AeroJet Co**. Parsons invented a formula mixture so as to make solid rocket fuel much more stable for storage, safer when working with, more powerful and reliable. By early 1942 liquid fueled rockets were also being tested and used for JATO. One of the early members of JPL was **Qian Xuesen** (**Tsien Hsue-shen** is an Englishized spelling and pronunciation), (1911-2009) who was a visiting Chinese professor in America, and who would be one of the founding members of JPL and so as make some helpful calculations. He was eventually given a US military rank of (honorary/temporary) Colonel in WW2 so as to help deal with the seized German rocketry tech, and after returning to China many years later in 1955, he became the founder of the Chinese rocketry and space program. It is of note that the USA and its Allies of WW2, greatly helped both Russia and China in WW2, and that both Japan and Germany were eventually allowed to govern their own countries again after being occupied and guided for several years.

By early 1942, the Americans began testing a liquid fueled (rocket) jet plane engine that used Whittle's jet engine design. By 1944, the still fairly secretive jet plane became a commonly known reality and future hope of human flight. In general, jet planes can obtain higher speeds than that of propeller driven airplanes, but then are less fuel efficient at lower altitudes where the air is denser. The first passenger jet plane built specifically for public or civilian transportation, and called today as "airliners", was ready for service by 1952 in England, and it was called the **Havilland Comet 1**, and it could carry a maximum of 44 passengers in reasonable comfort. This plane included the required internal air pressurization needed for high altitude flights, and which is a more fuel efficient flight. This plane could fly at a maximum altitude of about 40000 feet, hence well above the highest mountain - Mt. Everest. Its maximum speed was about 460 miles per hour. The first propeller driven, civilian passenger planes came at about 1936, such as the **DC3** in the USA, and there are some modernized DC3's still flying as of the year 2025. **Rocket engines** are much like a jet engine, however, rockets carry their own oxygen - usually liquid oxygen which is also then of a high density needed for high fuel combustion and the resulting high amount of forward thrust force.

On **October 4, 1957**, Russian scientists used a rocket to launched the first Earth orbiting man-made satellite called **Sputnik-1**, which in an English language translation, and which means "path maker", "space traveler" or simply: "Satellite 1", and this remained in orbit and transmitted routine radio pulses on about the 20Mhz and 40Mhz radio frequencies for 3 months before reentering Earth's atmosphere and burning up (melting to vapor) and-or breaking apart due to its high speed and the high amount of air friction and the corresponding heat energy created. This historic satellite mission also finally proved the basic concepts of orbit that were first scientifically proposed or theorized by Isaac Newton (ie., in "Newton's Cannon", thought experiment) many years previously. In just a few months after the successful launch of Sputnik-1, the United States successfully launched a satellite called **Explorer-1** into orbit about Earth on January 31, 1958. The rocket used was a military rocket converted for the benefit of mankind, and was launched from Cape Canaveral in the state of Florida. Soon afterwards during the same year, **NASA** (the **N**ational **A**eronautics and **S**pace **A**dministration) was formed so as to manage all things related to space for the United Space and some of its partners.

In just three and a half years later after the success of the Sputnik-1 satellite, the first man to be sent to outer-space and orbit (just once) the Earth is (astronaut/cosmonaut) **Yuri Gagarin (1934-1968)** from Russia on **April 12, 1961.** This flight quickly verified many aspects of human spaceflight, and Yuri became an instant global celebrity. **Gherman Titov** was the next person sent to space and was also from Russia. He was launched just a few months after Gagarin, and on August 6, 1961, and was the first person to have several orbits (17) of the Earth, and was first to do many common human and scientific research activities in space. At about 90 minutes per each of Titov's orbits: about (17 orbits)(90 min / orbit) = 1530 min = 25.5 hours = 1 day and 1.5 hours, and therefore, he was the first person to orbit the Earth for over a day. About a month after Yuri Gagarin's venture, and on May 5, 1961, **Alan Shepard** (1923-1998), from the United States of America (USA), was the first American astronaut to go above the altitude considered as the start of space, and his (non-orbital) flight lasted for 15 minutes, and at a maximum altitude of 116 miles, and he walked on the Moon ten years later in 1971 during the Apollo-14 mission.

In less than two months after the success of Sputnik-1, the President (the highest position for an elected leader) of the USA, **John F. Kennedy**, formally began the Apollo Moon program on May 25,1961, and so as to land a human on the Moon by 1970. This was a dream for many years since ancient times and the more modern times of Isaac Newton's scientific discoveries and theories. Modern (late 1960's) technology finally made it a possibility to begin to try it, but much work in rocketry, space travel, communication and many other things still needed to be created, improved and tested first. Each lesson learned would help all future rocket and space missions, and often, even help the general society so as to have a better life due to advancements in science and technology. Many of the achievements during this program would essentially pay for themselves many times over by helping the people of Earth. A good example is with weather forecasting satellites and their photographic imagery. A single advancement in technology often leads to an exponential growth in other technology.

On February 20, 1962 **John Glenn** became the first American to orbit the Earth. He later became a member of the U.S. Congress, and at 77 years old, and he flew aboard the Space Shuttle spacecraft in 1998 which orbited the Earth for several days. The famous actor **William Shatner** (b.1931), from Canada, who was an actor in the celebrated science-fictional, cherished outer-space movies made for TV broadcast starting in the year 1966, and it is known as the Star Trek movies, and he flew to a 66 mile high region of outer-space for a few minutes during a non-orbiting (sometimes called "sub-orbital"), 10 minute rocket flight on October 13, 2021, and when he was 90 years old. He was in the rocket capsule with three other people, and he had then become the oldest known astronaut in the world. The rocket was made by a rocketry and space company called **Blue Origin** and which was founded by **Jeff Bezos** (b. 1964), from USA, and he himself even flew on his own rocket upward to the border of space. Bezos founded the popular **Amazon Company** which is a popular "online" (ie., internet, "web", electronic media, communication) shopping website.

On June 16, 1963, **Valentina Tereshkova** (b. 1937) from Russia (aka, the Soviet Union, previously) became the first female astronaut. The spacecraft she was in made an incredible 48 orbits of the Earth.

Since airplanes require a difference in air pressure (or force) to cause a lift force, airplanes can not then fly in the vacuum of space above Earth's atmosphere which has no appreciable amount of air for wing surface pressure differences and the resulting lift force to be created. Different methods of propulsion and steering (aiming, direction) such as from rocket engines are needed in space. An advantage of space travel is that once a craft is in motion, such as in orbit around the Earth, and with little or no air resistance or drag force to reduce its forward velocity, it will keep moving without any extra rocket fuel or energy needed to keep it moving at the same orbit speed.

Speeds of several miles per second are common for spacecraft such as for the **Apollo-11** craft moving at about 7 miles per second on its way to the first manned Moon landing on July 20, 1969, and this is considerably more than the 0.64 miles per second that the Moon orbits about the Earth. **Neil Armstrong** and **Edwin ("Buzz") Aldrin** were in the Moon landing craft called "Eagle", and **Michael Collins** was the pilot in the Moon travel to, orbiting and return to Earth spacecraft called "Columbia" (Command Module for the mission) . Each astronaut mentioned was born in 1930; the same year planet Pluto was discovered using two telescope photographs of the stars, and with each photograph made at different time and then comparing both for any visible changes and-or movement. The launch of Apollo-11 to the Moon was on July 16, 1969, at 9:32AM, Eastern U.S. time, from Florida state, and returned to Earth eight days later on July 24, 1969 in the Pacific ocean. The Apollo-11 moon spacecraft ("Eagle") landed in the Moon's Sea Of Tranquility ("a mare" [marine, sea], a relatively flat, dark basalt (ie., a hardened lava stone) region) on the Moon at 4:17 Eastern U.S. time. The astronauts collected rock samples and walked on the Moon's surface for about 2 hours during their 20 hour stay there before firing its launch engine so that their landing craft could go back up to the orbit of the Columbia craft, and then dock (ie., attach, connect, join to) to it and return back to Earth.

Shortly before the Apollo-11 mission, and just 64 years after the Wright brothers first airplane flight in 1904, and 11 years after the first orbit of Earth with Sputnik-1, and 281 years after Newton's 1687 orbital theory, the **Apollo-8** mission craft was the first manned craft to arrive at and orbit the Moon on December 24, 1968 and three days after launching from Florida state of the United States. For the spacecraft to be fully "captured" by the Moon's gravity and to then orbit it, the spacecraft had to use its rocket motor in a reverse direction so as to slow its forward velocity to just that needed to orbit it at about 70 miles high in altitude from it. Some of the initial verses from the historic book of Genesis from the Old Testament Bible book were read and broadcast to the people of the world on December 24, 1968 by the astronauts in their spacecraft. This first manned mission to the Moon was profoundly important for all the later missions. Their craft didn't land on the Moon, but it was needed for proof of concept, telemetry (remote or distant sensing and-or measuring), communication, photographs, and many other initial tests, modifications and improvements needed before the future landing missions to the Moon. This mission could be thought of as mankind's rehearsal for the Moon landing. The world celebrated vanguard (first, leading) crew was **Frank Borman, Jim Lovell, and Bill Anders**. Their mission included lunar photography images so as to find some practical landing locations for the future landing missions. They orbited the Moon for a total of 10 times during nearly a day of Earth time. All of the Apollo missions that went to the vicinity of the Moon would eventually land relatively softly in water (aka, a "splashed-down" landing) in the Pacific Ocean, and usually near various retrieval ships having cranes and helicopters. Several minutes before landing, the spacecraft is caused to reenter the Earth's atmosphere at a calculated angle (set for enough time and atmosphere distance to safely slow down in velocity via atmosphere (ie., air) friction, and to also not to skip off the Earth's atmosphere and back into space), and so to reduce its kinetic energy and slow the spacecraft down from about 5 miles per second in outer-space to about 20 miles per hour (= 3600 s) or less at landing.

In March of 1969, the **Apollo-9** mission tested the lunar landing craft and the spacesuits for the manned Moon walks while in orbit about the Earth. In May of 1969, **Apollo-10** was a similar mission, but it also tested the lunar (Moon) lander at a height of only about 10 miles from the lunar surface. Through several years of time and Moon landings until the last Apollo space program Moon landing on December 19, 1972, a total of 6 craft and 12 people landed and walked on the Moon's surface from the Apollo-11 mission and up to Apollo-17 mission. Many scientific instruments such as a (Earth based) laser-light retro-reflector (ie.,essentially a efficient mirror), a SiesMonitor (a vibration sensor, Moon-quake sensor) were placed on the Moon's surface for studies to be performed when needed - such as to actually measure and calculate the distance to the Moon. Rocks and dirt were collected during all of the 6 manned landings, and this material was brought back to Earth to be studied until this day, and by more modern and advanced instruments and analysis concepts. These missions were made possible by the accumulation of knowledge, technology and talents of many people since ancient times to these modern times (2025), and as a recognition and goodwill gesture for the people of the Earth, a piece of Moon rock that was brought back from the Moon was honorably given to each country of the Earth at the time (135 total countries), and to each U.S. state (50) and partner territory. A few meteorites found on Earth have since been verified as being from Moon's surface, and most likely due to impacts from large and-or fast asteroids collisions then sending some surface debris away the Moon and into space. In general, it is illegal for people to own, purchase or sell any Moon rocks or part of that was brought back from the Apollo missions. A sample of Moon rock can actually be felt by tourists at the Johnson Space Center in the U.S. state of Texas, and at the Kennedy Space center in the U.S. state of Florida.

Outer-space has no pressure (0 psi) since it is a vacuum and generally void (empty) of any gasses (such as air) or fluids to induce or apply any constant, physical force and-or pressure upon an astronaut or spacecraft. The air pressure used within the astronauts spacesuits as they walked on the Moon during an EVA's (Exra-, or External Vehicle Activities) was a relatively low value at about 4.9 psi so as to reduce the total amount of force necessary to move the arms, legs and fingers inside a relatively thick and "pressure stiffened" (like the surface of a balloon constantly pushing [ie., a force] outward and trying to retain its shape) spacesuit. The required amount of oxygen needed for them to breath properly was supplied from (cold, condensed) liquid oxygen tanks in the spacesuit's backpack structure, and their exhaled carbon-dioxide gas was removed from the inside of their helmet (solid head covering) area. A spacesuit is also a temperature insulated and temperature controlled environment to sustain life, and also has radio communication installed in it. With a lower pressure in the spacesuit, astronauts must also avoid any decompression problems when they enter a region of different pressure such when they go back into their pressurized spacecraft (LEM, Lunar Excursion Module, the Moon landing craft). An air-lock is a small room that an astronaut can go into and close so as to be slowly adjusted to a desired air pressure such as perhaps 4.9psi, or the 14.7psi standard air pressure [STP]). If pressure changes happen too fast, dangerous forces, damage and health problems can result. Within the living quarters of the Apollo lander spacecraft, the pressure was maintained at about 5 psi, and which is a low value, however the amount of oxygen to breath was made to be higher than normal. Replaceable canisters containing **lithium hydroxide** was used to chemically remove ("scrub away") the carbon dioxide exhaled from the internal air of the living cabin of the spacecraft.

The rockets and spacecrafts of the Apollo space program were some of the first applications to use the newly developed, small (about a square centimeter of area) sized **i**ntegrated **c**ircuit (**IC**) on a single "chip" (ie., a small piece) structure. The Apollo crafts used these for many functions such as data acquisition, and some (automated, electronic, logical [ie., truth], decisions - and here made electronically) computerized steering guidance and control functions. Basically, an IC chip that is less than a square inch in size can contain many miniaturized, low power components such as transistors to quickly process electronic signals. Before the transistor electronic amplifier, a vacuum tube amplifier was required, and many of these would require a large amount of space, expense and power, and would therefore be impractical for even a small spacecraft. RAM (Random Access Memory, both readable and writable (to set and-or change the "1's and 0's") memory chips were still not yet available for the Apollo missions, and so an array of many hand-wound small magnetic cores (ie., ferrite material, hollow, ring shaped) wrapped with thin wire were used for the RAM (Random Access Memory) and ROM. ROM (Read Only Memory) is"hard wired" or hard-coded, and are not generally erasable and-or re-writeable) was available on IC's but the total amount of bytes (ie., data space and-or addressable memory or data locations) available were few. Many new, more advanced devices, materials, electronic and computer technologies were initially developed and-or proposed for the Apollo space program during the 1960's and early 1970's. This technology would later be used to develop powerful and affordable electronic hand calculators, **p**ersonal **c**omputers ("PC's"), and many other electronic devices in the next decade(s) following the Apollo space program.

Planning for the (reusable, relaunchable, cost saving) **Space Shuttle** Rocket program actually began before the last Moon landing with Apollo-17 in December 1972. The Apollo space program concluded with the (1973-1979) **Skylab** Space Station, and which was also like a test and step leading to the first **International Space Station (ISS)**. The Space Shuttle was first sent to its low Earth orbit in 1981 and **Astronaut John Young** (1930-2018) was the pilot, and who previously flew to and orbited the Moon with Apollo-10, and then walked on the Moon during Apollo-16. During this Apollo mission, the astronauts were given the news of the upcoming Space Shuttle program. The space shuttle was attached to the body of a large main booster rocket that used liquid fuel, and this rocket was also assisted by two smaller, solid fuel rockets and the liquid rocket engines of the Space Shuttle vehicle.. The space shuttle vehicle also had some smaller engines for steering in space and for reentry. Due to its high speed, the Space Shuttle spacecraft only needed small wings for the necessary lift force and steering during its reentry from orbit and space flight, and it could land like a plane on a very long runway and reused to save much costs. The ISS (International Space Station) was mainly built by using the incredible abilities of the (reusable, heavy payload lift, cost saving) Space Shuttle rocket which had a large cargo bay, and which also took and placed the world celebrated (Edwin) **Hubble Space Telescope** (**HST**, 1990, Nasa, Esa) and many other satellites into an orbit around the Earth. The first part of the ISS was launched on a Russian rocket in 1998, and the last part was launched in 2011. As of the year 2025, the HST is still continuing its space photography and allowing many new discoveries. As of the year 2022, for the ISS, its construction and technology has become relatively outdated and problematic, and it may be deliberately de-orbited and replaced by a new space station(s) within perhaps ten years after 2021.

In 2022 the celebrated **James Webb Space Telescope (JWST)** was launched and put into operation taking images with about twice that of the (camera image) resolution of the HST, and has a much larger objective mirror (here, an array) that can effectively sense much lower light levels. This telescope is in a special parallel-like orbit relatively near to Earth as Earth orbits about the Sun, and at about 1 million miles more distant from the Sun than the Earth is.

The first man-made spacecraft to reach the vicinity of the Moon was made by Russian scientists, and it was called **Luna 1**. On January 4, 1959, it came to be just a few thousand miles from the Moon's surface, and along its journey, it measured the "solar wind (of microscopic)" particles and transmitted this data back to scientists on Earth. It did not go into orbit about the Moon. **Luna 2** impacted the Moon on September 14, 1959, and without orbiting it first. The scientific instruments on Luna 1 indicated that the Moon did not have a magnetic field. Luna 2 had scientific instruments to measure magnetic field strengths and radiation levels during its journey to the Moon, and like Luna 1, they indicated that the Moon has a very low, insignificant magnetic field and strength about it. Due to the weight of all the other scientific instruments, Luna 2 was not equipped with a photograph system. **Luna 3** was the first to photograph the Moon's unseen, "far side" on October 7, 1959. These photographs had low resolution due to the (limited) photographic and digital technology available at those times for satellites, but they did show some prominent features (the larger mares and craters), and were therefore very important to all of mankind who have never been able to see the far side of the Moon until then. This mission was during a "new moon" phase, and where the "near side" of the Moon that we always see was dark (ie., not illuminated by the Sun), and its far side is then fully lit by the Sun when the Moon's orbit position is generally directly inline to, and between Earth and the Sun. It could also be said that the Moon's far side is periodically lit or illuminated by the Sun, and just as much as the near side is, and as the Moon rotates on its polar axis during a Moon day of time. After taking the photographs during a half-orbit of the Moon, the Moon's gravity was then used to ("gravity assist") cause, direct or steer Luna 3 back towards the vicinity of the Earth, and so as the stored Moon images could be electronically transmitted to the relatively close receiving antennas on Earth. This advanced level of flight control or orbital maneuvering was also a great first accomplishment for rocketry and space research.

Two months after Luna 1 was launched by Russia, United States scientists attempted lunar photography with a Moon "flyby" (ie., just passing by, close to, and then continuing onward in its journey such as a Solar (Sun) orbit, or perhaps out of the solar system such as for some modern spacecraft) on March 4, 1959 with the **Pioneer 4** spacecraft, but no photos were taken due to a system failure. Later, the United States launched the Ranger 3 spacecraft, however it only made a successful Moon arrival and then impacted (ie., collided, crashed) upon the Moon's surface on April 26, 1962, and without transmitting any data due to system failures. **Ranger 7,** from the United States, was much more successful, taking the first good resolution photographs of the Moon as it approached and impacted the Moon's surface on July 31, 1964. On February 3, 1966, **Luna 9**, from Russia, was the first lander to successfully land on the Moon without crashing into its surface, and it also took some photographs ("photos") and transmitted them back to Earth via (data) radio communication. **Luna 10 became the first man made, artificial satellite to orbit the moon on April 3, 1966**. It made 460 orbits and mainly measured solar radiation levels, but it did not have a camera system to take photographs and transmit them back to Earth. **Surveyor 1**, from the United States, landed on the Moon on June 2, 1966 and took many photos and transmitted them back to Earth. It is of note that Surveyor 1 went directly to the Moon without orbiting the Earth first. Parts of Surveyor 3 which landed on the Moon on April 20, 1967 were brought back to Earth for analysis during the Apollo 12 mission which landed very close (~ 200 m) to it on November 24, 1969. **Lunar Orbiter 1**, from the United States, was the first satellite to photograph the Moon while in orbit about it, starting on August 18, 1966. A total of 5 Lunar Orbiters were launched at later dates up to late 1967. Depending on the crafts altitude, these good to high resolution photographs would be used to locate possible landing sites for the Apollo program that would land people on the Moon in the late 1960's and early 1970's so as to gather a variety of rock samples, perform scientific experiments and measurements, and to take high resolution photographs of the surface. The image resolution varied throughout the program, orbiter and orbit altitude, and each image pixel represented (ie., actual image resolution, resolveability) a range from about 6 feet to 200 feet of distance of the lunar surface.

Before about 1970, many of the missions to the Moon by Russia, and also the United States were of very limited success and-or were often considered as failures, but they were also leaning experiences which various types of knowledge was gained and used to improve future missions. As the years went by, technology greatly improved, and this also allowed a greater probability of a mission success and-or science data returned.

The main rocket used for the Apollo Moon missions was called the Saturn-5. This rocket was usually composed of 3 rocket-stages or segments, and it carried liquid fuel. It was about 360 ft. tall, had a diameter of 33 ft., and weighted about 6.4 million pounds. The first or lower and most powerful stage of this rocket had a thrust of about 7.7 million pounds of force, and this resulted in a net initial available thrust force of: (7.7Mlb - 6.4Mlb) = 1.3Mlb. As fuel is used up in the rocket engines, the available net thrust force available increases. To electrically power the main Apollo rocket, command craft to the moon, a hydrogen and oxygen fuel-cell (a type of galvanic battery with a liquid electrolyte) was used to create electrical power (voltage and current, Pw = Vv Ia) with a typical conversion efficiency of about 60% when properly designed and made, and the landing craft to the Moon surface used a battery. Note that solar panels to generate electricity for these crafts was possible at the time, but it would also create some extra difficulties (size, aiming, deployment, etc) for these specific missions. A total of 24 people were sent to the vicinity and-or an orbit of the Moon. The Apollo-8, Apollo-10, and Apollo-13 spacecraft went close to the Moon vicinity, but did not land on the Moon. Each Apollo, Moon landing mission had 3 crew members, and the smaller landing craft contained 2 of those same crew members. After 6 Moon landings, a total of 12 people have walked on the Moon as of the writing of the book in 2024. These missions were very costly and dangerous, and the results were valuable teamwork, science, technology, data, experience and a further understanding of the Moon, rockets and further spaceflights such as for Earth orbiting space stations and spacecraft to orbit and-or photograph other planets, the Sun and asteroids. Apollo-15, Apollo-16, and Apollo-17 missions included an electric, four wheeled vehicle for two astronaut passengers, and it was called the **Rover**, and so as to easily travel up to a few miles away from the **Lunar Lander** to collect and return a larger variety of Moon rocks, etc. The rover also reduced the problem of accurately landing very close to the desired location.

As of the year 2022, scientific spacecraft have reached all of the known planets in the solar system, including Pluto and some asteroids, and much precious data and photographs were collected and sent back to Earth via radio communication signals. At these distances from Earth, the received signals are very weak and just slightly greater than the strength of all the ("background", natural, man-made) radio noise from space and the Earth. Much of this noise is effectively eliminated by using radio antennas that have a parabolic shape, and of which will then focus and highly concentrate the weak incoming radio signals from a relatively small area and-or direction in the sky and space. These collected, reception antenna signals will then be electronically amplified and (noise, signal) filtered to have most of the unwanted noise or bad data removed so as to record and study the desired signal and data (ex. image, photographic) contained within it more effectively and accurately.

Between 1970 and 1976, Russia successfully landed several unmanned crafts (Luna 16, Luna 20, and Luna 24) to land on the Moon, take photographs and bring collected samples back to Earth. **Japan** launched it's first lunar orbiter (Hiten) in 1990. The **European Space Agency (ESA)** launched its first lunar orbiter (Smart 1) in 2004. **China** launched its first lunar orbiter (Change 1) in 2007. **India** launched its first lunar orbiter (Chandrayaan 1) in 2008. **Korea** launched its first lunar orbiter (Danuri) in 2022 with the assistance of the United States. As of the current writing of this book (in 2025), United States, Europe (European Space Agency), Russia, China, and India have sent some (unmanned) landers to the Moon's surface. Many other countries have sometimes given some technological assistance to many of these countries mentioned and so as to be a part of those space missions. Very few countries have a fully capable space program and-or need, but with various types of cooperation, many countries can be indirectly involved.

Space debris (ie., junk, garbage, pieces, parts) from rockets and satellites is dangerous and has become an increasing safety concern due to the damage that it can cause to other space objects such as satellites, spacecraft, and astronauts because it has a high amount of kinetic energy (KE), mostly due to its high orbital velocity (ie., speed), and that energy can be converted to large values of force when a collision happens, and which can do much damage.

> Glass has a density of about 2.5g / cm^3 = 2.5g typical / 1000 mm^3. A 1mm^3 = (0.001cm)^3 piece of glass or sand (silicon-dioxide) has a mass that can be calculated by dividing both the numerator and denominator of this fraction by 1000, and which results in a mass and volume ratio of approximately: 0.0025g / 1 mm^3 = 2.5mg / 1mm^3 . 0.0025g = 0.0000025kg. If this piece of mass is moving at say a (ISS orbit) speed of 28000 km/h = 28000 km / 3600 s = $7.7\underline{8}$ km / 1 s =~ 7778 m / s , its kinetic energy is: KE = mv^2 / 2 joules = (0.0000025 **kg**)(7778 **m / s**)**^2** / 2 joules =~ $7\underline{6}$ joules of energy. If this is set equal to GPE using 1kg mass: KE = GPE = 76J = mv^2 / 2 = mgh = (weight kg)(height) = (1kg)(9.81m/s^2)(h), the height (h) will calculate to that of being 7.76 meters, hence that 1mm^3, 0.0000025kg = 0.0025g = 2.5mg piece of glass moving at 7778m/s has the same amount of energy as 1kg raised or dropped from a height of 7.76 meters and-or a 1kg mass moving at a velocity of. v = square-root of [2 KE j / m kg] m/s = sqrt[2 (76 J) (1kg)] m/s = 12.33 m/s =~ 40.45 ft/s

Some noted first successful flights and missions:

Launched in late 1964 in USA, and reaching closest to Mars on July 15, 1965, the **Mariner 4** space-probe (research spacecraft) was the first human-made craft to arrive nearby to, and (crude, low tech and resolution) photograph Mars. These images showed Mars as having an ocean-less, cratered surface. Mariner 4 came within about 6000 miles of Mars, but did not orbit it, but simply flew past Mars and went into a large elliptical orbit about the Sun. For electrical power, such as for the camera and radio communication with Earth, it utilized solar-panels and a battery. Data was saved onto a (magnetic) tape recorder, and it took about 9 days to transmit the initial volume (about 20, low resolution photos) of data back to Earth since the (digital, binary) signals used a low bit rate (data or bits / time), and which does help reduce some possible communication and-or (send and-or read) data errors. On November 14, 1971, **Mariner 9** became the first spacecraft to orbit Mars.

Mars 2 and **Mars 3** missions by Russia were the first to attempt a landing on Mars. Mars 2 crashed on Mars, and it is thought that Mars 3 landed safely on Dec 2, 1971, but the imagery was not functioning properly. Nonetheless, their main mission, lander platforms were orbiting Mars as artificial satellites which sent many valuable photos back to Earth.

Mariner 10 was the first spacecraft to flyby and photograph planet Venus, and on February 5, 1974, and later, it took some photographs of planet Mercury.

Venera 7, from Russia**,** was the first spacecraft to safely land on Venus and provide some surface measurement data on December 15, 1970, and **Venera 9** was the first spacecraft to orbit, photograph and land on Venus, and starting on October 22, 1975. The lander part of Venera 9 was the first to (briefly) photograph the surface of Venus. Venus is very bright when viewed from the Earth, and generally is seen before sunrise or after sunset since it is relatively close to the Sun like Mercury which is the closest planet to the Sun. Venera 1, in 1961, paved and-or proved the way for many types of deep space travel and exploration to the other planets, however it only came close to Venus. Venera 3 did make it to the surface of Venus, but it crashed landed in 1966. The atmosphere of Venus is much thicker and denser than that of Earth due to having a high percentage (> 90%) of carbon dioxide from volcanoes. The temperature (about 860 °F) and pressure (about 1200 psi) at surface of Venus is very high and this environment quickly degrades the condition and abilities of any landing craft to gather and transmit data before it is incapable. With much thermal radiation from the Sun and having a thick atmosphere, Venus is said to be like a very hot greenhouse.

Pioneer 10, launched March 3, 1972 in the USA**,** became the first craft to flyby (at about 80000 miles) Jupiter on December 3, 1973, and of which it obtained good resolution photographs. The flyby of Jupiter and its gravity attraction also increased the speed of Pioneer 10. **Pioneer 11**, launched on April 5, 1973, also made it to Jupiter on December 2, 1974 and used what is called a "gravity assist" (ie., to change speed and-or direction) of Jupiter (or any other planet, etc.) so as to direct its course to the more distant planet Saturn. Pioneer 11 reached Saturn on August 8, 1979 and took good photographs. Pioneer 10 and Pioneer 11 both continued on a path out of the solar system. By 1979, and due to their electrical power being depleted, communication from these spacecraft has ceased.

Viking 1, and then **Viking 2** soon afterwards, were the first spacecraft to successfully land on Mars and take many photos and obtain other data. The orbiter part of the spacecraft and mission also took many photographs of Mars. Electricity for each lander was provided by an on-board, thermometric electricity generator which converted the heat energy from a radioactive substance into electrical energy. Viking 1, was launched in USA on August 20, 1975, and landed on July 20, 1976. Viking 2, launched in USA on September 9, 1975, and landed on September 3, 1976. Since then, throughout the years, several other landers and-or mobile rovers on wheels have traveled and searched Mars for several miles and have gathered many high resolution photographs and much scientific data.

The Magellan probe, from the USA, produced good resolution (about 100m per image pixel) radar images of the surface of Venus after it began orbiting on August 10, 1990, and gathered images until October 1994.

Some other spacecraft you may research: Voyager 1 (Jupiter in 1979, and Saturn 1980, flybys [non-orbit] and-or for gravity assist]), **Voyager 2** (Jupiter in 1979, Saturn in 1981, Uranus in 1986, Neptune in 1989, flybys). By the year 2023, communication from these two very distant spacecraft has been said as becoming difficult. Being so far from the Earth, the photographs of the stars at this distance from Earth can then help determine the distance to them by using what is called **parallax** which basically can show the apparent, greater movement of closer or nearby stars among the more distant stars in background (ie., farther away). By comparing two images or photographs separated by a large distance makes this use of the parallax method possible, and then trigonometry can be used to estimate the distance to those closer stars. Telescopes on Earth can also use the parallax created when Earth is on opposite sides of its orbit about the Sun - an average distance between both locations is twice the radius distance from the Sun, hence (2)(93Mmi) = 186Mmi.

Clementine, from the USA, Orbited the Moon between 1994-1995 before it malfunctioned, and it made medium-resolution Moon photography of the surface of the Moon, and with an average of about 12 meter =~ 36ft surface per pixel image resolution, and gathered other science data. **Galileo** (Jupiter), **Cassini-Huygens** (Saturn), **Messenger** (began orbiting Mercury on March 2011), **Dawn** (orbited Vesta in 2011, and began orbiting Ceres since 2015; both are proto-planets, however Ceres is a round sphere), **New Horizons** (Jupiter, **Pluto** on July 14, 2015, with a world celebrated flyby and photographs, and since not having enough fuel to reduce speed for an orbit of Pluto), **Lunar Reconnaissance Orbiter** (LRO, Launched in June 2019 by the U.SA, and into a polar orbit around the Moon for high resolution photography and science. The highest image resolution of its digital camera is about 20 inches =~ 1.67 ft. in length or width, hence an area of 20 in^2 = 400 in^2 =~ 2.78 ft^2, hence things smaller and-or details of this area of larger things cannot be seen in the images. LRO has imaged all six of the Apollo landing sites and craft. **BepiColombo** (Mercury, EU and Japan, is scheduled to orbit Mercury in 2025). China space stations: **Tiangong-1** ("**Heavenly-Place**" in English translation, 2011-2016, reentry 2018), and **Tiagong-2** (2016-2017, reentry 2019), and **Tiagong-3** (Launched in 2021) which has an average altitude of 250 miles above Earths surface, and has an orbit inclination of about 42 degrees. Russia space station: **Mir** (1986-2000, reentry 2001). The Space Shuttle has docked (temporarily arrived and connected to) with Mir on several occasions.

Most rocket and-or satellites are launched into a westward to eastward orbit of travel, and of which may also be at an incline or angle with respect to the equator plane of orbit and-or the solar plane. This is especially so since many launch sites are not located at the equator region, and even if they were located there, they may still have a deliberately planned, inclined orbit. It is of note that an orbit cannot be just at a certain latitude about Earth, except for a geostationary orbit which is essentially located at 0° latitude with respect to the Earth. Since the seasonal tilt of Earth is an illusion and-or apparent only, the location of objects in orbit will not be affected by this apparent tilt.

Since the Earth is spinning westward to eastward, an object on its surface effectively has a horizontal velocity toward the eastward direction. We do not notice this velocity due to relative motion and locations of us and other objects on Earth's surface that are also going at the same speed or velocity, and appear to as going at a speed of 0. This horizontal speed will still be present in a rocket heading to space, and so it is beneficial to launch in the westward to eastward direction so as to utilize that initial velocity and-or kinetic energy.

It is possible to have a "backwards" or **retrograde** orbit of travel about the Earth, and where an object travels from the eastward to westward direction about Earth. It is also possible to have a **polar orbit** where the object travels northward to southward during one half of the orbit, and then southward to northward on the other half of the orbit about Earth.

The unaided eye without binoculars or a telescope is capable of seeing satellites travel across the sky as a small dot of light, much like a moving star, and usually in a westward to eastward direction. The light seen is due to the reflection of sunlight from its surface, and when permitting due to the geometry of the Sun, satellite and observer need to be in favorable alignment without the obstacle of the Earths surface, daylight. various "light pollution" issues, and-or cloudy weather at night.

The Basics Of Rocket Science

Rockets can be powered by a variety of fuels, and its rocket engine will be designed to utilize one and-or a mixture of fuels. Many rockets to space use liquid propellants (fuels that propel [move] the rocket). For safety reasons, this fuel is often put into the rocket's fuel tanks (ie., containers, usually circular or cylinder to help distribute internal pressures) inside the rocket, and just before launch (ie., "blastoff", rocket engine ignition, and upward travel). Much of the fuel of the rocket is not actually used to lift the relatively small and-or lite-weight payload into space, but it is rather needed to lift all the weight of the fuel needed to get the payload to a high altitude and high velocity (perhaps 5 miles per second) orbit. It is often said that the fuel combustion in a rocket engine is a "controlled explosion" (ie., a very quick combustion and-or a fast chemical reaction and "burning", creating gas particles with high kinetic energy and heat energy). Here the word "controlled" generally means a slower, manageable combustion and-or explosion so as to reduce heat and vibration. For combustion to occur, oxygen is needed, and this is often supplied by an internal tank of liquid oxygen.

A typical rocket fuel may have a combustion efficiency of about 75%, that is, it will convert 75% of its potential or chemical energy to hot gases (particles with a very small mass) with a high amount of kinetic energy. When the fuel combusts (here, a "controlled" or "slower explosion", as mentioned), hot gasses travel outward at high speed in a spherical direction. About 50% of the hot gas force or pressure created will be used to lift the rocket upward with its total combined kinetic energy of the gas molecules, while the other 50% is simply wasted in the opposite or downward direction of the rocket. It is also of note that the pressure upon the gasses is also less at the open "bell" or cone shaped end of the rocket. With this basic rocket system analysis, the efficiency of its engine system is: (75%)(50%) = (0.75)(0.5) = 0.375, hence about 37.5% of the rocket fuel energy is actually being applied to lift the weight of the rocket. Much fuel will be used just to overcome the inertia of the heavy mass and-or weight of the rocket and begin to move it. Drag forces, much like friction, particularly in the denser lower atmosphere, will effectively reduce fuel efficiency. It is often said that at orbit altitude and its required velocity, that the overall or total efficiency of a rocket fuel and engine system is very low, perhaps 1%. A theoretical energy efficiency of a rocket fuel system could be defined and calculated as equal to:

Total rocket fuel and engine efficiency of a rocket =

$$\frac{\text{(kinetic energy + gravitational potential energy of the mass in orbit)}}{\text{(total fuel combustion energy before launch)}} = \frac{\text{E out}}{\text{E in}} \quad : \text{E out} = (\text{E in} - \text{E losses})$$

For a rocket engine to move the rocket and-or its weight vertically, it must overcome that weight (a force) by a greater force so as there is a net difference in force in the forward direction. The lift force created by the rocket engine is formally called **thrust** (or forward force), and this is similar to the lift force of a plane that causes it to go higher.

lift force = rocket engine combustion vertical force - weight of the rocket :the effective lift applied to the rocket
: lift force = vertical or upward force.
: Note, weight = a downward force

Using these values in a different mathematical expression, we will have a (vertical) **thrust to weight ratio**, and for the rocket to move upward, this ratio must be greater than 1, and the higher this value is, the better. The thrust force must be greater than the weight (a force in the opposite direction) of the rocket for it to move upward. A higher engine thrust force and-or (net) lift force also means that the rocket will have a higher acceleration (a = (f / m) = (change in v / change in time)) which leads to a higher velocity (v = at), and therefore, more distance (d = vt) per unit of time.

In theory, even if the lift force was just 1 pound or 1N of force, perhaps because of the rocket being very massive and-or weighty, the rocket would still move vertically upward, but it would be very slow at first due to the relatively low amount of the net, resulting or effective lift force applied. A low effective lift force creates a low amount of rocket acceleration (a = f / m), and therefore a low rocket speed (velocity = at), and the rocket would probably "run out" (ie., "use up", deplete, drain, not have any left to use) of fuel well before it reached orbit if it did not have enough fuel. From these equations: f=ma , a=f/m , and if the force and-or energy applied low, the corresponding acceleration and will be low. It takes more energy (ie., fuel) and-or work to lift (ie., f=ma, and work = fd = mad with units of joules) a more heavier (due to more mass) object a unit or certain distance. The longer a force is applied to the rocket, the greater the KE (mv^2 / 2) gained by it, the greater its acceleration (a = dv / dt) and current velocity (v). When the force applied stops, the acceleration will stop and the velocity of the object will remain the same until some force is applied to the object again.

rocket engine vertical thrust force   > 1   is needed for the rocket to move or be lifted upward or vertically
rocket weight   : Thrust to weight ratio   ,   weight = a downward, vertical force

A rocket will launch (begin to move vertically) when its fuel is combusted in the rocket nozzle or combustion chamber, and the net sum of the force from each atom and-or molecule (billions of them) with their high kinetic energy that strikes or collides with the bottom of the rocket will be used to created the net (sum, total, resulting) vertical lift or thrust force. After some amount of time, the same combustion or thrust force of the rocket engine will then be used to produce both a vertical or lift force so as to go both higher and also provide more horizontal force so as the rocket can reach a high horizontal velocity needed to ("free-fall") orbit around the Earth.
.
In place of the term: (rocket engine thrust), the term (rocket engine vertical force) can be used, particular when it is rising up into the atmosphere vertically. In place of the term (rocket weight), the term: (gravity induced force on the rocket mass) can be used. For the rocket to move upward or vertically, the upward or lift force must be greater than the downward force of gravity which is the weight of the rocket, hence their difference must be greater than 0. These forces (mathematically equal to f=ma) will cause a corresponding acceleration of the mass such as a rocket, and the vertical acceleration must be greater than the downward acceleration due to gravity. so as the rocket can have a net vertical acceleration and move upward. In other words, the upward force applied to the rocket must be greater than the downward force or weight of the rocket, and for that rocket to move upward or forward into the air. If an object, perhaps a plane, was at a constant altitude, the upward force would then equal the downward force of gravity which is the weight of the plane. The (instantaneous and-or constant) lift force (f=weight=ma) and acceleration (a = f/m = weight/m) generated by the wings must equal the downward acceleration or fall of the plane due to the force of gravity affecting it, and for it to then remain at the same height or altitude. Regardless of the mass and-or weight of the object, the gravitational acceleration in the downward direction is a constant of -9.8m/s^2 near the Earth's surface.

As the rocket depletes (ie., uses up, reduces) its limited amount of fuel, the mass and weight of the rocket will get lower, and the thrust to weight ratio will then be increasing, and this improves the efficiency of the fuel energy. The rocket will then accelerate more and go faster since the same combustion force is now applied to a smaller mass and-or weight. From F=ma we have: a = F / m = (change in velocity) / (change in time). When (m) gets smaller, (a) gets larger when the force (f) is constant. Some rockets may have an additional stage (additional rocket section(s) placed on top of each other vertically), and the thrust to weight ratio may change, and mostly due to the next rocket stage in use utilizing different, perhaps fewer and-or smaller, less powerful rocket engines. The rocket stage(s) with the empty fuel tank are then quickly discarded as useless weight to not keep lifting and wasting energy. As the rocket climbs higher, there is less friction with the air and-or atmosphere because the air pressure and-or density is less at higher altitudes. This friction and-or force against the forward thrust of the rocket is sometimes called the rockets **dynamic pressure**, and at a certain point or altitude during the rocket flight, this friction or dynamic pressure force will be at maximum kinetic or dynamic pressure (often called as the "**Max-Q**" point), friction or drag due to the combination of the rocket's speed and the air pressure and-or density at that certain altitude. Surely the air pressure is relatively low at several miles high, but the rockets velocity is a high value when it is impacting the air molecules which will then gain some kinetic energy from the impact or friction from the rocket, and this causes a reduction of the kinetic energy (KE = mv^2 / 2) and-or speed of the rocket. The rocket must be designed to withstand this pressure and-or impact force at Max Q, and it may "throttle down" (ie., reduce its rocket engine output thrust force) for a few seconds to reduce this pressure encountered. Max-Q will occur at an average altitude (ie., height above the Earth's surface) of about 8 miles.

The pointed tip or "nose cone" of a rocket helps reduces air resistance (ie., friction) or drag, and the pressure (P tip = F fip / A tip) per unit area is effectively reduced. In short, the pointed tip creates a situation where the kinetic energy transfer from the rocket to the air gasses is less, and the impact with each gas particle is less since the collision is not a direct collision but rather at an angle directed away from the length of the rocket.

Though the final efficiency of the rocket fuel system may be as low as 1%, and the cost per rocket launch is relatively high, the social value is very useful, and therefore very valuable in itself, and often financially profitable, such as if the rocket successfully placed a communication and-or weather satellite into orbit.

How much thrust can a rocket engine make? To find this value, the rocket engine is usually tested on a fixed stand so as to check for flaws, stability, efficiency, and the force (ie., thrust) it can produce. The rocket engine is started and the amount of fuel used and the corresponding force it produces is measured and recorded, such as data points on a graph. This data will be used to determine things such as the acceleration to expect [ie., a = F / m = (engine thrust) / (mass of the rocket)] and the resulting velocity of a rocket to orbit, and for a resulting velocity of spacecraft in orbit. By knowing the acceleration (a) of a mass due to a specific engine, a specific and-or required amount of time to ignite a rocket engine to accelerate and change its speed or velocity can then be calculated and determined.

From: (a) = F/m = (change in velocity) / (change in time) , we have: (change in time) = (change in velocity) / (a=F/m)

Rocket engines can also be rated in general terms of how much thrust it can produce for a given amount or 1 unit of fuel such as a kilogram of its mass, or a liter of its volume. This rating is called the **specific impulse (ISP = Isp** , = Impulse Specific**)** of that particular rocket engine system. Different fuels can have different amounts of potential energy available, and this will then affect the specific impulse value and-or thrust force value of that rocket engine. The higher the amount of thrust produced per unit of fuel, say 1kg of fuel, the higher the ISP rating of that engine. Given two identical rocket engines and using the same type of fuel, the one that receives the most fuel will produce more thrust per instance of time, time unit or second, and will therefore have a higher ISP rating also. The higher the rate of using fuel, say kilograms/second, the more instantaneous force produced, but the less amount of time it will be available if the amount of fuel quickly reduces to 0 liters, gallons or kilograms of rocket fuel. The longer (ie., more time) a force can be created in the rocket engine and applied to transfer kinetic energy to the rocket, the more the object or rocket will accelerate and go faster in speed or velocity. For some extra reference, the units of **impulse** (I) are: Ns = Newton-Seconds = Ft = (force applied) (number of seconds the force is applied). If two rocket engines produce the same amount of force, even if they use different fuels and its usage rate (ie., amount of fuel used / time), the main variable for comparing these engines then becomes the number of seconds that the force can be applied to the rocket. Isp is like a measure of fuel combustion efficiency, and also a measure of thrust and momentum per unit of fuel.

Impulse = (force)(time) = F t = (Thrust)(time) = mat = mv : a change in momentum
Specific Impulse = **Isp** = impulse / weight of fuel = mv / mg = v / g = (m/s) / (m/s^2) = **s :s = seconds, a time unit**
Also , Isp = mv / mg = Ft / mg = (F / m) (t / g) = a t / g = v / g = s

Isp = thrust / propellant = thrust / 1 unit of propellant : as an equivalent fraction

Also note this ratio: impulse / mass = mv / m = v : the lower the mass, the greater the velocity given a certain value of kinetic energy

Ex. The engine in a certain rocket is said as having an ISP of 100s , this can be considered as:

1 unit of thrust / 1 unit of fuel = seconds = 1 kg of thrust for or from each 1 kg of fuel, for 100s of total time

For the rocket to rise into the air, the amount of thrust must be greater than the total rocket weight = mg due to the force of gravity (9.81 m/s^2) causing a deceleration, and which is constantly applied to the rocket, and it needs to be constantly overcome until it is into orbit and where the engine thrust is no longer needed. The effective or net thrust force (Fn) applied to the rocket is then: Fn = (thrust - weight of the rocket) , and if this value is low, a low force will cause a low acceleration (a = F / m = [change in v / change in t]), and then the average velocity = (v = d / t) = (at^2 / 2) / t = at / 2 = v / 2) will be low right after launching.

Most modern space rockets can reach a low Earth orbit (LEO) altitude of about 200 miles in about 9 minutes of time due to its high speed or velocity developed later in flight, and where the weight of the rocket fuel is much less than at launch, and the acceleration (a = F / m) is much greater. 9min = (9min)(60s/min) = 450s. Over time, air (a mixture of gas) particles (atoms, molecules) of Earth's upper atmosphere will collide with an orbiting space vehicle, and more so in low altitude orbits, and this friction or drag force will cause the space vehicle to loose some of its kinetic energy, decelerate slightly in the opposite direction, and therefore, reduce its forward orbital velocity. When the orbital velocity required for a specific orbit is reduced, the orbiting space vehicle will reduce in altitude more and more as time goes on. To then undo this situation, the space vehicle will occasionally need to use the energy and force from a rocket engine(s) to raise it higher to its intended altitude of orbit and velocity.

To "escape the gravity" of a planet would be to have an acceleration greater and in the opposite direction (ie., upward or outward from the surface, or radially from the center) than the local and constant, downward or inward gravitational force and acceleration it induces upon a mass such as a rocket. At the surface of Earth, and for low altitude (say, less than 200 miles) orbits about the Earth, gravity acceleration is about 9.8m/s^2. If a rocket engine can supply enough force to overcome the local gravity and weight of the rocket, it can eventually "escape the force of gravity" of Earth. As an object, mass or spacecraft orbits (ie., effectively tangent, parallel or horizontally to Earth at any instant) the Earth, it no longer needs the power of a rocket engine to overcome gravity so as to remain at that altitude. While in orbit, the object such as a spacecraft or satellite is in "free-fall" or "in a perpetual, endless falling" as the curvature of Earth below the spacecraft is also increasing its distance from the orbiting object by the same amount or rate that the spacecraft is falling downwards, and this effectively negates or "cancels" any change in altitude due to gravity, and the orbiting object will effectively remain at the same altitude. Nonetheless, Earth's gravity is only slightly lower in low altitude orbits, and is still constantly pulling an object downward, hence gravity has not actually been "shut-off" to 0m/s^2 during orbit and-or "free-fall".

A discussion of orbiting has been previously mentioned in this book, such as in the topic of Kepler's Laws of orbital motion.

A spacecraft on its way to the Moon from the Earth must take into account that the Moon is also moving as it orbits the Earth, and that the spacecraft must then be aimed not at the current Moon position, but at where the Moon will be at a later time. For the Apollo missions, it took about 3 days on average for the spacecraft to reach the current position of the Moon. The Moon will move or travel a distance and-or angle during that 3 days time and will be further in its orbit about the Earth. While traveling farther outwards from Earth, the spacecraft will still have some circular-like orbital motion about the Earth, and the direct line to the Moon is actually similar to that of a curved line or arc of a circle. While the spacecraft is traveling to the Moon, it is still under the influence of a low value of Earths gravity and force will therefore be constantly slowing it down in velocity. There is a location called a **gravitational neutral point** between the Earth and the orbiting Moon where the gravity (ie., gravitational acceleration) of each upon the spacecraft is the same value: Ge = Gm, and therefore Ge - Gm = 0 m/s^2. At the neutral point, and object with a mass will experience the same gravitational forces from the Earth and Moon: Fe = Fm. When the spacecraft is in the vicinity of the gravity of the Moon, it can then be gravitationally attracted to the Moon and can either go (ie., fall) directly to it or go into orbit about the Moon at the necessary velocity according to its desired orbit height (typically a value between 60 miles to 100 miles high) above the surface of the Moon.

To prevent the human body from experiencing health problems on long duration space travel, say greater than 1 month of time, methods to create **artificial gravity** in a spacecraft have been proposed. In 1952, Werner Vaun Braun proposed a large circular spacecraft (ie., a "space station") having a shape like that of a wheel, and where people and objects in the craft near the outside rim will experience artificial gravity. This craft would have to spin fast enough to achieve this effect. Another method in theory is if a large rocket ship having many floors and therefore much floor and living space, and also having enough fuel can then constantly accelerate at say a constant value of 9.8 m/s^2. Objects in the craft that would otherwise be floating as weightless (but not mass-less), would then be moved toward the floor(s), and they will then experience a force (ie., artificial gravity) upon them, much like how the entire rocket-ship is experiencing a force upon it from the rocket engine. Due to objects and people in the craft having some inertia or resistance to movement, accelerating at a high speed can cause much force and damage to them, and so therefore, the acceleration of the craft and resulting effective gravity should be gradually increased.

The formula for the escape velocity (Ve) from a gravitational, free-fall orbit is:

$$Ve = \sqrt{\frac{2GM}{r}}$$

: Formula for escape velocity (Ve)

G = Universal gravitational constant , and is not the same value as earths gravity (g).

M = a spherical-like or uniform mass being orbited by the rocket or satellite ,

r = radius or distance from the center of the mass being orbited, as (r) increases, the necessary escape velocity will decrease, and this is due to that the force of gravity is then lower. G m/s^2 , M in kilograms , (r) in meters. And:

Letting g = local gravitational acceleration at an altitude or (r) = $\frac{G M}{r^2}$, Ve can be expressed as: $Ve = \sqrt{2 g r}$ =~ $1.414 \sqrt{g r}$

When (r) increases, the effect of gravity upon the orbiting body is less, and it is easier for it to then escape from orbit, and its escape velocity will be lower. Just the same, for an object to go into an orbit about a mass, it must be going at a velocity less than the escape velocity. Another way to consider escaping the effects of gravity is to accelerate away from the mass being orbited by an amount equal to the local gravity at that altitude. At the surface of Earth (where r equals the radius of the Earth) and in a low (altitude) Earth orbit (LEO), if the rocket is accelerating at slightly greater than 9.8m/s^2, then it will eventually escape from Earths local gravity value near the surface. For higher or farther orbits, this value will be lower since the local gravitational acceleration there will a lower in value. Even though an object is said to have escaped the orbit of a body or mass, that object will always be slightly influenced by the gravity of that same mass and every other mass in the universe, and depending upon their mass and distance from the object according to the law of gravitation of two objects and-or masses. Even though the force of gravity may be very weak upon another object and-or mass, a constantly applied force such as gravity or a small amount of thrust from an engine will cause an acceleration and therefore a constant increase in velocity unless it is in a circular orbit about a mass such as a planet or moon. For orbiting conditions, the (inward) centripetal force due to gravity is equal in value to the (outward) centrifugal force of the object wanting to move away from its orbit as it would if the gravity ceased. While in a stable orbit, the net or effective force upon the orbiting mass is 0N: Fc = Fg , and Fc - Fg = 0 Newtons

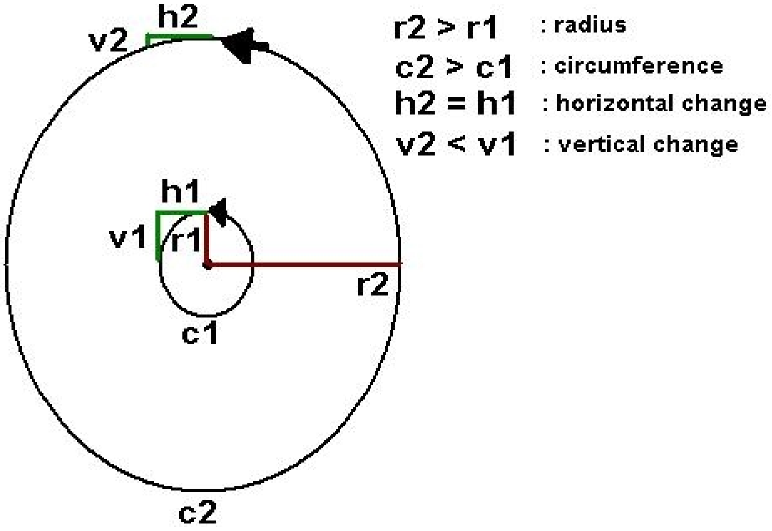
The ratio of the escape velocity to orbital velocity is about the square root of 2 =~ 1.414 , here is the verification:
ve^2 / vo^2 = (2 G M1 / r) / (G M1 / r) , after solving for ve , we have ve = $\sqrt{2}$ vo

Objects in farther natural orbits will travel slower.

An object at perihelion is at its farther distance in its elliptical orbit and it will be traveling slower. This discussion here will focus on natural circular orbits at farther orbit distances and the objects traveling slower. An example of a distant orbit is an object in geosynchronous orbit. Objects in a low altitude or radius from the center of Earth, say less than 1000 miles high, need to travel much faster and regardless of its mass it will be the same value, and this is a reason low Earth orbit objects of any mass need to be on a very fast rocket, and which will require much fuel to be that fast. Although objects in a father orbit will be traveling slower, they will still require much rocket fuel to get to that height (ie., having much GPE = Gravitational Potential Energy), altitude or radius of orbit.

Objects in farther circular orbits will have a lower amount of curvature in their orbit and the figure below shows a method to explain this. If the orbit is very distant and-or the radius is very large, the curvature of its path or orbit is nearly a straight line for a period of time, such as for a minute of time. Though this curvature is slight or low and has a corresponding small mathematical value, the actual radius of orbit and-or curvature associated with it is actually high in value, and this is an inverse type of mathematical relationship, and a pseudo expression for this is: amount of curvature per unit distance = 1 / radius of curvature. Just the same, the effective angle of inclination or declination of travel will be inversely related to the radius of orbit. For an orbit with a low amount of curvature, the angle of declination will be low as shown in the figure below. It could be said that a measure of curvature is the rate of change of the angle and-or height with respect to time or distance. An amount of curvature could also be considered as corresponding to the height of the curve or arc(s) with respect to its two endpoints and their (chord) distance apart. A pseudo expression for this would be: amount of curvature = (height of curve) / (arclength or distance between the arcs two endpoints), and this is similar to a pseudo expression for curvature: curvature = (change in vertical distance) / (change in horizontal distance) = slope of the line connecting the endpoints of the two lines or arc. Note however, with a circle, this slope is not actually a constant value for each same horizontal change, and that is why its a pseudo expression for curvature, but the figure below is enough to give an essence of understanding to the concept. An alternate idea for a pseudo expression for curvature would be the (shortest distance (horz. or vert.)) / (longest distance (horz. or vert)) per unit of time of travel and-or angle

traveled.
[FIG 249]



In the above figure: h = horizontal distance or change per unit of time, and v = vertical distance or change per unit of time. c = circumference of the circular orbit , and r = radius, height or altitude of the circular orbit.

We see that the orbit with c2 has a lower amount of curvature per horizontal distance and-or the amount of rotation angle about the center point of orbit. Observe that when h2 = h1, v2 is much less than v1 due to the farther orbit distance.

In the orbit c1, with the shortest radius, a curve or arc segment of the orbit or circumference is actually said to have a higher amount of curvature, and this actually means a higher mathematical amount of curvature with respect to the small radius value and-or arc length. Given the same arc length of any radius of orbit, if the corresponding radius is small, the radius of curvature is said to be high, and the curve may be thought of as a narrow radius, sharp and-or a large amount of bending of which could also generally mean quickly changing in direction with respect to distance and-or time.

The farther the radius of orbit, the less gravity force constantly being applied to and affecting the spacecraft and therefore, the slower it will be free-falling downward toward the Earth, and the less distance it will fall per unit of time and-or distance moved forward. For farther orbits or altitudes, both the vertical drop of the spacecraft in orbit and the downward curvature of Earth's surface are equivalent in distance, but here, it is a less distance fallen per unit of horizontal distance orbited. Due to this, a spacecraft in a more distant circular orbit will require and have a slower speed or velocity to maintain (ie., keep) that orbit. Since the velocity for farther distanced or radius, natural orbits is less or slower, it will take a longer time to make a complete orbit of the Earth, and this is sometimes called the (cyclic, repetitive, constant) **period of orbit**.

In short, the radius of curvature of an arc, segment or portion of a curve is defined as the radius of a circle having a circumference and-or arc segment of it that corresponds to it. There are various ways and-or instruments to measure the radius of curvature of an arc and-or sphere surface so as to find its corresponding radius and so on. One such tool is called a **spherometer**, and where 3 legs having the same height are set apart in a equilateral triangle formation and will define a flat plane which corresponds to a chord line and endpoints on it, and-or a chord plane, and a central depth gauge can be used to measure the maximum height of that arc from the plane.

If you have a curve segment or arc on a graph and draw lines perpendicular to it, you can see where those lines intersect and you can then locate and measure the distance to that point of intersection so as to have the approximate radius of curvature value, and in fact, this is also a method to find the center point location in a circle. There are also mathematical ways to calculate this radius value given both an arc segment length and the chord length beneath it and-or the height of the arc from the chord or distance line between its two endpoints, and of which is also called the **sagitta** of the curve segment.

To go to a larger orbit having a larger radius and-or to go to another planet.

For a spacecraft to go from a circular, low Earth orbit (LEO) to a higher circular orbit, and here, considered being on the same solar plane as that of Earth or perhaps another plane of orbit, the spacecraft must get a force from its rocket engines so as to do so. At a higher altitude of orbit, the spacecraft will have more gravitational potential energy (GPE). Rather than direct the rocket thrust to be radially away from the center of Earth for a higher orbit, the spacecraft can increase its velocity and effectively "overshoot" its regular orbit and increase its distance from the Earth beneath it, however, this will then put it in an elliptical orbit which must then be corrected if the spacecraft is desired to be in a circular orbit. This particular method to transfer from one orbit to another is formally known as a Hohmann Transfer Orbit. A Transfer Orbit is the formal name for the process and-or location between two stable orbits. It was conceived by **Walter Hohmann** (1880-1945), from Germany, in 1925. More recent discoveries in orbital mechanics such as using what is called a Low-Energy Transfer to change orbit require much less fuel, but will then require much more time to do so. This method is similar to a Hohmann Transfer Orbit, but the rocket uses several increasing elliptical orbits and their altitudes, and then uses some fuel to go into to a final or circular "parking" or stable orbit.

Since a particular radius and-or altitude has a particular natural orbit velocity, and regardless of the mass of the orbiting object, there is a particular natural time or period corresponding to that orbit.. Consider that even: Distance = (Velocity)(Time) = vt, and regardless of the mass. Time = Period of Orbit = Distance / Velocity = d/v , Velocity = Distance / Time. = v = d / t. As a reminder, consider two masses dropped from the same height in a airless vacuum, and they will both reach the ground at the same time, and this is another instance when the mass of the object(s) does not make a difference, and that both will fall in the same force of gravity causing an (gravitational) acceleration of:
32.2 ft / s^2 = 9.81 m/s^2 In the case of an orbiting spacecraft(s), whether in orbit or not, it will fall at a rate of acceleration due to the strength of the local gravity there, perhaps 9 m/s^2 , and regardless of its mass.

When a spacecraft is no longer traveling or going at the natural orbit velocity for that altitude or radius of orbit, its orbit will change to an elliptical one, and it will continue unless it is corrected to be circular. In a circular orbit, the gravitational force of Earth pulls the spacecraft downward in the vertical direction, and there is no horizontal gravitational value of force pulling it forward or essentially backwards when it is slowing it down. While in an elliptical orbit, the Earth's gravity is still mostly pulling it downward vertically, but the remainder of that force is pulling it in a horizontal direction so as to create that elliptical orbit, and as you can imagine, the closer it is to the Earth the greater the gravitational force and the faster (v) it will be traveling due to it accelerating by a constantly applied force (here, the increased local gravity) giving it more kinetic energy (KE = mv^2 / 2). The sum of the total orbiting energy which is the sum of the kinetic and (gravitational) potential energy of a spacecraft in orbit will remain the same constant value, although the actual values are constantly changing by a small amount each, and while one is increasing, the other is decreasing: Total spacecraft energy in orbit = KE + GPE = constant for a constant or stable orbit. When the spacecraft moves away from the Earth during its elliptical orbit path, it will begin to slow down due to the force of gravity still upon it and pulling it toward Earth. The spacecraft will loose speed and-or its total kinetic energy, but it will gain and store that amount of energy as gravitational potential energy (GPE) as it effectively moves to a higher altitude (ie., height) and-or distance in its orbit. The farther it is from Earth, the less the gravity of Earth upon it, but it will still be constantly applied to it and pulled toward the center of the Earth while on its (somewhat circular, elliptical) path or orbit.

According to Newtons's laws and verified by modern space travel, we know that an object in motion will continue in the same direction and speed unless affected by a force that will change them. An example of this to help simulate this on Earth would be a piece of ice first being pushed across a frozen puddle of water, hence ice, and without much surface friction involved. It can also go a great distance after an initial force is applied to it so as to give it some kinetic energy. Due to an initial surface friction, some extra force must be initially used to overcome it so as motion can start. The amount of force applied will then also determine its speed or velocity. The direction the force is applied will determine the direction it will take. If the force is constantly applied, the piece of ice and its speed will constantly accelerate in speed as more energy is transferred to it and it gains more KE. If it were not for the small amount of friction on the ice due to its weight as it travels, it would continue its motion in a straight (ie., like a line) direction. The force of friction upon both surfaces in contact is essentially in the opposite direction to its forward motion, and this force will reduce the kinetic energy (KE =

mv^2 / 2) of the moving piece of ice until it stops its motion. Space travel is similar to this piece of ice traveling on ice, except that there is no friction due to that nothing is in contact with its mass. Remember, the weight of an object is the downward force of an object, and this will effectively increase the actual amount of surface contact when friction is considered. Though most surfaces appear smooth, but when they are viewed under a microscope, they are rather jagged with mico-sized hills and valleys which can then interlock and slow movement when no further energy is input to maintain the kinetic energy of the object.

If a spacecraft was traveling in a forward direction and it used its left side engines so as to make a right turn so as to move rightward, that spacecraft will still have its forward component in its motion, and in fact, it will still have the same velocity in that forward direction, and will now also have a velocity in the rightward direction. To reduce and then remove or cancel out any of the original forward motion and-or direction, and just have the rightward direction of motion, the spacecraft must temporarily use a rocket engine so as to provide some thrust (ie., force) in the opposite direction to that forward motion so as to reduce and-or eventually cancel out any momentum or motion in that forward direction.

How much will an object on Earth weigh on the Moon?

First, any amount of mass on Earth or elsewhere, will still be the same amount on the Moon since the value of mass is universal. 1g of mass on Earth will still be 1g of mass or substance on the Moon. Since the Moon is geometrically smaller than Earth, and its mass is less than that of the Earth, its gravitational acceleration value (a=gm) will be less than the gravitational acceleration value (a=ge) of Earth. The Moon's local gravity is about **(1/6)** = 0.166667 = $16.\underline{7}$% that of the Earth, and an object will then weigh (1/6) on the Moon as it does on Earth. Force = Weight = ma. Just the same, an object on Earth would be said to weigh 6 times more than that on the Moon's surface. Here is the derivation of this value:

First, consider that there could be any other mass near the moon using Newton's Gravitational Force equation. Lets assign this other mass (M2) have a value of 1kg, and this will simplify Newton's equation so as to having just one mass, and that is for the mass of the Moon = M1. After all the Earth is very far from the Earth, and its local gravity upon the surface of the Moon is almost negligible. The height of the liquid (fluid, low density) sea or ocean tides on the surface of the Earth due to the Moon' gravity is a very small fraction, almost negligible, of Earth's radius. For (r), we will use the radius of the Moon.

Fgm = G M1 M2 / r^2 =~ (6.674)(10^-11) Nm^2/kg^2 (7.35)(10^22) kg / ((1738)(10^3)m)^2 =~ $1.62\underline{4}$ N / kg :
1N = (1kg)(1m/s^2) , 1.624N / kg = (1.624)(1kg)(1m/s^2) / kg = **1.624 m / s^2** : slightly more than (1/6) of Earths

A scale calibrated to Earth's gravity, will need to be re-calibrated (ie., correctly set, adjusted) on the Moon since for example, a 1 gram mass will still need to be displayed as 1 gram on the Moon when using a common weight-to-mass scale. The 1 gram of mass will weigh (ie., a force) less on the Moon, specifically (1/6) as that of its Earth's weight, but the scale will need to be display the same amount of mass of 1 gram. To do this, for example, the gram value using this scale would need to be multiplied by 6, either internally or by the user. Weight = W = F = m a , therefore, m = W / a . We see that if (a) or (W) is changed by a factor of (n), that the other will automatically change by that same factor, hence keeping the equivalent fraction and same mass value: m = W / a = W / g = (n) W / (n) g.

$$gm = \frac{ge}{6} = (1/6)\ ge \quad , \quad \text{mathematically:} \quad ge = 6\ gm$$

Force = Weight = (mass)(a) = (mass)(g) : mass = Weight / a

Gravity on the Earth: Weight of a mass on Earth = m ge = (mass) (9.81 m/s^2)

Gravity on the Moon: Weight of a mass on Moon = m gm = m (0.166667) ge = (mass) (0.166667) 9.81 m/s^2 =
= **(mass) ($1.6333\underline{3}$ m/s^2)**

Ex. A 60 lb weight on the Earth will weigh: 60 lb / 6 = 10 lb on the Moon.

How much will a 1 kilogram of mass on Earth weigh on Moon?

Weight on Moon = (1 kg) (1.63333 m/s^2) = 1.63333 N , and a weight-to-corresponding-mass scale on the Moon should be calibrated to display the mass as:

From F = weight = (mass)(acceleration) = ma , m = F / a = 1.63333 N / 1.63333 m/s^2 = 1 kg

On the surface of Earth, 1 kg of mass will weigh (ie, a force due to gravity upon a mass) :
(1kg)(9.81 m/s^2) = 9.81 N =~ 10 N , extra: 9.81 N on Earth / 1.63 N on Moon =~ 6

Extra: A ball having a certain mass and-or corresponding weight is thrown at the same force and angle into the sky from both the surface of the Earth and the surface of the Moon. Since the Moon has (1/6) less gravity or downward force, the ball will travel 6 times farther on the Moon than at the surface of the Earth, and before reaching the ground due to the gravity of the Moon.. That is, the ball will also take 6 times longer in time to land on the surface of the Moon. The horizontal velocity of the ball is still the same at both the Earth and the Moon. The vertical velocity just before impacting the surface of the Moon will also be 6 times as less. The force of the impact of an object dropped vertically on the Moon will be 6 times less than that on the Earth when dropped from the same height. F=ma. For the ball to go the farthest horizontally and vertically, the throwing or thrust angle should be 45°, and where the vertical and horizontal velocity components and-or vectors are both equal in value. If the angle is higher, the horizontal distance of travel would be less, and if it was 90° perpendicular or vertical to the horizontal surface, the horizontal distance of travel would be 0. If the angle is less than 45°, the time until it reaches the surface will then be less and it will not travel any further horizontally.

Extra: The gravity on **Mars**: At the surface of Mars, the local gravity is 3.71 m/s^2, and this is about 37.8%, roughly 38% that of Earth's gravity value at it's surface. This value is slightly more than twice that on the surface of the Moon.

The ratio of the gravity on the Mars with respect or in reference to Moon is:
(3.71 m/s^2 on Mars / 1.6333 m/s^2 on Moon) =~ 2.28 time more

Extra: When two masses are small, if the radius or diameter of one increase by a small value, the change in gravity might be considered as negligible. Now consider two planet sized masses, if the radius of one increases by a small value, say 1 foot, this is actually 1 foot over its entire surface area, and the extra volume of matter and-or mass is then very large in value and has actually increased exponentially (consider Area = s^2, and Volume = s^3). When the mass increases by a factor of (n), the force of its gravity will increase by a factor of (n^2). In other words, the force of gravity changes exponentially when mass changes linearly.

Standard Air Pressure And Barometer Values Derivation

When climbers climbed high mountains in the past and even today, they will quickly find that it is more difficult to breath after being just a few thousand feet high, and even after resting there. This is due to that there is just not enough oxygen in each breath, and that they needed more physical effort to even breath in due to the less air pressure which helps inflate the lungs. With less oxygen in each breath, it is a natural reaction to then breather deeper so as to get the oxygen the body needs. They eventually realized that there was a less amount of air at higher altitudes and more air at lower altitudes, and deduced that the air density and-or pressure is greater at lower altitudes, and less at higher altitudes. This is very similar to the anciently known fact that water pressure is likewise greater at the deeper (ie., lower) depths in the water, however, we now know in more modern times that water, being a liquid and much denser than air gas, generally cannot be compressed any further so as for it to be any denser on the atomic or (H2O) molecule level.

Without knowing the specific value of air pressure, it was notice that in a sealed vertical tube, perhaps 35 feet high or higher, that the column of water placed in an open (ie., no seal, no lid) container of water at the bottom end would then always remain at about **33.8ft** high. This is due to the local air pressure having the force (ie,, pressure) to keep that amount of water suspended and not let it drain out of the tube. That is, the air pressure in the local atmosphere and upon the water surface in the container has enough force upon it so as to keep that amount of water from draining out and-or to keep it suspended to that height in the vertical tube. When the force from the air pressure upon the water equals the weight of the water, there is a force and-or pressure are then in balance and the water remaining in the tube will not drain or move out. This volume of water in the vertical tube will calculate to weigh and-or have a pressure of **14.7 pounds per square inch** (14.7psi) at sea level (ie., average sea water level), and which is the a reference height or altitude considered as 0ft. When the air pressure changes, such as due to a local rain storm, the pressure upon the surface of the water in the container will change, and the level of the water in the vertical tube will then change.

It was later found that if the altitude of this **barometer or** air-pressure instrument, increased, then the air pressure decreased. This indicated that air had weight (ie., force and which can cause a pressure upon a surface, P=F/A), and it is also spoken as the vertical column of air had weight (ie., force due to gravity) per unit of area of the surface and air. It was found that air is denser near sea level and thinner (less) at higher altitudes. As mentioned previously, this was noticed by mountain climbers who have difficulty breathing at higher altitudes. It is recommended for hikers and-or travelers of poor health to not increase their elevation by greater than 1 mile in a short amount of time (say less than a few hours hiking, or less than about 25 minutes if traveling in a vehicle) due to the air pressure change and lower amount of oxygen there which can take some time to help try to adjust to while temporarily (say two hours or less, depending on their health) being at that altitude.

Air or air-gas, or any other gas for that matter, density is proportional to the local air pressure, and inversely proportional to the local air temperature. A simplified expression of these mathematical relationships: gas density = air pressure / air temperature.

At the top of Mt. Everest where the air pressure is about 33% of that at sea-level, and the density of air at the top is also about 33% of that of sea-level. Depending on their health and-or altitude, anyone climbing and-or hiking any mountain may require an supplemental oxygen tank with or near to them. It is recommended for inexperienced climbers, walkers, hikers or other physical activity, to first get accustomed to that activity(s) over an amount of time (days, weeks, years) and experiences, and so as to be more physically and psychologically fit, and to prevent health and safety issues.

The derivation of the standard or reference value of air pressure:

1 cubic inch of water = 0.554 fluid ounces = 0.554 fl.oz : a volume measurement
1 cubic inch of water = 1 in^3 of water weighs 0.578 wt-oz = 0.578 oz = 0.036127 lb : as weight and-or equivalent dry ounces of weight

1 cubic centimeter of liquid water (hydrogen and oxygen molecules) = 1 cm^3 is defined as having a total mass of 1g of mass and-or, 1 gram-weight = 1 gram of force at Earth's surface gravity force level.

$\frac{14.7\text{ lb}}{1}\left(\frac{16\text{ oz}}{1\text{ lb}}\right) = 235.2\text{ oz}$: this is the weight of 14.7 pounds of water

$\frac{235.2\text{ oz}}{\frac{0.578\text{ oz}}{\text{in}^3}} = 406.92\text{ in}^3$: this is how many cubic inches in 235.2 oz of water = 14.7 lbs of water

If each of these cubes having a height of 1 in each, was stacked vertically, 12 of them would make a foot high. Here is how many feet high that 406.92 in^3 would be:

$\frac{406.92\text{ in}^3}{\left(\frac{12\text{ in}^3}{1\text{ft}}\right)} = 33.91\text{ feet}$: the height of a vertical column of water at sea level that will cause or induce a pressure of 14.7psi at the bottom of it due to the force of gravity, and this will also be held back and-or suspended at that height in the tube due to the external air pressure of equal value and-or force per unit area.

1 gallon = 1 gal = 128 fl.oz. : a gallon is a volume measurement, and not a weight measurement

Considering that 1 fl.oz volume of water roughly weighs 1 oz = 1 dry ounce of weight, and this is how the British (England) people first defined and used the word "ounces" for both a volume (ie., "fluid volume) and weight a measurement:

128 fluid ounces of water weighs about 128 dry ounces = 128 oz , or that:
128 dry or weight ounces of a substance corresponds to about 128 fluid or weight ounces of water:

$\frac{235.2\text{ oz}}{\left(\frac{128\text{ oz}}{1\text{ gal}}\right)}$ or= $\left(\frac{235.2\text{ oz}}{1}\right)\left(\frac{1\text{ gal}}{128\text{ oz}}\right) = 1.8375\text{ gal}$: 1.8375 gal weighs **14.7 lbs**
Standard Air Pressure at sea level is 14.7 psi
1 gal = 128 floz or wtoz water / (16oz / lb) = 8lb
1.8375 gal = (1.8734 gal) (8 lb / gal) = **14.7 lbs**

If a heavier and-or denser) liquid, such as mercury (Hg), is rather used than water in a barometer, the height of its column will be much less so as to balance with the external standard air pressure at 14.7psi , and this will make the barometer instrument device smaller and more portable, and therefore more practical.

1 in^3 volume of mercury weighs 0.49 lbs = 7.84 oz and this is 13.56 times heavier than 1 in^3 of water.
(14.7 pounds) / (0.49 lbs / 1 in^3) = 30 in^3 , and by the above reasonings, this corresponds to the pressure of 30 vertical inches of mercury (Hg) = 30Hg. 30in = 762mm.

1" = 1 inch = 2.54 cm = 25.4mm

Stormy weather brings a lower pressure to a region (ie., a local area), and for ex., 28in. Hg = 28Hg = 711.2mm.
Low pressure, warm air will rise high into the atmosphere when cool, more dense air displaces it upward, and the moisture in it will eventually condense into rain drops and-or snow in the cooler temperatures higher in the atmosphere. When cool, more dense air replaces the warm air (such as from a storm having some thermal energy), this will cause an increase in the local air pressure, and it will eventually be at the normal and-or average value after the storm(s).

NEWTON'S LAWS OF MOTION

In 1687, **Isaac Newton** presented his celebrated equation for force: **force = (mass) (acceleration) = ma**

Newton, essentially put together what was already known in some ways, but combined and placed the facts together into a simple and valuable equation form, much like how Ohm later made Ohm's law equation based on what was already known in some ways. Newton knew that to move and-or have a speed or velocity of an object or **mass**, a **force** needs to be applied to it. When a force is constantly applied to an object or mass, it will **accelerate** it. Clearly, these values are related in some way, and Newton wrote his formula for their relationship: acceleration = force / mass = a = F / m , and from this we have: F=ma . The velocity (v) or speed of an object is result of, and rooted in the amount of force applied to its mass, hence the energy and acceleration given to that mass. acceleration = (change in velocity) / (change in time) , and which can be simplified to an average-like value having units of: distance per time^2. For ex.: a = (meters / s^2)

Since: F = ma , if either (m) or (a) increases by a factor of (n), then force will increase by that same factor of (n). If mass is a constant, and if F increase by (n), then (a) will increase by that same factor of (n).

1. An object or mass at rest (not moving, no change in location, a speed of 0 if no motion) will continue to be at that same speed and direction unless a force is applied to that object. The force can be an externally applied force such as a push from a person or collision with another mass, or an internal force due to releasing energy from an internal propulsion system (such as using fuel in a rocket motor). A measure of motion is called **momentum** = p = mv. Momentum is generally considered as a measure of the ability to keep moving and-or doing something. Unlike the pure scalar value of kinetic energy with just a magnitude or value in joules , momentum is a vector quantity with both a magnitude and direction, and of which can be considered as a hypotenuse side of a triangle, and analyzed using the two component (ie., causing, constructing, contributing) momentum vectors considered as the right sides of a corresponding triangle which can be solved for using the Pythagorean Theorem..

2. The speed of an object or mass will usually change when a force is applied to it. The force or impact from a moving mass applies and transfers energy (here, kinetic energy, KE) to that object. This change in speed is called **acceleration** (ie., accelerate, a = F / m) if it is an increase in speed or velocity, and called **deceleration** (a = -F / m = -a) if it is a decrease in speed or velocity. A deceleration will cause a loss in velocity, and may be expressed as a "slowing" of the object. Acceleration is generally given a mathematical positive sign, and **deceleration** which is essentially the opposite or negative of acceleration is therefore given a negative sign. Once the force is no longer applied, there will be no more application of energy to that object, and therefore no further gains or losses in energy (ie. kinetic or motional energy) of that object, and no further acceleration or change in the objects velocity. The object will remain at the same speed and direction, and this may even be a circular or elliptical direction and orbit about another planet or object.

3. When a force is applied to an object, there is an equal and opposite force from that object. This could perhaps be roughly considered as a force or resistance to a change in motion. A simple example of an equal and opposite force would be when a spring is compressed or expanded by a force, and at the same time of doing this, it is also trying to expand or compress back to its original, stabilized size with that same value of force. The energy used to create that force to compress the spring is transferred to and stored as ("potential") energy in the molecules of that compressed spring. The energy in the spring can generally (ie., without other issues) be stored indefinitely and be applied and transferred to another object by its internal and-or potential force.

When an astronaut is in outer-space, that astronaut is traveling at the same speed as the space station and all other objects in it. Surely they are traveling fast in space, but when they travel at the same speed (horizontally and vertically [free-falling downward due to gravity alone]), the difference in the vertical and-or horizontal speeds of the objects and people is 0. It could be said that the astronaut and objects have the same relative speed, and that their actual spacecraft orbit or traveling speed then appears to have no effect on them. While in orbit they will not reduce in altitude due to free-falling downward because the distance they effectively travel over the level horizon and curving (downward) Earth effectively increases their height above the Earth by this same value that they fall downward for each unit of time. If an astronaut applies a force to a (seemingly, effectively) "weightless" (but not mass-less) object in space, so as to give it a push or pull, there is still an equal and opposite force applied back to the astronaut from that object. This force is equal to: force = (mass)(acceleration). As long as the force is applied, there will always be energy transferred to the object and it will accelerate (from F=ma, a=F/m) and increase in speed, and the equal and opposite force will be felt by the astronaut. If an astronaut is braced in or on a spacecraft and has their motion stabilized, it is much easier for them to move and control an object.

Friction, essentially a mechanical-like collision of two surfaces and-or force in the opposite direction that consumes, depletes and-or wastes some of the energy available and-or used to do something like move a box across the floor or rug. For an object, perhaps a bicycle, car, boat or train to continue with the same initial amount velocity and-or momentum, this amount of wasted or lost energy due to friction must be continually replaced, and if not, that object will continue to decelerate in velocity or speed and will eventually stop moving. A typical gasoline or petrol fueled car might loose a total of about 80% of its fuel energy, and-or 50% of its available engine combustion energy to various (mechanical) internal energy losses due to friction such as in its gears and wheels. A typical electric car which has less mechanical parts might only loose 25% of its available battery energy to various internal electrical and mechanical friction losses. A moving vehicle with a given weight, area size, and an amount of kinetic energy and-or power will loose up to about 20% of that energy or power due to roadway friction and wind (ie., air mass which can apply a force) resistance, and of which are sometimes called as moving or rolling friction. Energy wasted due to friction (force) is usually converted to heat energy.

In outer-space, there is generally no friction between two surfaces, and so an object will continue in its motion (velocity, direction) unless it is affected by gravity which is a force upon it.; and technically, space is filled with various amounts of weak or low-level gravity from distant objects (asteroids, planets, stars, galaxies, nebula) in space. When this gravity (ie., a force) is constantly applied to an object, it will eventually change its course (ie., direction) or velocity.

With a force (the application and transfer of energy), an object such as a ball can gain kinetic energy and travel upward (vertically) into the air. During its flight upward, there is a constant force of gravity on that object or mass. This force equals the weight of that mass. For an object to even travel upward, the applied force = (ma) must be more than the weight = (ma)=(mg) of that object. As the object goes upward, this constant, gravitational downward pull upon the object is effectively applying energy and a force in the opposite direction to that of the upward direction of the object. The object will gradually decelerate or loose speed and kinetic energy due to this constant gravitational force applied to it. Since momentum = mv, the object will loose momentum when it looses its speed. When the kinetic energy (KE) of the object finally reduces to 0, and-or its vertical momentum is reduced to 0, the object will stop moving upwards and will then start going downwards since the downward force of gravity is still acting on it and influencing its motion. While at its maximum height, all of the energy to place it there has been converted to what is called as **gravitational potential energy** (**GPE**). As the object falls toward the ground, it will then gradually gain kinetic energy (KE = mv^2 / 2) due to the force of gravity constantly affecting it and accelerating it towards the ground. If the energy losses in this system are small: Energy Out = Energy In , and just before it returns to the initial launch point and lands. If the object had a rocket engine to provide a force equal to its weight, that object would be able to hover (be suspended, not moving) in the air, or to land slowly (a low velocity) when the force created by the rocket engine is slightly less than the weight of the object.

More about momentum and kinetic energy:

If an object if forced or thrown not only upward, but farther away outward or more distant, hence to move at an angle at some value between horizontal (level) and vertical (upward), the object will have both a vertical velocity and a horizontal velocity. Its motion will have both a horizontal component of motion, and which is called a vector (both a ["scaler"] amount, and direction or angle), and a vertical component of motion or vector. Momentum (p = mv) is formally a vector because its factor of velocity can be formally described as a vector. Its motion and-or momentum (mv) will have two component vectors: a horizontal momentum = px = (m vx), and a vertical momentum = pv = (m vy). Its forward motion and-or momentum can then be described as a resultant director of its two component vectors and-or vice versa. These three vectors can be analyzed and-or calculated using right angle trigonometry. For an object moving vertically, its upward or vertical momentum will be changing and-or reducing due to gravity, however, it will regain that lost momentum as it travels toward the ground. The total energy of the object cannot exceed the input energy: Energy Total = KE + GPE , and when either KE or GPE is gained, there is a loss or reduction in the other variable. For example: KE = Energy Total - GPE

Ex. How much energy is needed to make a 1kg mass travel at 100 km/hr , and-or 100km/hr faster?

We see that the question is essentially asking for the input energy, and we are given some factors of its output energy.

First, velocity or speed = $\frac{\text{distance}}{\text{time}} = \frac{100\text{km}}{1\text{hr}} = \frac{100\text{km}}{3600\text{s}} = \frac{0.02778\text{ km}}{1\text{s}} = \frac{27.78\text{m}}{1\text{s}}$

If KE out = KE in , = KE = mv^2 / 2 = (1kg)(100 km/hr)^2 / 2 = (1kg)(27.78 m/s)^2 / 2 =~ (1kg)(772 m^2/s^2) / 2 =

= (mass)(m/s^2)(m) / 2 = ((mass)(acceleration)) (distance) / 2 = (force) (distance) / 2 = N-m / 2 = work / 2 = energy / 2 = 386J

COMMON EQUATIONS FOR MOTION

The study of motion is also called kinematics, and the equations for motion are also called **kinematic** equations or **kinetic equations** since the word: "kinetic" is an old Greek word that means movement. These equations include one or more variables, and often three variables with one being the result: The main variables are distance (d), velocity (v) or speed, and time (t). A fourth variable used for some more advanced calculations is acceleration (a). Some of these equations were previously mentioned in this book, and this is a more general analysis or discussion.

d = distance = length . When an object changed or is changes location from a given reference location, it has moved or is moving to another location. This change can be called and measured as the distance (d) or displacement value of the object. Consider that a car can went along a winding road for several miles of traveling length or distance. It is then of note that on a map, this distance the car traveled is usually not the same as the straight line (ie. the shortest distance) distance between the starting and ending locations. Due to these reasonings, there is then two distance concepts to consider, and where one distance is during the process, and of any length and in any direction, and the other distance is due to the resulting location in a three dimensional, point coordinate (X, Y , Z) system, and having a (linear, line, straight when graphed) distance from the starting reference location, and this distance can also be shown to have a corresponding direction and-or angle on a graph.

If the total distance is due to several smaller distances, either all the same length or of various lengths, the total distance is the sum of those smaller, (travel) segments or partial distances:

total distance = segment1 + segment2 + ... = length1 + length2 + ... = dt = d0 + d1 + d2 + ...

There is a length difference or change in distance between each successive distance segment, and this can be expressed as:

(change in distance) = (dn+1 - dn) , mathematically:

dn+1 = dn + (change in distance) = dn + Δ dn : the triangle means "a change of" or "a change in" and it is also called the delta or change symbol.

A common generalization of this is often:

(change in distance) = (d1 - d0) or (change in distance) = (d2 - d1) , etc.

Also discussed in this article is: velocity (v) or speed (s), time (t), and acceleration (a) and also when it is a gravitational acceleration (a=g) due to the gravity of Earth and when an object is in "free-fall" (in the force of gravity only) from a height. Gravitational acceleration gets its name from that the force of Earth's gravity is (constantly) applied to objects near to it, and that force will therefore (constantly) transfer more (kinetic) energy to that object as long as the force is applied to it, and therefore it will cause the object to constantly increase its speed or velocity. An change that is an increase in speed or velocity is called an **acceleration** (ie., to accelerate, constantly increasing in value) of velocity.

The most common and basic equation for motion is the distance equation:

First, it is obvious that it will take an amount of time (t) to go or travel a distance. If we make this into a ratio, we can find the (average) distance traveled per unit of time:

$\frac{\text{distance}}{t}$ = distance traveled per unit of time = a rate of the change in distance , lets call it velocity (v)
The units of velocity are then those used for: (d / t), and velocity is than describe as the rate of change of distance with respect to a change in time and-or time taken.

While traveling this distance, we will go a certain speed or velocity which is determined by the amount of engine power used. The above formula can be rearranged to show that distance is the product of both velocity (v) and time (t) :

distance = (speed) (time) = (velocity) (time) = v t : this is a linear equation of the form: $y = mx$, and here,
m = speed or velocity = (change in distance / change in time)
= the slope of a line. If the velocity is not constant, the slope will no longer be constant as it is for a true line on a graph.
This also does not necessisarilly mean that the object has changed direction either, and it may be headed in the same direction at just a different speed.

From the above equation we see that mathematically, speed or velocity is the rate of change of distance with respect to time and is the (m) variable.

d = (velocity) (time) = (change in distance / change in time) (time) = m t

$d = v t$ and mathematically:

$v = d / t$: speed or velocity is the rate of the (change in distance) with respect to (time), or more precisely stated as: velocity = (change in distance) / (change in time)

$t = d / v$ **:** time of travel , or = $t = (1/v) d$

The units for distance (d) are usually: miles (mi), feet (ft), meters (m) or kilometers (km)
The units for time (t) are usually: hours (hr) or seconds (s), but may occasionally be minutes (min.)
The units for speed (v) are therefore a distance unit divided by a time unit. Speed or velocity is a rate or ratio value that can be considered as the average distance moved per unit of the time duration considered.

Graphing distance versus time

For some assistance, please view the next FIGURE shown below before and during this discussion.

As mentioned above and in various other articles in this book: $d = v t$ or (distance) = (velocity) (time) has the basic format of a linear equation such as:

(dependent variable) = a (independent variable), and where (a) is a multiplying factor , but may also be a value of (1) and in that special case, the line is a horizontal line with a slope of 0.

$y = mx + b$, and where m is the slope (ie., steepness, angle) of the line that is equal to: $m = (y - b) / x$ =
m = (change in y) / (change in x) , and which can be reduced to the equivalent fraction and-or concept of :
m = (change in y) per (1 unit change in x).

A linear equation such as $d = v t$ will always graph as a line. Here, (v) is the slope of this line.
v = (change in distance) / (change in time) . The higher v is, the more vertical the line will be when placed on a graph.

If a moving object is accelerating, then (v) will not be constant, but will be increasing, or decreasing such as when the object is experiencing a deceleration. When an accelerating object is graphed, it will not appear as a line, but as a curved upward or more vertical during the time it was accelerating, and this is due to that when the velocity increases, the distance traveled for each unit of time will also increase.

a = (change in velocity) / (change in time) = ((change in distance) / (change in time)) **/** (change in time)
a = (change in distance) / (change in time)^2 = v t

$v = a / t$: and if a=0, the object will still retain its last velocity value

On a graph of a curve such as $y = x^2$, and which has an upward curve shape of a basic parabola, it can likewise be said that the rate of change of (y) with respect to (x) is not constant. Here, slope of the curve at any point along it is constantly increasing as (x) increases. It could be said here that (y) is accelerating in value with respect, or in reference to, (x)

.

If there was an initial distance involved:

dt = ending distance or total distance = starting distance + (change in distance)

In this cause you cold assign say d0 as the starting distance of which can then be considered as part of the total distance..

Expressing each distance value with their corresponding velocity and time values:

$$dt = d0 + d1 = (v0\ t0) + (v1\ t1)$$

Given $d = v\ t$, if either (v) or (t) increase by a factor of (n) when (t) is constant, (d) will likewise increase by that same factor of (n), and this keeps the equation in balance. For example, for an object to travel twice (n=2, double) as far or distant during the same amount of time, its velocity will have to double.

$dt = d1\ v1$, after multiplying each side by 2:

$(2\ dt) = d1\ (2\ v1)$

If an object is at rest (ie., not moving), its velocity is 0. For an object to start moving, some force must be applied to it and until a certain desired speed is reached, and then the force no longer needs to be applied. If there is a friction force reducing the kinetic energy and-or velocity, then some small force will then need to be applied. Between 0 and that certain desired speed, the object is increasing in speed when a force is constantly applied. If the force is constant, the acceleration will be constant: $a = F / m$. It is said that its speed or velocity of the object is changing per unit of time, and this is called an acceleration (or acceleration, and increasing of or in its velocity) of the objects motion and-or its speed: When the force applied to an object stops, its acceleration will stop and its velocity will ream its last value and continue to move such as either in an orbit about a planet or other mass, or in a strait line across a smooth floor, or to a distant planet, other mass or location.

ending velocity = initial velocity + change in velocity : this will be shown to be: v = initial velocity + (at)

$v1 = v0 + \Delta v$: mathematically: $\Delta v = (v1 - V0) = a\ t$

The change in velocity per unit time is called acceleration (a). **Acceleration** (a) is calculated as the rate of a change of speed or velocity with respect to the time used or taken, hence the amount or change in time needed to make that change in velocity. For a velocity of an object to change, there needs to be an acceleration of the objects motion, and this is done by applying a force to it: $F = ma$. , and then (change in velocity) = a (change in time) or simply: (change in velocity) = a t

Let: (change in velocity) = (v1 - v0) , if v0 = 0 , (change in velocity) = (v1 - 0) = v1

Let: (change in time) = (ending time - starting time) = (t1- t0) , if t0 = 0 , (change in time) = (t1 - 0) = t1

Letting: v = v1, and t = t1:

$$a = \frac{\text{(change in velocity)}}{\text{(change in time)}} = \frac{v}{t} = \frac{(d / t)}{t} = \frac{\mathbf{d}}{\mathbf{t^2}}$$

with units of: **(m / s^2)** , also note, **v = at**

Note also: **d = a t^2** , $a = d / t^2$, $t = \sqrt{d / a}$

Ex.: $a = g = \frac{9.81m}{s^2}$: (constant) gravitational acceleration of the Earth near its surface, due to the constant amount of force of gravity near its surface. Can be expressed as: 9.81 m / s^2

velocity = (acceleration) (time) = at : from the general equation of: a = v / t

From: force = (mass) (acceleration) = ma , we can then have:

v = at = (force / mass) t = f t / m ,

Clearly, the smaller the mass for a given applied force, the greater the velocity, and the greater and-or longer the time that the force is applied, the greater the velocity. The greater the force, the greater the velocity, and even its only a quick pulse or a brief impact applied to the object.

a = (change in velocity) / t : when t = t2 and t1=0, mathematically:

(change in velocity) = (v1 - v0) = at , if the initial velocity v0 was 0, and letting v = v1, the new velocity is:

v = d / t = at , i f the acceleration was due to the constant force of gravity causing a (gravitational) acceleration;
(a) = (g) of Earth and applied to an object or mass: (g) on Earth = 32.2 ft/s^2 = 9.81m/s^2
a t = g t = F t / m = (Weight)(t) / m , g = W / m

d = vt = (at)t = at^2 or= gt^2 when considering an object dropped from a height and being affected by the constant force of gravity, its velocity will accelerate and-or have an acceleration or constant increase of it. The distance an object will fall is related to the square of the time (t) it is falling, and this will result in an exponential increase in the distance traveled per unit of time.
g = d / t^2 , d = gt^2 = (W/m) t^2

If the object started out at velocity of 0 and was constantly accelerating at a certain value due to a constantly applied value of force, its velocity will be constantly changing; here an increase, and we must then use the average velocity to find the distance traveled since the ending velocity (v1) = (v0 + Δv) = (initial velocity + change in velocity) was not consistent or constant throughout the total time of travel so as to simply use: d = v t, and now due to acceleration being involved into the velocity and distance, we must then use something like:
d = (vav)(t) = ((v1 - v0) t) / 2 = (v1 - 0) t / 2 = v1 t / 2 = v t / 2 when the acceleration is a constant value.
Also, when an acceleration is involved: **d = vav t = v t / 2 = g t^2 / 2 = a t^2 / 2**

If an object had an initial distance (d0) associated with it at t=0:
dt = (d0 + d1) = (v0 t + a t^2 / 2) = (v0 t + g t^2 / 2) = (d0 + g t^2 / 2)

When V0 = 0, and the acceleration is a constant value, the average velocity = vav = v1 / 2 = v / 2 = at / 2 ,
or: **vav = (v1 - V0) / 2** when the acceleration is constant. Also: v = at = 2 vav , a = v / t = 2 vav / t
average velocity = vav is not a constant between various points of travel or motion since acceleration is causing the velocity to constantly increase.

Letting d = v / t = (vav)(t) be expressed as: **d** = v/2 t = v t / 2 = (at) t / 2 = **(at^2) / 2** :
Also:: d = v t = (vav) (t) = (v1 / 2) (t) , we have **v1 = 2d / t** * : where v0 = 0 and t0=0
d = v t = vav t = (a t) (t) / 2 = (a t^2) / 2 **= g t^2 / 2** : or= 0.5 at^2 = (gt^2) / 2 or= **0.5 gt^2**

Ex. **For a free-falling object in Earth's gravity (g = a):**

After 1 second of time, a free falling object will travel:
d = (0.5) g t^2 = (0.5) (32.2 ft/1s^2) (1s)^2 =~ 16.1ft = 4.9 m
v = 2d / t = 2 (4.9m) / 1s = 9.8 m / 1s = 32.2 ft / 1s : note , v = 2d / t = g t = a t

Ex. After 2 seconds of time, a free falling object will travel:
d = (0.5)(32.2 ft/1s^2)(2s)^2 =~ 64.4 ft = 19.6m

v = 2d / t = 2 (19.6m) / 2s = 19.6 m/s = 64.4 ft / s

Ex. After 3 seconds of time, a free falling object will travel:
d = (0.5)(32.2 ft/1s^2)(3s)^2 =~ 145 ft = 44.1m
v = 2d / t = 2 (145 ft) / 3 =~ 96.6 ft / s = 29.4 m / s

Ex. After 4 seconds of time, a free falling object will travel:
d = (0.5)(32.2 ft/1s^2)(4s)^2 =~ 258 ft = 78.4m
v = 2d / t = 2 (258 ft) / 4 =~ 129 ft / s = 39.3m / s

Notice in the examples above that when the time (t) doubles = (2t), that the total distance traveled will increase by **4** due to that the time variable is squared in the equation:
Ex.: (t)^2 = 1t^2 and (2t)^2 = 4t^2 , and these have a ratio of: 4t^2 / 1t^2 = 4

Notice also in the examples above that vav = 2d / t = a t , and that v = d / t = at is a linear-like equation.

From the above equation for (d) = (at^2) / 2, we can solve for (t) with units of seconds (s):

$$\mathbf{t = \sqrt{\frac{2d}{a}} = \sqrt{\frac{2\,d\,ft}{32.2ft/s^2}} = (0.249222\underline{4})\sqrt{dft}\ \ s}$$

: here, dft = distance in feet, but unit-less
: the units of dft and (a=g) must be the same.

If g = a = 9.8m/s^2 was used:

$$\mathbf{t = (0.45175\underline{4})\sqrt{(dm)}\ \ s}$$

: here, dm = distance in meters, but unit-less

From v = a t = g t , we can also find (t) as:

$$\mathbf{t = \frac{v}{g} = \frac{v}{a}}$$

Extra: Setting the two equations for (t) as equal, it can be shown that : $v = \sqrt{2dg} = \sqrt{2da}$

It is clearly seen in the above formula that time is directly related to the distance of travel, and inversely related to the acceleration since a higher acceleration means that a higher velocity and the faster it will take to travel or move a given distance and, therefore, the time needed is shorter or less. The (ft) and (meters) units are shown in the equations above as reminders of what (unitless) value to place there, and that those units are not in the result, and only the seconds = (s) is.

Ex. How long will it take a free-fall object starting out with 0 speed, and to then travel downward a distance of 9.8m = 32.2ft ? (Note that 1m = $3.28\underline{1}$ft and 1ft. = 0.3048m)

$t = (0.451754)\sqrt{(9.8m)}$ seconds
t = 1.414 s : it took longer than 1s because its initial velocity or speed was 0. and:
When t = 1s: d = 4.905m =~ 16.$\underline{1}$ ft when the object starts at 0 speed.
This value is half of: 9.81 m =~ 32.2 ft
At the 1 second point, that the velocity of the object has reached 9.8m/s, and after the object has accelerated to that speed from a speed of 0m/s.
d = a t^2 / 2 = g t^2 / 2 = (9.81 m/s^2 / 2) t^2 = (4.905 m/s^2) (t^2) meters

Ex. If an object of any size mass is traveling horizontally and at any velocity, the force of gravity will constantly give that mass some kinetic energy and cause it to move vertically downward at an increasing speed when that gravitational force is constantly applied. The constant gravitational force will cause it to accelerate its velocity by a = g = 9.8 m/s^2 = 32.2 ft/s^2. The distance it actually moves per unit of time, say after 1 second, depends on its velocity at a given instance in time, and of which the velocity is constantly changing and increasing. Starting at 0s where its velocity is 0m/s, how long will it take for the object to move 1ft = (12 in)(2.54cm/in) = 30.48cm = 0.3048m?

First: When an object is dropped from a height above the ground considered as height=h=0 units, and in the presence of Earth's constant amount of gravity at those heights, it will experience a constant amount of force applied to it before it reaches the ground. Because this force is constantly applied, the object will gain more kinetic energy (KE = mv^2 /2) and therefore, its speed will constantly increase, and this is called an acceleration in its speed or velocity. Since the force (f = ma) is constant, the acceleration (a = F / m) will be constant and not increasing like the velocity does. The change in velocity will increase for each change in time. a = (change in velocity) / (change in time) , ex: a = (v1 - v0) / (t1 - t0), and acceleration (a=g) is constant in Earth's gravity. Since velocity is changing or increasing per unit of time, the distance moved per unit of time is also increasing: (a change in distance) = (change in velocity) (change in time) which can be mathematically reduced or simplified by dividing each side by the same value, and resulting to: d = (changed in velocity) (1t unit) = (change in velocity) (1s) , but since the velocity is constantly changing, we should rather use the average velocity between the starting and ending velocity per unit of time:

d = vav t = v1 / 2 t = ((a t) / 2) t = a t^2 / 2 : = gt^2 / 2 in earths gravity, and object free fall in it

$$t = \sqrt{\frac{2d}{g}} = \sqrt{\frac{(2)\ 0.3048m}{\frac{9.8m}{1s^2}}} =\sim 0.2494 \text{ s} =\sim 250\ (10^{-3}) \text{ s} = 250 \text{ milliseconds} = 250 \text{ ms}$$

Ex. If an object, vehicle or spacecraft started out at 0 m/s and ended at 100 m/s after 10s of time, what was its (assumed constant, such as due to a constantly applied amount of force) acceleration during that time?

Clearly, the object got faster in speed or velocity during that time of travel. Since it got faster and gained kinetic energy, some energy must of been applied and transferred to it, and this is usually done by an external force, or an internal engine producing a force. If the force was a constant value applied during this amount of time, the acceleration also had a constant value during this amount of time. a = f / m and f=ma. When a force (ie., the application and-or transfer of energy) is applied to an object, that object will accelerate and gain speed or velocity and kinetic energy.

acceleration = a = (change in velocity) / (change in time)
= (v1 - v0) / (t1 - t0) = (100 m/s - 0m/s) / (10s - 0s) = 100m/s / 10s = 10m/s^2

ending velocity = (initial velocity) + (change in velocity)
v2 = v0 + v1
v2 = 0m/s + at : from: a = (change in velocity) / (change in time), if v1=0 and t1=0:
a = (v1 - v0) / (t1 - t0) = (v1-0) / (t1-0) = v1/t1 = v / t , and v=at
v2 = v = 100m/s = at

acceleration = ending velocity / (time considered for the acceleration) = v / t = 100m/s / 10s = 10m/s^2

The velocity of the craft after 5s is:
v2 = v0 + v1 = 0m/s + at = 0m/s + (10m/s^2) (5s) = 50m/s

The velocity of the craft after 6s is:
v2 = v0 + v1 = 0m/s + at = 0m/s + (10m/s^2) (6s) = 60m/s = 50m/s + 10 m/s

Notice that after each 1 second of time, that the velocity of the object changed (here an increase) by +10 m/s more. Because the velocity is changing and is accelerating in value, the distance traveled per unit of time will also change and constantly accelerate or increase in value.

Ex. If a vehicle had a mass of 1000kg, what would be the constantly applied force needed to accelerate it at 10m/s^2?

Form: (force) = (mass)(acceleration) = f = ma , we have:
f = (1000kg)(10m/s^2) = 10000 kg-m / s^2 = 10000 Newtons (= 10000N) of force

Extra: Energy and-or Work needed in = Energy and-or Work out = F d
and here it is: F d = (10000N) (distance in meters) j = (10000)(dm) joules

Power in = Poiwer out , P = joules of energy needed or used / second = Pwatts = Pw

For the above example: Pw = (10000)(dm) / s : with units of watts

If a craft (ie., a vehicle) is slowing down in speed, it is decelerating (ie., and (a) will be negative in value, hence (-a)) due to a force applied to it in the opposite direction to its motion and reducing its velocity. Its ending velocity, and-or its velocity after an amount of time is:

ending velocity = (initial velocity) + (change in velocity) , since the change in velocity is a decrease, this is expressed using a negative sign:

ending velocity = (initial velocity) + (- change in velocity) , and which can be simplified as:
ending velocity = initial velocity - change in velocity
v2 = v0 - v1 = v0 - (at) = v0 - at : here for example, V0 might be say 100m/s

If a rocket moving at 30 m/s then had two different values of accelerations, say a1 = 10m/s^2, and a2 = 20m/s^2, how fast would the object be traveling if a1 lasted 5s, and a2 lasted 7s:

vt = initial velocity + (increase1 in velocity) + (increase2 in velocity) : increase = (a change)
vt = v0 + v1 + v2 = v0 + (a1 t1) + (a2 t2) = (30 m/s) + (10m/s^2)(5s) + (20m/s^s)(7s)
vt = (30m/s) + (50m/s) + (140m/s) = (30 + 50 + 140) m/s
vt = 220 m/s

A helpful note about acceleration:

From F = m a , if an object has a factor of (n) times more mass (m), then the force required to accelerate it to the same amount of acceleration will need to be increased by that same factor of (n);

(10) F = (10 m) a , mathematically:

a = (10 F) / (10 a) = F / m

A helpful note about inertia:

If the acceleration applied to the larger mass is still the same original acceleration value as that of the smaller mass, then that larger mass will then accelerate much slower and travel at a slower velocity than the original mass with less value. It could then be said in this comparative situation, that the larger mass has more resistance or **inertia** to motion when the same amount of force is applied. Since motion can be relative, it can also be said that a moving object even has resistance or inertial to a change in motion, and particularly so when its momentum (p=mv) and-or kinetic energy (KE = mv^2 /2) is already high and the force applied to it is in the opposite direction of its motion so as to slow it down and-or reverse its direction.

Due to the inertia of the mass of an object, if the acceleration changes, say increases due to an increase in the applied force, it will take some amount of time **(t)** for the object to reach its intended, or final speed, and of where there is no further acceleration and the object will be traveling at the new intended higher speed. An object such as a ship in water will experience the drag-force (ie., friction [much like micro-collisions], resistance, interference) of the water molecules and it will reduce the craft's kinetic energy and speed due to colliding with the water and transferring some of its kinetic energy to those water molecules and pushing (ie., a force applied) it aside. The ships engine will have to then provided enough constant energy to produce an extra amount of force just so as to maintain its speed at a certain desired and-or constant value. In space, there is usually no drag forces for a spacecraft to encounter, but occasionally, high velocity collisions with some gas atoms will cause a small drag force and corresponding small reduction in speed, particularly when the craft is at a low orbit about Earth, and it collides more frequently with some atoms of Earth's thin (low density) atmosphere. So that a craft does not slow too much in velocity and go lower than its desired orbit it will occasionally need to use its rocket engines to raise it back up higher in altitude to its intended orbit If not, it will eventually fall out of its natural orbit and return to Earth.

If an object is to change (ie., measured as a difference, such as (v1 - v0)) to a new speed (ex., v1 = v0 + change in speed), the larger the desired change in speed, the more time it will take to reach that speed for a given amount of force applied and-or acceleration. Although acceleration can change almost instantly to a new value if a force is applied, the larger the mass of the object, the more inertia (ie., resistance to a change in momentum or motion) it will have and the longer it will take to reach a desired speed or velocity if the force applied is the same original value creating the acceleration. .

From: **Force = F = ma** and **a = F / m = (change in v) / (change in t)** **and-or:**
F = (mass) (acceleration) = m (change in v) / (change in t) = m (d / t) / t = m d / t^2

acceleration = a = v / t = F / m = (force / mass) = (change in velocity) / (change in time) , we have:
(change in time) = (time) = **(t)** = v / a = (change in velocity) **/** (acceleration) = (change in velocity) (m / F)

As can be seen by the equation above, the higher the force and-or acceleration, the less time it will take to change to a new desired speed or velocity, and this is an inverse mathematical relationship. The larger the mass (m), the more time it will take for it to change in velocity. The larger the change in velocity, the more time it will also take to have a desired velocity:

(change in time) = (t) = (change in v) m / F and: (change in v) = F (change in time) / m

The total energy of an object can be described as equal to the sum of its existing kinetic energy and potential or stored energy. If an object is not moving, it has 0 kinetic energy, hence = 0 Joules of kinetic energy (KE).

From: Work = Energy = Joules (J) = (force)(distance) = F d , we have: F = J / d and d = J / F

Total energy of an object: (besides its thermal and other possible energy), hence this value of energy is due to its motion only.

Et = KE + PE : Joules : PE is usually called **GPE** = **Gravitational Potential Energy** if the stored energy is due to its height above the ground, and its mass will be influenced by the gravity (force) field of Earth and its force and associated acceleration, and will change (increase) its amount of speed and, and therefore increase in its kinetic energy it falls toward Earths mass.

KE = Et - PE and PE = Et - KE

As the object falls, it looses its potential energy due to its height and PE value being less, however, its speed increases and therefore, its kinetic energy (KE) increases. The total energy of the object is still the same and is said to be "conserved" (ie., maintained, a constant) since the energy put into that system, such as raising it to a certain height or distance remains stored with that system until some or all of it is transferred ("used up") to KE and-or converted to work ((force x distance) Joules)) when it collides with something.

If energy is used (ie., transferred, work) to raise an object or mas (m) to a height (h) on Earth, its potential energy is:

PE = work = fd = (ma)(h) = mgh , Joules : mass in kilogram units, g=9.8m/s^2, height with meter units, and its kinetic energy is: KE=0 Joules when not moving. If it is then allowed to free-fall under the force of gravity only, all of its potential energy will of been converted or transformed to its (available) kinetic energy just before it reaches the ground at height=0 and then impacts the ground with that energy and its associated impact or collision force = (m)(-a).

Ex. How much GPE does 1kg and-or each kilogram of mass of an object have at 100 km high in altitude have?

GPE = mgh = (1kg)(9.8m/s^2)(100km) = (1kg)(9.8m/s^2)((1km)(100) = (1kg)(9.8m/s^2)(1000m)(100) =
= (1kg)(9.8m/s^2)(100000 m) =~ (1kg)(980000 m) joules =~ 1000000 J =~ 1 MJ

> Since this equation is linear to altitude or mass, an object twice as high or twice as massive will have twice the GPE and-or require that much energy to lift it that high.

KE max = PE max :Just before reaching the ground where PE=0, and all of its GPE energy was converted to KE.

$\frac{mv^2}{2} = mgh$:from this we can solve for (v), and here, it is the object's velocity just before reaching the ground: Note that mathematically, after multiplying both sides by 2: mv^2 = 2mgh , and after dividing both sides by m: v^2 = 2gh = (acceleration)(distance) , checking: (M/s^2)(M) = (M^2 / s^2) = (M/s)^2 = d/ t = v^2 , (here, let **M** = **M**eter units of distance)

Note that: GPE = mgh = (mg) (h) = (weight)(h) = (Force)(height) or= (Force)(vertical distance) = work

$\frac{mv^2}{2} = mgh$, from this we can solve for (v), and here, it is the object's velocity just before reaching the ground:

$v = \sqrt{2gh} = at$: velocity of a free falling object just before impact or reaching the ground. The square root of (2g) is a constant.

velocity (meters/second) = $\sqrt{(2)(9.8)\text{m/s}^2 \text{ (height m)}}$ = $\sqrt{(19.6)\text{ (height) m}^2 / \text{s}^2}$

velocity (meters/second) = $4.427\underline{2}$ m/s $\sqrt{\text{height m}}$: use a height that is an absolute value of meters

velocity (feet/second) = $8.02\underline{5}$ ft./s $\sqrt{\text{height}}$: use a height that is an absolute value of feet
: due to using: g=32.2ft/s^2

$h = \frac{v^2}{2g}$: here, (2)(g) = 2 (9.81 m/s^2) = 19.62 m/s^2 = 2 (32.2 ft/s^2) = 64.4 ft/s^2

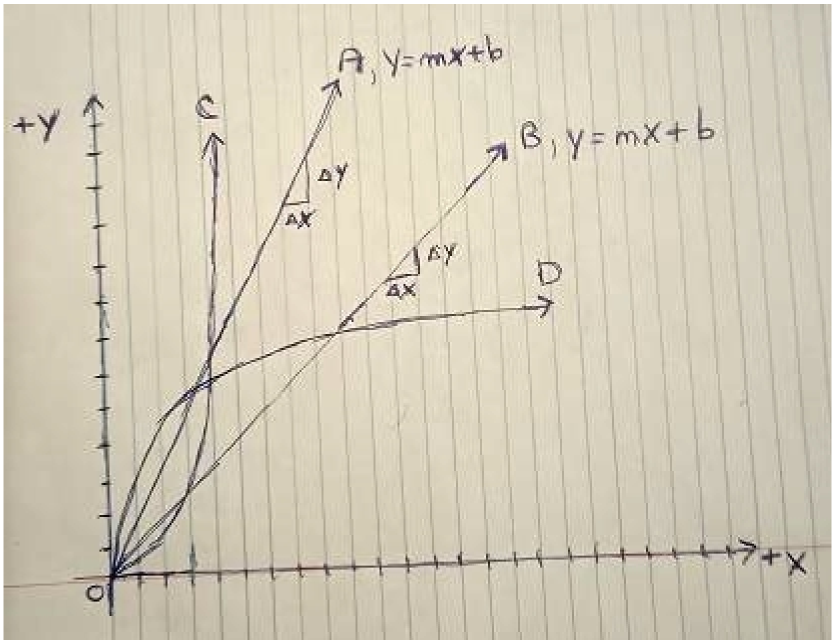
g = v^2 / 2h : "extra"

In general, for a moving object to go slower, it must loose some KE, and to go faster, it must gain some KE. To change speed, an acceleration (or deceleration) of the object must first take place. To cause an acceleration of an object, a force must be first be applied to the object so as to increase or decrease its momentum (p=mv) = KE (mv^2 / 2). Force is the application of energy to an object and can be measured as:

Force = (mass)(acceleration). and acceleration = Force / mass

Using the above formula, mass can be defined as: mass = Force / acceleration , and if there is less acceleration of the object when a given force is applied, the more mass of that object. More massive objects have more **inertia** or resistance to a change in movement, and are therefore more difficult to accelerate it to a given speed or velocity for a given amount of force.

[FIG 249B]



In the above figure, A and B indicate the lines graphed from linear equations. Line A is more vertical in nature and has a higher slope than that of line B. For each unit increase in X, the corresponding change in Y for line A is greater. C indicates a curve such as a parabola or exponential equation, and-or an object that is accelerating and its velocity is getting faster and faster per unit of time which would be the horizontal axis, and velocity as the vertical axis. D shows a deceleration in distance moved per unit of time, and is similar to a graph of a logarithmic or root type of equation, or possibly an exponential equation where the exponent is less than 1, and if it keeps up, the velocity will be 0, and the distance = y will not increase in value over a unit of time, etc.. For a linear equation, the slope is constant, and the line will continue to point into the same direction, and it will not curve towards a new direction. Again, for a line equation:
y = mx + b, the value of b can be 0, and omitted, and even the value of m can be 1 and omitted, leaving the equation y = x.

A Note About Common Weight Scales And Gravity

Most "weighing scales" such as most modern digital scales for home and everyday use, do sense the weight or (gravitational induced) force of the object placed upon it, however, the result displayed is its corresponding mass value. After all, grams and kilograms are (in the modern, technical sense) amounts of mass and not weight. A 1kg of mass actually weighs 9.8 Newtons (of Force) on Earth. In a reverse manner, a 9.8N weight (ie., a force) corresponds to 1kg of mass on the Earth. The machine or "scale" is essentially calibrated (ie., adjusted, set) to automatically divide the weight by 9.8 so as to find the equivalent amount of grams or kilograms, and then it displays that mass result. force = weight = (mass)(acceleration), therefore, mass = (weight / acceleration). People may say that this is the objects "weight", but it is actually the sensed weight converted to and expressed as its corresponding or equivalent mass. It is more correct to say it is the weight of the mass or "mass-weight". Expressed in simple terms, most scales are actually a "mass scale", rather than a "weight scale". Many cooking recipes use grams of certain food substances, rather than say how many Newtons of weight of it are required. Nonetheless, it is possible to have a scale calibrated to just display the "gravitational weight" or force of an object or mass in Newtons of force. Whereas the weight of an object is not universal due to planets having different gravity, mass or the real, physical amount of matter is universal, constant, and does not depend on any specific value of gravity in the universe, such as on another planet. An object with a mass of 1 gram, or 1 kilogram, of matter will always be 1 gram, or 1 kilogram. on all the various planets, or in empty space or anywhere in the universe. Mass is a constant physical property of the object itself, but weight is not since it is due to a force affecting that object or mass, such as the constant force of gravity pulling upon it and giving it an acceleration and weight (force). Mass and weight are physically and mathematically proportional, so therefore, a factor increase in one equates to the same factor increase in the other, and this will always be correctly displayed on the scale. It could be said that the relative changes in the mass and its corresponding weight are identical. If someone says an objects weight has increase by 2, then its mass had increased by 2. A weight to mass conversion scale created for use on Earth would not display correct results on other planets that have a different mass and amount of gravity. The scale would only work if Earth's gravitational force of acceleration (9.8 m/s^2) preset (ie., calibrated as a divisor) in that scale is changed to be that of that planets gravitational acceleration constant.

weight = force = (mass)(acceleration) N , N = Newtons = kg m/s^2 , therefore mathematically:

mass = weight / acceleration = weight / g = weight / (9.8 m/s^2) = kg / (9.8 m/s^2) = lbs / (32.2 ft/s^2)

Ex. 1 gram of mass will weigh (ie., a force due to gravitational acceleration):

First, for the weight or force to be expressed in Newtons (n), the mass must be expressed with units of kilograms (kg).
1 gram of mass = (1/1000) kg = 0.001kg of mass.

Fn = (mass)(acceleration) = (0.001kg)(9.8m/s^2) = 0.0098N : about a hundredth of a Newton of force = 0.01N
The weight of a kilogram = 1000g of mass = Fn = (1.0kg)(9.8m/s^2) = 9.8N : about 10N

If you were to take an object that is calibrated or indicated as 1g of mass and place it on a typical weight (or weight to corresponding mass) scale, it will still display 1g. Under the influence of Earth's gravity, the weight (ie., force) of an object having 1 gram of mass will be: (0.001kg)(9.8 m/s^2) = 0.0098 Newtons or "Earth Newtons" due to that Earths gravity constant is considered and used in the equation. .

A Note About Energy, Work and Power

Ex. How many joules of energy or work does it take to lift a 1 gram of weight (ie. a force under the influence of gravitational acceleration) to height of 1 meter?

work = (force)(distance) = (0.0098N)(1m) = 0.0098Nm = 0.0098 **joules** = 0.0098 (kg m/s^2)(m) = 0.0098 kg m^2/s^2
= 0.0098 kg v^2

This work or kinetic energy applied would be converted to the objects gain in potential energy due to its position above the ground and in the gravitational force field which could then apply a force to and accelerate that mass and convert its potential energy to kinetic energy. If the object was already at a height, it already has some amount of potential energy, and then raising it higher will give it more potential energy.

PE total = (existing PE) + (change or gain in PE) = (X Joules) + (0.0098Joules)

Ex. If it took 1000J of energy to lift an object to a certain height of 2 meters in 10 seconds, the energy used per second is:
power = energy / time = 1000J / 10s = 100 J / s = 100 watts : an average power value

Ex. If it took 1000J of energy to lift an object to a height of 1 meter in 10 seconds, the energy used per second is:

power = energy / time = 1000J / 10s = 100 J / s on average = 100 watts on average

We see that the actual height, mass or weight does not take part in the power equation, but those are rather part of the total energy needed and used. Power is an (average) measure of the total energy usage and not of mass or weight.

Ex. If it took 1000J of energy to lift an object to a height of 1 meter in only 5 seconds of time, the average energy used per second is:

power = energy / time = 1000J / 5s = 200 J / s = 200 watts.

Something, such as a machine rated with a "higher wattage" or power than another machine, can get things done (ie., do work or a task) quicker (a less or shorter amount of time) because more energy is available and-or can be delivered per unit of time or per second. More energy can be used to create more force so as to apply and transfer that energy. More "wattage" (output, available) means more energy available (output), used and-or required (input) per second.

Ex. If a device uses 10 watts of power and is used for 1 minute, how much energy did it use?

From: **power = energy / time , watts** we have:
energy = (power)(time) , joules since 1min = 60s of time:

energy = (10 watts)(60s) = $\left(\frac{10 \text{ joules}}{s}\right)$(60s) = (10)(60)joules = 600 joules of energy

Energy And Pressure

The force applied to or available from an object is: $F = ma = mg$. The localized or concentrated force at the site or area of the impact is called the **pressure (P)** applied from that force: **Pressure = Force applied / area**. , $P = F / A$ = force per unit of area. If a force is applied to a very small area, the pressure and transfer of energy can be very high and more useful for certain things, such as for a hammer to pound a pointy nail into wood, or pointed wedge to split wood. If a hammer is used to apply force to a nail, that force is effectively concentrated, focused, available to, and applied to a small area at the pointed tip of the nail which has a very small surface area. Note that the total energy available at the hammer just before impact is not actually amplified or increased at the tip of the nail. Energy out = Energy in. What is rather amplified is the force per unit area = pressure. Pressure is essentially an amount of concentration of force. This is much like how a large amount of light is gathered, concentrated or focused by a telescope lens or mirror. The total amount of light received is not increased or amplified, but the concentrated light energy into one spot or area makes the light energy per unit area much higher as if it were actually amplified, and objects will then appear as being brighter. It could also be said that the energy density = (energy / area) is now higher. A funnel shape can be used to concentrate audio or sound waves so as they are effectively louder from the source. With the hammer and nail, the total amount of available energy is being applied to and transferred to a small region or area, hence the energy is effectively being concentrated into one spot or area so as to be more useful to do certain things such as making the tip of the nail go more easily into to the wood.

Extra: Letting: P = Pressure , F = Force , A = Area , we have:

$$\mathbf{P} = \frac{\mathbf{F}}{\mathbf{A}} = \frac{(\text{mass})(a)}{m^2} = \frac{N}{A} = \frac{N}{m^2} = \frac{N\ \ (m^1)}{m^2\ (m^1)} = \frac{N\text{-}m}{m^3} = \frac{N\text{-}m}{\text{Volume}} = \frac{\text{Work}}{\text{Volume}} = \frac{\textbf{Energy}}{\textbf{Volume}}$$

: mathematically and:

$$\textbf{Energy} = \textbf{(Pressure)(Volume)} \quad : = (F / A)(V) = \frac{F\,V}{A} = \frac{mg\,(d^3)}{d^2} = mad = \mathbf{mgh}$$

:such as for a column or height of liquid
that applies pressure on a surface,
PE, Static or **P**otential **E**nergy

$$\textbf{Energy} = (\text{Pressure})(\text{Volume}) = PV = \mathbf{pghV} = mgh = KE = \frac{\mathbf{mv^2}}{\mathbf{2}}$$

: p = density of the substance = mass / V ,
Ex.: p = mass per cubic meter = kg / m^3, and:
KE = Dynamic or Kinetic Energy , due to motion
g = gravitational acceleration , h = height

In a pipe with a flowing liquid passing through it, the Energy and flow rate (Volume / time) of that liquid is constant at any point along it, and therefore Energy, Volume (V) and mass (m) and (1/2 =0.5) are constants in this equivalence:

Energy = PV = mv^2 / 2 and the resulting (P and v) relationship we are interested in is this: Considering the conservation of energy, and the relative values:

(constant) = (directly related to P) (directly related to v^2) , if we let (constant)= a relative value of 1.0:
1 = (directly related to P)(directly related to v^2) their relative changes are also reciprocals:
1 = (relative change in P)(relative change in v)^2 : here, each factor is the reciprocal value of the other factor, and is expressed below

If the amount of energy is a constant value, P and V are then inversely related, but not necessarily reciprocal in value. Here, as one changes by a factor of (n), the other changes by a factor of (1/n), and these change factors are reciprocal in value to each other. Due to the above equation, for a given amount of energy, mass and volume (V), P and (v^2) are reciprocally related in value of each other.

Due to this condition, is shows how, Pressure and velocity^2 affect each other, and in a inverse manner since Energy remains the same value. If one factor of a constant value increases, the other(s) must decrease, and this is an inverse mathematical relationship expressing an inverse real or physical relationship. These discussions of **Bernoulli's principle and equation** here can be associated with the discussion(s) about **Bernoulli's Principle** given previously in this book.

For an ideal **pipe (a hollow cylinder)** and fluid, a change in pressure is inversely related to the square of velocity:

$$\text{(relative change in Pressure)} = \frac{1}{\text{(relative change in velocity)}^2}$$

: Ex. If v1 = 5, and v2=10, the relative change is v2 / v1 = 2, the relative change in P = 1/(2^2) = = 1/4 = 0.25

$$\text{(relative change in velocity)}^2 = \frac{1}{\text{(relative change in pressure)}}$$

$$\text{(relative change in velocity)} = \sqrt{\frac{1}{\text{(relative change in pressure)}}} = \frac{1}{\text{sqrt (relative change in pressure)}}$$

If velocity doubles or changes by a factor of **n**=2, the corresponding pressure changes by a factor of: **(1 / n^2)** or= (1 / n)^2 = (1/2)^2 = 1^2 / 2^2 = 1/4 = 0.25

Ex. v1 = 1 and P1= 20 , if the velocity changes to 2 or doubles, what is the corresponding pressure (P2)?

(relative change in velocity) = v2 / v1 = 2 / 1 = 2 :given in the example
(relative change in pressure) = 1 / (relative change in velocity)^2 = 1 / (2^2) = 1/4 = (0.25)

Given a constant amount of (KE), when v or P changes, it affects the other value in a specific way, such as being changed by a specific factor or relative value:

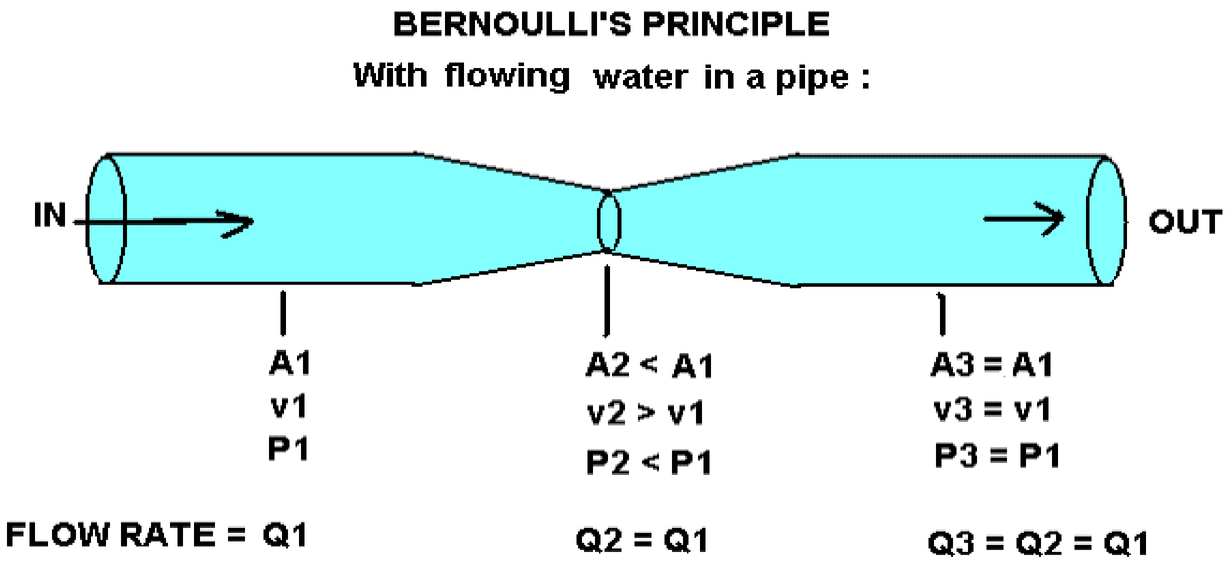
v2 = v1(relative change in velocity) = 5(2) = 10 and
P2 = P1(relative change in Pressure) = 20 (0.25) = 5

As a check, the product of two (relative change) factors should equal 1:
1 = (relative change in velocity)^2 (relative change in Pressure)
1 = (2)^2 (0.25) = (4)(0.25) = 1 : checks

Note that the equation of the form: (1/n^2) has the format of an inverse square law equation, and where the result reduces rapidly when the denominator increases. This is like the inverse of n^2 and where the result increases rapidly as expected for the power of a value greater than 1. Also:

Note that the equation of: $\sqrt{1 / n}$ has the format of the square root of a reciprocal or inverse of (n). If (n) increases greater than 1, its reciprocal value is less than 1 and decreases, and the square root of that value will also be less than 1. Shown in this book is a similar mathematical discussion for Newton's Cradle and kinetic energy.

[FIG 250]



Before we move on to Bernoulli's Equation, there is a way to calculate the velocity of a fluid in a pipe by knowing both the flow rate (Q) and the area (A) at a location along the pipe:

The **flow rate (Q)** expresses the volume (V) of the fluid that will pass a point in one unit of time: **$Q = V / t$** , The Volume of this fluid can be calculated from the equivalent geometric volume within that section of the pipe. Here the pipe is a tube or cylinder shape, and has a circular cross-sectional area and is equal to A = (pi)r^2. The cylinder shape has a height=length=distance that the fluid will travel in that unit of time:

Volume = **Volume of a cylinder** = (cross-sectional area of the pipe or cylinder)(distance) = **V** = Ad
Expressing both volume expressions (V, and Ad) with respect to time so as to have a time rate:

$Q = \frac{V}{t} = \frac{d^3}{t} = \frac{d^2 d^1}{t} = \frac{Ad}{t}$, therefore: $Q = \frac{A(d)}{(t)} = \mathbf{Av}$, and:

$\mathbf{v = \frac{Q}{A}}$ = **velocity of a fluid in a pipe = (flow rate) / (cross-sectional area of the pipe)**

A flow rate can be physically determined by letting the fluid flow into a container, and then dividing by the time it took to reach a certain volume: Q = Volume / time = V / t

$\mathbf{v = \frac{Q}{A}} = \frac{(V / t)}{A} = \frac{V}{\mathbf{At}} = \frac{d^3}{d^2 t} = \frac{d}{t}$ mathematically: : **$V = Qt$ = (flow rate)(time of flow)** and:

$V = Qt = Avt$

When the cross sectional area of a pipe decreases, in order for the flow rate to remain a constant volume per amount of time throughout the pipe and, into it and out from it, the velocity will naturally increase. A high energy or pressure is being applied to a smaller amount of substance at the start to this area and-or pipe section, and then forcing that substance through a smaller area, and a higher force upon a substance means an acceleration and results in a higher velocity of that substance . The mathematical relationship between velocity and area is an inverse-proportional (ie., inverse, and by the same factor) one, such that when one changes in value by a factor of (n), the other will change by the inverse of that same factor, hence (1/n). This can be seen in the above equation if the Volume is constant.

From: $V = Qt = Avt$,
$V = Avt = (n/n) Avt = nA (v/n) t = (A/n) (nv) t$

Note for example, that when the internal diameter of a pipe is half, its cross-sectional area is: A = (pi)(r/2)^2 = (pi)r^2 / 4, hence its area is only one-fourth, and the velocity of the substance will then increase by 4. V = (A/4)(4v) t = V
Since internal pressure is part of the energy per volume of the substance flowing in a pipe, and if this amount of energy is constant, if the velocity of a substance increases in the pipe, the pressure (such as upon itself and the internal and-or external wall at a right angle (90°) to the flow in the pipe) will decrease. A higher velocity means some of the energy per volume of the flowing substance has been converted to more kinetic or motional energy of that substance, and there is less internal pressure energy available, and which can be thought of as stored energy due to compression, like a spring.

Bernoulli's Equation states the that sum of pressures contained within a moving fluid is a constant value, and this is very similar and to, and due to that the sum of Potential (ie,. static, stored) Energy and Kinetic (ie., dynamic, motional, moving, and such as applying force or pressure to the fluid in front of it). Energy is constant in a flowing fluid system. The output energy will equal the input energy, less any losses.

Total Energy = Et = KE + PE .

Energy can be in 2 main forms, and much of this is discussed elsewhere in this book:

1		2
Potential Energy (PE),	and	Kinetic Energy (KE),
static or stationary	,	motional or moving

Potential energy is also called stored energy that can be used when able or needed. It is also thought of as energy due to position such as a compressed spring, or and object lifted to a height and placed there. These object required an initial energy and force to put them in that state (status, condition) or position, and the energy can be released when able or needed. A system can have both PE and KE, and of which sum to the initial or total input energy. Due to the concept of the conservation of energy: Energy out = Energy Out.

Since Energy = Work = (force)(distance) = (Fd) = (mass)(a)(d) Joules, if the distance is equal to a height above reference height, the energy needed to raise it, and or stored in an object is: **(Fh) = (mass)(g)(h) J**. This value of energy may also be added to any amount of potential energy the object may of already had.

When a gas or liquid is compressed (perhaps by a pressure upon it) into a smaller volume, it's own pressure will increase. The energy used to compress that gas or liquid is transferred to the gas or liquid and stored in its structure, much like how a compressed spring can store the energy used to compress it. Some of that input energy is converted into heat energy in the substance. This stored or saved energy is called potential energy. The gas or liquid will condense when pressure is applied and it becomes more dense per unit volume. Density = mass/volume, however water is very difficult to compress, much like a solid.

Water that was raised to a height in a tower or dam by using energy (ie., work), can store (gravitational) that input energy as potential energy (PE), and when that water can flow downward from that height, its energy is converted to kinetic energy and can provide the force to turn a turbine wheel of a mechanical device or an electrical power generator. The kinetic energy and-or velocity of this water will be at its maximum value just before it reaches the bottom of the pipe. In theory, this KE per volume of water at the bottom, will equal the PE per volume of water at the top height, and the total amount of available energy is the same: KE = PE.

Ex. If a water tank up high on a water tower is storing 100J of (Gravitational) PE = Fd = (weight)(height) = (mass)(g)(h). The energy per volume is then: PE / V = (m)(g)(h) / V = (m/V)gh = (density)gh = pgh,
Since p = m/V, m= pV, and the amount of energy stored in relationship to the volume of the liquid is:
PE = mgh = pVgh . For the fluid of water, it has a density of 1g/cc = 1000g/ 1000cc = 1kg/L. g=9.81m/s^2.

If it takes 50s of time for all that water to flow through a pipe to an electric generator, then that stored 100J of PE would be converted to 100J of KE energy in an ideal (low power losses, full energy conversion) system. The rate of using this energy would be:

Rate, or time rate, and power of using this amount of energy in 50s is: $\frac{100J}{50s} = \frac{2J}{1s}$ = 2 watts of power
P = 2w

For an ideal energy system and-or conversion, 2 watts of electrical power would be generated and-or available. Also in an ideal system, the flow rate (Q = Volume / time = V / s) is constant and the available and generate power will be constant, but since the water is draining from the container, it contains less stored potential energy, and less depth (distance from the surface to bottom) of the water as time increases, changes, progresses or passes, and therefore, the water pressure at the level of the outlet pipe is constantly being reduced if that volume drained out is not resupplied into the container.
Since the (water or fluid) pressure in the pipe is less, the force and the application of that potential or pressure energy will also get less, and the available and generate power will be less. As the fluid in the container drains, it will loose both its Gravitational Potential Energy (GPE) and the available (static) pressure energy and-or force, but as the water reaches the bottom of the tower, it will regain, convert or transform that GPE as kinetic energy (KE). If the fluid moved a distance of 1 meter per second in the pipe or middle (a low resistance and-or friction region) of a water steam, it is then said that its velocity = v = distance / time = d / t = 1 meter per second. In theory, and for an ideal system, a turbine or power transfer wheel with a circumference of 1 meter distance, and placed into this flowing water, would turn or rotate once each second if the friction or force against its movement was low, hence it would have a maximum rotational velocity or rate of 1 revolution (360°) or cycle per second =1 rps = 60 rpm.

To calculate the rps value: From v = d / t , v / d = 1 / t = frequency = cycles = revolutions,
ex. cps = hertz = hz

$\frac{v}{d} = \frac{v}{c} = \frac{1}{t}$ = hertz = rps = frequency : c = circumference = 2(pi)(r)
: d = distance
When time has units of seconds (s).

Ex. If the water velocity is v = 1m/s = 3600m/h = 3.6km/hr, and circumference of the wheel is c = 0.25 meters:
rps = velocity / circumference = v / c = 1 (m/s) / 0.25 m = 4 (1/s) = 4 hertz = rps

For torque (effective rotating or twisting force, equivalent to an amplified linear force) applied to this wheel or turbine:

From: Pressure = Force / Area = P = F / A , F = PA.

Torque = (Force)(leverarm) = PA(leverarm) =
Torque = T = PAr : r = radius of the wheel or turbine , and:
P = water Pressure on the wheel
A = surface contact Area between the flowing water and the wheel.

Bernoulli's Equation states that at any location or point in a pipe or moving fluid:

Total Pressure At A Point In A Pipe = Pt = Input Pressure + Dynamic Pressure + Static Pressure

Pt = Total pressure at point1 = Total pressure at point 2

The pressure at a point = $\frac{pv^2}{2} + pgh$ **: (h) is the height above the reference height (considered at 0m). If the fluid is raised a height, it gains potential energy KE) which**

in terms of pressure, can be called potential pressure energy, and this will reduce the available KE or kinetic pressure energy at that point by that same value, and since the total amount of energy at a point is constant. Dynamic pressure is the same as kinetic pressure. This pressure sum and equation is much like a sum of energies and-or forces at a point. p = fluid density

pgh = PE / volume : derived in this book , mathematically, **PE = pgh / V = static pressure / Volume**

As mentioned by Bernoulli's Principle, the pressure within a moving fluid, such as in a pipe, will change if the diameter of the pipe changes. The relationship between the pressure and velocity is an inverse square type of relationship. For a fluid to move, it must have an initial pressure upon or within it to do so, and it will move to the lower pressure region. The initial pressure may be a static pressure form of potential energy due to the height of a fluid stored in a container, and this fluid then has stored or potential energy and the ability to do things.

When a fluid is moving, its potential energy was converted to kinetic energy. When a fluid is moving, it's static pressure was converted to dynamic pressure. The dynamic pressure in a fluid will be less than the initial static pressure because some of that initial energy and high value of static pressure is now part of the kinetic energy and dynamic pressure. When a static fluid begins flowing into a lower pressure region, that fluid then becomes less pressurized itself, but gains velocity and kinetic energy due to the initial force or pressure applied to it and causing it to move. With a given amount of energy, an object will move slower through a region of higher pressure, it is essentially in a region with an increased resistance to movement.

If a fluid is raised to a height it has stored that energy to do so as potential energy (PE):

PE = pgh : p = density of that fluid or substance=mass/volume, kg/m^3 , : pgh is derived in this book
g = Earth's gravitational acceleration: 9.8m/s^2 pgh = KE / volume
h = height

Work = Energy = (force)(distance) = (mass)(acceleration)(distance) = **mad or= mgh** joules
Work = Energy = (weight)(height above a reverence line) = mgh joules

Pressure = **force / area or weight / area** = N / m^2 = **pgh** Pa : Pa = Pascal units of pressure

Since PE = pgh and Pressure = pgh : **,** Pressure is sometimes called "pressure energy". Pressure = force / area , and force is the application of energy, Pressure, such as in a compressed gas or fluid raised to a height, is like a stored amount of available or potential force, hence like a stored amount of energy.

Pressure = PE : Potential Energy (ability to release energy, stored energy)

From: **Energy = (Pressure)(Volume) = PV , Pressure = Energy / Volume = "energy density"**

Energy = (Force / Area)(L^3) = (F / L^2)(L^3) = FL = **Fd** = **Fvt** = work = energy : L = length = distance
Energy = (Pw)(time) = Fd = Fvt , joules , note mathematically:
Energy / t = **Power = Fv or = (Torque)(v)** **:** Power in watts , F in newtons , **linear v in m/s** , and:
Fn = Pw / v = E / vt = E / d and **Pw = Ev / d** and **d = vt = Ev / P ,** hence**: t = E / P :** P is a rate

$$\textbf{Pressure} = \frac{\text{force}}{\text{Area}} = \frac{\text{Energy}}{\text{Volume}} = \frac{J}{V}$$ with units of: joules / m^3 , also: **F = J / d = joules / meter**

Pressure $= P = (F / A) = (J / V) = ma / d^2 = J / d^3$, mathematically:

ma d = (force)(distance) = J = Work = Energy = PV = FV / A **: J = joules of energy**

$P = (F / A)$ = Weight / A = mg / A , $PA = F$ = Weight = mg

Kinetic Energy density of a moving liquid $= \frac{KE}{Volume} = \frac{mv^2 / 2}{V} = \frac{mv^2}{2V} = \frac{pV\,v^2}{2V} = \frac{pv^2}{2}$ = **Dynamic Pressure**
p = density

For the last term above, the units are : $\frac{mass}{V}(m/s)^2 = \frac{kg\,m^2}{m^3\,s^2} = \frac{kg}{m\,s^2}$

We see that Dynamic Pressure is equivalent to the Energy (KE) density of a volume of a moving liquid, and that its equation contains the density (p = mass / volume) of the liquid's. The denser it is, the more energy it will have at a given or particular, constant velocity.

Note: P = pressure = force / area :"force density" , p = density = mass / volume :"mass density"

Dynamic pressure can be thought of as the pressure (= force/area) of the moving liquid pushing (applying force, applying energy) on the liquid in front of it. From the above equation, we have:

KE = (Volume)(Dynamic Pressure) **: "(dynamic) pressure energy" of a moving volume of liquid**
$KE = (V)(pv^2 / 2) = (mv^2 / 2)$: here p = density of the substance (liquid or gas) , and that p can be derived here as: $p = m / V$

E = Work = Fd joules = mad = m (change in v) / (change in t) d = m (ch. v / ch. t) v t = $m v^2 / 2$
This is an average energy value since $v0=0$ and it will take time to reach the velocity of movement.
It could also be thought of as due to an equal and opposite force, say friction, receiving energy, and half the energy input does not get transferred to the mass. If the distance was a height, then: E = W = mah joules or= mgh joules in Earth's gravity of 9.81m/s^2

Bernoulli's Equation:

P = pressure , p = fluid density , v = velocity , g = gravitational acceleration , h = height

At each location in a pipe:

Pt = (Initial Pressure Energy) + (Kinetic or Dynamic Pressure and Energy) + (Potential or Static Pressure and Energy)

Total Pressure At Location 1 = Total Pressure At Location 2 , and:

$$P1 + \frac{(p)(v1^2)}{2} + (p)(g)(h1) = P2 + \frac{(p)(v2^2)}{2} + (p)(g)(h2)$$ **: Bernoulli's Equation**

A related note to consider is if you have a column of water in a container on the floor. The bottom of the container will have a water pressure associated with the depth of that column of water. The deeper the water, the greater the pressure at the bottom. This is static pressure energy. If you were to raise this entire column, container or tank of water up a height or altitude above the ground, such as onto a table or tower, you have used energy to do this, and this energy is stored as potential energy of that column of water. This is static pressure energy and potential energy.

The Basics About Collisions Of Objects

A brief discussion on this topic was previously given in this book with Newtons's Balls, and here is some more to consider:

For an object: **weight = F = mg** , and a constant mass and constant gravitational force induced acceleration (a=g) of the mass will produce a constant weight of an object. weight = mg = (a vertical, downward force) = F = ma

If object1 will collide with object2: : or mass1 will collide into mass2 :

Object1 is moving and has **momentum** (p=mv) and kinetic energy ($ke = mv^2/2$) and will collide (impact, contact and apply force to) with object2 which is at rest. Object1 will then loose some of its energy by transferring it to object2. More specifically, Object1 will apply a force (ie., the application of energy) to object2 and some of its energy will be transferred to object2. Much of this energy will be kinetic energy. As object1 looses kinetic energy and decelerates, object2 will accelerate. During this process, due to the concept of equal and opposite forces, when object1 collides with object2 it will be as if object2 is applying the same amount of force to object1, and in the opposite direction, and therefore object1 will decelerate. The impact force (application of energy) is related to the amount of acceleration (f=ma) or deceleration of an object, and also determines the amount of energy transferred. Remember that: power = watts = Joules/second. If the energy transferred is high and-or the time is a low value such as for an impact, the power can be a high value for a brief amount of time, especially if the acceleration or deceleration is quick such as during an impact or collision. A brief and large pulse or release and transfer of energy can cause significant damage to both objects if the collision is not "elastic" and where much of the input energy is converted to heat.

The force of an impact depends on the total kinetic energy available in the objects and the directions they were moving, such as towards each other, one being still, or both going in the same direction with one being faster and one being slower than the other behind it. The kinetic energy in an object is due to its mass and velocity. Total momentum = p = mv, and total kinetic energy = $mv^2 / 2$ and this equation which is similar to that of momentum is needed since if the velocity of the object doubled, its kinetic energy is actually four times more, but its momentum is only doubled. Momentum can be considered as a measure of an objects motion and to stay in that motion, rather than its stored energy.

The momentum of a mass is: **momentum = mv** : a change in velocity will create a change in momentum, this will not be instantaneous, but will take some amount of time for it to accelerate from one velocity to another.

$$F = ma = m\,\frac{\text{(change in velocity)}}{\text{(change in time)}} = \frac{\text{(change in momentum)}}{\text{(change in time)}}$$

: showing force as (equal to) the amt. of change in momentum (ie., motion ability) with respect to a change in time. Mathematically:

(change in momentum) = (force)(change in time) = (N)(s) = (ma)(s) = ($kg\ m/s^2$)(s) = kg-m / s = (kg) (m/s) = (m)(v) , and where (v) is the change in velocity.

A force (the application of energy), including friction, will cause a mass to change its velocity and-or accelerate (or decelerate) during the time that the force or energy is applied to that mass. The more mass of a moving object, the more potential or kinetic energy it has, and therefore the more energy needed to change it to another velocity. As an example, mass1 is a small mass, and mass2 is a larger mass, and both have the same velocity. Since momentum = (mass)(velocity) = p = mv, momentum1 is less than momentum2. Less energy is needed to slow down a mass with less momentum. If mass1 was traveling faster it could then have as much momentum as mass2.

More energy is needed to slow down a mass with more momentum or kinetic energy. If the force applied to a mass is not much Newtons, or it is applied for only a short amount of time, the total energy applied and transferred (or effectively removed from it so as to slow it down) to it so that it will have energy to do things was not much, and it will then take more time to apply and transfer more energy to slow it down. Still, regardless of the rate of energy use (ie, work done) or transfer of energy, the application (force) and transfer (power=joules/second, watts) of a same total amount of energy will be required to slow a mass with kinetic energy down to a certain speed or stop = 0 speed. In short, the smaller the constant applied force, it will then take longer to slow down an object or increase its speed to a certain value. A smaller applied force means a smaller acceleration of the object being forced. F=ma and nF = m(na), and a = F/m. For a constant value of mass, If the force applied is small, the acceleration of that mass will also be small.

If two objects collide and they both stop their motion, all the kinetic energy is converted to a force. This force may compress and-or deform one or both of the objects. This is the case when an object is dropped from a height onto the Earth's surface which has a large mass with a high inertia, but a small amount of its kinetic energy is converted to sound energy. Another example is when a meteorite collides into a planet or moon, and its kinetic energy is converted to force, and some heat (thermal energy), which makes a crater (ie., a dent or hole shape) after forcing or pushing matter out of the impact area. That matter will gain kinetic energy by the impact and travel outward to an effective "lower pressure region", and away from the point of impact and effective "higher pressure region" due to that force.

The amount of force a moving mass (M1) can apply to another large, difficult to move, non-moving mass (M2) depends on its velocity. A mass with a higher velocity has gained and is storing more kinetic energy, and has more **momentum (p = mv) or ability to stay in motion and its direction**. The more kinetic energy an object is storing in its amount of mass and motion, it can apply more force (the application of energy) and do more work (= energy, joules):

Force = F = (mass)(acceleration) = ma

For a given or fixed amount of mass of an object, in order to have a large impact force and release or exchange of its (kinetic) energy, a high amount of acceleration or deceleration is needed.

To have a high amount of acceleration (or deceleration, in the case of an impact where an objects speed or velocity decreases) the speed of the object must decrease quickly::

$$\text{acceleration} = (a) = \frac{\text{change in velocity}}{\text{change in time}} = \frac{(\text{final velocity - initial velocity})}{(\text{final time - initial time})} = \frac{(v2 - v1)}{(t2 - t1)} = \frac{\Delta v}{\Delta t}$$

If the change in time is small, such as the time it takes to make a quick impact, the acceleration will be a very high value, and therefore, the impact force or "force of impact" will also be a very high value. All the kinetic energy of the object or mass will be quickly expended, used up, and transferred rather than slowly used up over a longer period of time. A high impact force means a high amount of energy was used and transferred, however the total (kinetic) energy of the mass or object is limited to some value, and if much of it was used during the impact, very little, if any, will be then available from that mass to be applied elsewhere.

Since: Power = $\frac{\text{energy}}{\text{time}}$, If the time of applying the force (the application of energy) is a small or quick value, the available or instantaneous power, which can be considered as the effective or average energy and-or force available during that brief or instantaneous amount of time, will be a high value.

With forces and-or collisions (ie., forces being applied to an object), vectors (ie. such as a force magnitude and direction) also need to be considered. For a given force, if the momentum of an object is increased, that amount of force applied to that object will have a less effect. If an object is say going in the (y) direction on an x,y, rectangular coordinate system of measurement. It could be said that the motion of the object does not contain any (x) or horizontal "component (ie., part)" motion and-or direction. and if a object and-or force is applied to it in the (x) horizontal direction, such as during a collision, that object will than have both a vertical (y) motion and-or direction, and a horizontal (x) motion and-or direction. A common and practical example of collisions can be seen with the game called Billiards or Billiard Balls, and which is also known as Pool. In this game, a player uses a pool-stick to apply a force to one ball which will then cause it to collide at a certain angle and-or location (directly or a side of) a second ball, and in such as way as to produce a desired movement (velocity and direction) of that second ball. In general, for this game, a player must "clear the table" of their corresponding balls by making them all go into one of several (here, 6) pockets (ie., holes) on the side of the playing table. Often the first and second ball are not in line with the pocket, and the first ball will have to then collide with the second ball at the appropriate locate on both of their masses so as it will be caused to then travel directly to the intended pocket.

Momentum between two objects or a system of objects is said to be conserved, that is, its sum is a constant value if there are no external (energy, and-or momentum) losses to the outside of the system.

Here is a study and example of the momentum of two objects, and which will collide:

momentum of object1 , momentum of object2 : momentum is considered as: p = m v

p1 , p2
m1 v1 , m2 v2
(5kg) (6 m/s) , (7kg) (10 m/s)
30 kg m/s , 70 kg m/s :

KE1 = m1v1^2 / 2 , KE2 = m2 v2^2 / 2
KE1 = 90 J , KE2 = 350 J

pt = p1 + p2 = 30 kg m/s + 70 kg m/s = 100 kg m/s : total momentum of this system, and it is a constant value when momentum is conserved. If after a collision, if one object gains momentum, the other object has lost that same amount of momentum.

If after a collision, if the velocity of object2 is less, its KE is less and therefore, it has transferred some of its KE to object1 which will then have a higher or " faster" velocity. Let v2 = 5 m/s after the collision. Find v1 after the collision.

p2 = m1 v1 = 7kg 5 m/s = 35 kg m / s

(change in p2) = (p2 new - p2 old) = (35 kg m/s - 70 kg m/s) = - 35 kg m/s : ie., loss of p2 = - (gain of p1)

p1 new = (p1 old + (change in p1)) = (30 kg m/s) + [- (-35 kg m/s)] = (30 kg m/s) + (+35 kg m/s) = 65 kg m/s
or:
p1 = pt - p2 = (100 kg m/s) - (35 kg m / s) = 65 kg m / s.

(change in p1) = (p1 new - p1 old) = (35 kg m/s - 70 kg m/s) = 35 kg m/s

pt = p1 + p2 = (65 kg m/s) + (35 kg m/s) = 100 kg m/s : the same value after the collision
p1 = pt - p2 , p2 = pt - p1

From: p = mv , v = p / m

v1 = p1 / m1 = (65 kg m/s) / (5 kg) = 15 m/s
(gain in v1) = (v1 new - v1 old) = 15 m/s - 5 m/s = 10 m/s

KE1 new = m1 v1^2 / 2 = 5 kg (15 m/s)^2 / 2 = 562.5 J
(gain in KE1) = (KE1 new - KE1 old) = 562.5 J - 90 J = 472.5 J

Obviously, since the objects are now moving at a new velocity, their kinetic energy is now different: KE = mv^2 / 2

Is KE conserved, that is, is their total sum the same after a collision? During a collision, the objects are compressed (even if temporarily, like two rubber balls colliding), and this will cause the masses to increase in temperature. The result is that some of the objects kinetic energy is converted into heat (thermal, increase in atoms and-or molecules motion, hence KE) energy, and therefore, is unavailable to the overall motion of the objects and is lost from their KE. In a theoretical perfectly **elastic collision** , KE is conserved since none will be lost as heat but rather converted to potential energy of the compressed and-or slightly deformed (like a compressed spring) molecules and-or crystal arrangement of the atoms, and given back as a force to induce motion, hence KE.

More equations for distance, velocity and kinetic energy:

For an object that is already going a certain velocity (v1) and then uniformly (through the entire distance) accelerates to another velocity (v2), the distance traveled is equal to the average velocity (Vav) times the time (t) or duration of travel:

distance = (speed)(time) = (velocity)(time) : here (time) is the total time (t) of travel
distance = (average velocity during the acceleration(s)) (time) , (average velocity) = (total distance) / (total time)

$$\text{distance} = \frac{(v1 + v2)}{2}\, t \quad , \quad \text{since } v2 = v1 + \text{change in velocity} = v1 + at \quad , \quad t = \frac{(v2 - v1)}{a}$$

$$\text{distance} = \frac{(v1 + (v1 + at))}{2}\, t = \frac{2v1t + at^2}{2}$$

$$\mathbf{distance = (v1)(t) + \frac{at^2}{2}} \quad : \text{total distance} = \text{initial distance} + \text{change in distance} \quad : *$$
$$: \text{mathematically: } d / t = \text{(average velocity)} = v1 + at / 2$$

$$\frac{\text{distance}}{t} = \text{average velocity} = \frac{v1 + v2}{2} = \text{(starting velocity + ending velocity) / 2} \quad , \quad \text{mathematically:}$$

$$\text{distance} = \frac{(v1 + v2)}{2}(t) = \frac{(v1 + v2)}{2}\,\frac{(v2 - v1)}{a} = \frac{v2^2 - v1^2}{2a} \quad , \quad \text{mathematically:}$$

From the above equation (*) for distance, if the initial velocity (v1) is equal to 0, such as for a still object dropped from a height, then the equation reduces to:

distance = $at^2 / 2$

Work = energy = (force) (distance) = (ma) $(at^2 / 2)$ = $m(a^2t^2) / 2$, joules
Since **$v = at$** , and squaring both sides: $v^2 = (at)^2 = (a^2t^2)$, and substituting this into the above equation:

$$\mathbf{Work = energy = KE = \frac{mv^2}{2} \text{ , joules}} \quad \mathbf{: KE = Kinetic\ Energy} \text{ , motional energy}$$

Note for example, that if a moving object gains a KE value of 10J, then it took, or will take or require, 10J of input energy so as to give it that amount of KE. If you know an objects KE, you can find its velocity from:

$$\mathbf{velocity = \sqrt{\frac{(2)(KE)}{mass}} \text{ , (meters / s)}}$$

For a given or constant amount of energy (KE), if mass increases, the velocity decreases, and this is an inverse relationship.

Energy = Work = Joules = (force)(distance) = (ma)(d) = Fd = N-m = Joules , mathematically:

$$\mathbf{Force = (mass)(acceleration) = ma = Newtons = \frac{Joules}{meter} = \frac{J}{m} = N} \quad \mathbf{: J = N\text{-}m \quad : Netwon\text{-}meters}$$

$$\mathbf{F = \frac{J}{m} = \frac{J}{d} = \frac{Energy}{Distance} = \frac{PV}{d} = \frac{Pd^3}{d^1} = Pd^2 = P A} \quad \mathbf{: mathematically,\ P = F / A \text{ , or by:}}$$
P = pressure , F = force , A = area, V = volume

$$\mathbf{P = \frac{Energy}{(A)(Distance)} = \frac{J}{d^2\, d} = \frac{J}{d^3} = \frac{J}{V} = \frac{Fd}{V} = \frac{Work}{V} = \frac{Energy}{V} = \frac{F}{A}} \quad \text{from this we find:} \quad \mathbf{: V = volume}$$

$$\text{Energy} = PV = \frac{(F)}{(A)}V = P(d^3) = P(d^2)(d) = PAd = F\,v\,t = F\,d = \text{Work} = \text{Joules} = KE = M\,a\,d$$

$$F = M\,a = \frac{\text{Energy}}{\text{distance}} = \frac{J}{d} = \frac{J}{v\,t} \quad \text{, therefore,} \quad \text{Energy} = Fd = F\,v\,t = PA\,v\,t = \frac{M\,v^2}{2} = KE$$

$F = M\,a = P\,A = \frac{KE}{d}$: here showing that Force is the application and-or transfer of energy to another object.
Since $d = vt$: $F = KE / d = KE / vt$, $Fv = KE / t = \text{joules} / t = \text{Power}$

Special note: Since F = PA, if the force is a specific value or constant, pressure and area are inversely related to each other. If one increases by (n), the other will decrease by (n). If the area is a very small area, such as that at the tip of a nail, the pressure value induced by that force will be very high.

$$F = PA = 1\,(PA) = \frac{(n)\,PA}{(n)} = (nP)\,\frac{(A)}{(n)} = (nP)\,(1/n)A = (1/n)\,P\,nA \quad \text{: for a constant amount of force}$$

Considering a gas is in a container, or a fluid in a pipe, Pressure and Volume are inversely related, and are reciprocals of each other if their product is a constant value such as: Energy = PV . We can create a relative analysis and let Energy = 100% = 1, we have: 1 = PV , and P = 1 / V , and V = 1 / P . Clearly, P and V are inversely related to each other, and are reciprocal in value to each other. If one factor changes by a relative value or factor of (n), the other will change by the reciprocal of that factor = (1/n). Given a container with an amount of warm gas which has an amount of volume associated with it, if you press down on a compression rod and piston inside that volume, you will compress that gas. The amount of gas and-or its mass is still the same, but the volume of that gas has decreased, and the pressure of the gas has increased. The gas density = (amount of gas / volume) = (mass / volume) has also increased since the volume has decreased. Note that even though the density of the gas has increased, the mass is still the same value for this system.

Further Kinetic And Force Equations To Consider

$v = a t = \frac{f}{m} t = \frac{f t}{m}$: the velocity an object or mass can get after a force is applied for an amount of time
v=velocity , a=acceleration , t=time , m=mass , f=F= force = ma

$f = \frac{v m}{t}$: the force to apply so the mass has a certain velocity after a certain amount of time
d = v t , v = d / t , f = vm / t = (d/t)m / t = dm / t^2 , t = sqrt (f / dm)

$t = \frac{v m}{f}$: the time to apply a force to the mass so as to achieve a certain velocity
mathematically:

mv = ft : momentum

Work = W = E = F d joules , d = v t = E / F , Given a certain or limited supply of energy, and a certain value of constant force (ma) applied to move an object (m), it will move a distance of (d). Also, let: f = F = E / d = E / v t = P / v

Work = W = Energy = E = F d = **F v t** in joules , **F v = E / t = Pw** = **P**ower in watts = Pw = joules / s
W = F d = E = P t = F v t joules , Force = F = ma = P / v = (E / t) / v = E / t v = E / d = joules / d
v = E / F t = P / F = P / ma , P = mav = m (F / m) v = **Fv , or from: v = Pw / F , F = Pw / v**
Pw = (power in watts) = Fv = (pressure)(area)(velocity) = PAv , F = Pw / v = ma = PA and Pw = P A v

f = **m a** = m (change in v) / (change in t) = m (d / t) / t = **m d / t^2** , **d** = **v t** = **f t^2 / m = mat^2 / m = at^2**
v = d / t = f t / m = mat / m = **at** = P / f , mv = ft , d = f t^2 / m , f = m d / t^2 , t^2 = m d / f
d / t^2 = f / m = a , and: d = v t = a t^2 = f t^2 / m = P t / f , P = E / t = f d / t = f v = f^2 t / m
t = d / v = sqrt (d / a) = sqrt (dm / f) = (E/ f) / v = E / (f v) = fd / mav , and:
P = E / t = J / s = V A = J A / Qc = f d / t = mad / t = mvd / t^2 = f v , f = ma = m v / t , t = mv / f
mv = f t

AN EXAMPLE OF FUEL USAGE AND A MOVING VEHICLE

The average car vehicle weighs about 4000 lbs =~ 1814 kg and has a rated distance to fuel usage of 20 mpg = 20 miles per gallon = 20mi / 1 gal = $32.18\underline{7}$ km / $3.78\underline{5}$ L , and after dividing both sides of this fraction by 3.785, we can reduce this fraction to: 8.504 km / 1L. 1 gallon = 128 fluid ounce = 128 fl.oz. = 3.785L and 1L = 33.814 US fl oz.

Ex. If a car is rated as having 20 miles per gallon, to travel 60 miles of distance will require:
total distance **/** (distance / gallon) = 60 mi / (20 mi / 1 gal) = 3 gallons. If gasoline is $5 per gallon, the total fuel cost is:
(cost per gallon)(number of gallons) = ($5.00 / 1 gallon)(3 gallons) = $15.00

If the car described above is moving at 60 miles per hour = 60 mph =~ 96.6 kph = roughly 100 kilometers per hour, the amount of kinetic energy (KE) it will have is:

KE = mv^2 / 2 = (1814kg)(100^2) / 2 = 9,070,000 Joules

As the car travels on a consistently made road surface, it will loose a certain value of that energy every amount of time and-or distance due to the friction or collisions of the tires ("wheels") and the road surface. To maintain speed and-or the same amount of KE, the car will require a certain amount of fuel so as to accelerate (in velocity) back up to the desired speed or velocity of 100 km/h. The faster the car, the greater the distance it will travel per unit of time, and the greater the friction losses per unit of time, and therefore, it will take more fuel and-or energy per unit of time to maintain a higher velocity.

Actual or current fuel used for a certain situation (ie., a certain vehicle , speed or velocity) can be described as:

(fuel usage) = (x gal / hr) : a fuel to time rate of using the fuel , this depends mostly on the speed , **or**
(fuel usage) = (x mi / gal) , and this is equal to the cars (typical or average) fuel rating
(fuel usage) = (x gal / mi) : this is the reciprocal of the above, but here, it is expressed as a fuel to distance rate

At 60 mph, a car rated at 20 mpg will require a fuel usage = (x gal / hr) of:

From: total = (60 mi / h) = (fuel rating) (fuel usage rate) = (20 mi / 1 gal) (fuel usage rate) , mathematically:
fuel usage rate = **(**60 mi / 1hr**)** **/** **(**20 mi / 1 gal**)** = 3 gal / 1 hr , and-or: 3 gal / 60 mi

This value of 3 gal / 1 hr can also be found using an equivalent fraction or "proportion equation":

$$\frac{20\text{ mi}}{1\text{ gal}} = \frac{60\text{ mi}}{X\text{ gal}}$$, solving for X we have: X = 3 , and if the amount of time was 1 hr, we have: 3 gal / 1 hr

$$\frac{3\text{ gal}}{1\text{ hr}} = \frac{3\text{ gal}}{3600\text{s}} = \frac{0.000833\text{ gal}}{1\text{s}} = \frac{0.107\text{ oz}}{1\text{s}} =^{\sim} \frac{3\text{g}}{1\text{s}} = \frac{1\text{oz}}{9.346\text{ s}} =^{\sim} \frac{28\text{ g}}{9.346\text{ s}} = \frac{1\text{g}}{0.333\text{s}}$$: 1oz = 28.35g

100 km / hr = 100 km / 3600s = 1 km / 36s = $0.0277\underline{8}$ km /s =~ 27.8 m / s =~ 91.21 ft / s
60 mi / hr = 60 mi / 3600s = 1mi / 60s = 1 mi / 1 min = 1 mi / 60s = 0.01667 mi / s = 88 ft / s

For the car to travel at a velocity of 60 mi / hr =~ 100 km / hr =~ 88 ft/s , the amount of fuel usage per second to maintain that speed or velocity will be about 3 g / s =~ 0.107 oz / s = 6.47 oz / 60 s = 6.47 oz / min. The useful (actual combusted fuel portion that is actually converted to forward thrust or movement) energy in 3 grams of fuel per second is what is needed to replenish the KE lost per second due to the weight and friction(s) (road, bearings, etc) at a velocity of 60 mi / hr =~ 100 km / hr . Technically much of the fuel to a typical car engine is eventually wasted as heat due to mechanical friction such as with the "drive train" or "power train" (the mechanical parts to transfer the energy from the engine to the wheels), and wheel bearing friction , and a low combustion efficiency, etc. An average car engine system is only about 35% at producing KE or forward motion from the fuel, and therefore, there is much wasted fuel and-or energy. The miles per gallon rating is the actual result or distance to expect after the fuel and-or efficiency losses.

Other considerations: A diesel fueled engine may have about twice the miles per gallon rating as that of a gasoline fueled engine. This is manly due to that the diesel fuel is denser and has more potential energy per unit of volume, and that the combustion efficient of that type of engine is greater. It is possible to use some types of vegetable oils as a fuel in a diesel combustion engine. A gasoline (fuel combustion) powered electric generator to produce electricity are only about 20% efficient maximum, and only when then having a relatively high electric load of 80% of its maximum rated electrical power output. Due to a diesel engine being more fuel efficient, and mainly due to that the energy density of diesel fuel is greater than that of gasoline, a diesel fueled electric generator will be about 40% efficient or twice that of a gasoline fueled electric generator. For general reference, a typical solar panel is about 18% to 22% efficient at producing electricity, however, the fuel (input energy) is essentially free sunlight for up to 8 to 12 hours per day, and hence it is wise to also charge up energy storage batteries for any system if possible. A battery also permits a temporary high amount of power that a common solar panel is not even capable of.

Extra note: Various fuels for various engines are often made from **crude oil** (**petroleum**) that is pumped out of the ground. Crude oil contains a mixture of various hydrocarbon (hydrogen and oxygen) molecules. This crude oil is heated (typically to about 370°C = °F) so as to cause it to evaporate. This is done inside what is called a **fractional distillation** chamber (ie., like a container vessel). This structure is vertical in construction, and the smaller. less dense, lighter, more volatile (ie., having a lower flash point) carbon molecules will rise further upward in the distiller and will then condense back into a liquid in the upper cooler areas. At the bottom of this chamber will be bitumen which is also known as asphalt or tar, and of which has a density of about 1.0 on average, and gasoline and other fuels will condense higher up at different levels, and to be drawn off by a pipe. Somewhat of a surprise is that the volume of the substances distilled from crude oil is about 7% more than the crude oil used, however the total mass and-or weight will be the same if all of the substances made from it are considered in the calculation. Why is the volume more? It is so because of the longer chains of the connected molecules and the larger molecular structures created in this process, and causing its size or volume to effectively expand in size. For example, if a gram of a substance had a volume of 1cc, hence a density of 1g / 1 cc , and after this same amount of mass expanded in volume to say 2 cc, its (mass to volume) density will then be 1g / 2 cc , and which this fraction can be reduced by dividing both the numerator and denominator by 2, and be mathematically equal to 0.5g / 1 cc, hence actually a lower (mass to volume) density than before the expansion and a corresponding lower weight to volume ratio. The weight to mass ratio, or mass to weight ratio will still be the same value.

Here are some of the distilled products from crude oil which has an average density of about 0.883g / 1cc. All oil products should be handled with care and with gloves and eye protection due to explosion, fire, corrosion and-or toxicity issues. Avoid breathing the gas or fumes of petroleum products. Exposure duration increase chances of cancer.

Product	**Average Or Typical Density**	**Typical % Of Crude Oil Volume**
Bitumen	1.0 g / 1 cc	3% , Used for asphalt or "tar" for making roads, etc. has a "thick" viscosity, hence low and-or slow flow rate, due to the attraction of the specific molecule - somewhat like a weak crystal. Between the Bitumen and Diesel evaporation layers, is various fuel and lubricating oils.
Benzene	0.876	:C_6H_6 , a solvent, such as for paints, and used in some fuels. **A known carcinogenic.**
Diesel	0.83 g/cc	20%
Kerosene	0.82 g/cc	10% Various hydrocarbon molecules from: $C_{12}H_{26}$ to $C_{15}H_{32}$, and this includes both Kerosene, Jet fuel, and some rocket fuel. : mainly a fuel for heating and lighting. **Paraffin** (0.8 g/1cc, alkane, C_nH_{2n+2}, and n has a range from 22 to 27) is nearly similar in density. Kerosene is sometimes called "heating oil" or "paraffin oil" and the word "kerosene" is based on the words for "waxy oil". Kerosene is sometimes used as a degreaser to remove oil off of metal parts so as to clean them. Kerosene, when mixed with oxygen, is highly combustible and is used in jet and rocket engines.

Jet Fuel	0.79 / 1 cc	: Jet engine fuel , a type of Kerosene
Naptha	0.765 / 1 cc	: a solveant, a fuel, used to help make plastics. Naptha has the chemical formula of: C_nH_{2n} , and where n has the range from 5 to 8.
Gasoline	0.75 g / 1 cc	45%, the majority product, and Gasoline, Diesel and Kerosene compose 82% of crude oil. : gasoline = "**petrol**" , a word derived from (liquid) petroleum. Dividing both the num. and den. by 1000, we have: 750g / 1000cc = 0.750Kg / 1L

Hydrocarbon Gas Liquids (HGL) 2% total , and here are some examples:

Butane	0.56 / 1 cc	: C_4H_{10}, is a "thin", low viscosity oil, high volatility and-or evaporation. Can be added to gasoline, and also combined with propane to make Liquefied Petroleum Gas (LPG). Note that Natural Gas = NG is mostly methane, and LNG is Liquefied natural Gas.
Propane	0.493 / 1 cc	: Propane, C_3H_8, is a gas at standard temperature and pressure, but it is often condensed and sold as a pressurized liquid gas in a hard metal tank, and having a l large amount of mass and stored energy. When the valve to the tank is open, it will reduce the pressure inside the tank, and the liquid propane will boil and create propane gas, such as used for heating, cooking and some combustion fuels for vehicles.

Mineral oil is also made from refined petroleum after fractional distillation. This is a clear oil often used to lubricate machine parts so as to prevent friction wear. About 1% of refined crude oil is mineral oil. High grade, clear mineral oil is sometimes used in the medical and food fields as being non-toxic and does not go rancid (essentially oxidize) in taste and smell like other oils can after they degrade from light and-or heat. Some people may have an allergic reaction to ingesting (ie., orally, eating) mineral oil. Paraffin, both liquid and solid forms such as for candles, is a product similar to mineral oil. Vaseline (tm, R) jelly is made from a mixture of mineral oil and wax solids. The main ingredient of baby oil is mineral oil. Mineral oil, a hydrocarbon, does not polymerize or dry to a harder state such as plastic-like coating that linseed and other oils can.

Plastics are long-chain hydrocarbons (ie., many hydrocarbon molecules joined end to end like a chain, and giving the plastic structure some pliability, flexibility, bendability), and which are often made from crude oil (petroleum) liquid into a solid material. Plastics are made applying further chemical processes to some of the refined crude oil products mentioned above, and can account for about 4% of the crude oil volume. Considering average and-or typical values: For harder plastics that sink in water, their density is about 1.28g/cc on average, and for soft plastics, their density is about 0.91, and for the foam types of plastics, such as styrofoam (a type of polystyrene plastic) that is often used for insulation and water flotation products. The density of styrofoam is about 0.1g/cc and which is much less than that of water which has a density of 1.0 g/cc.

Many types of materials such as plastic can and should be recycled when no longer needed. Some experienced hobbyists will first wash, dry and then nearly melt many (relatively soft plastic) water bottle caps and other small pieces of plastic of the same type in a home oven set at about 250 °F, and produce pressed and molded blocks before it cools. The result is thicker and seemingly harder bulk plastic material so as to be used for any purpose needed.

As of about the year 2020 or so previously, the oil industry is said to be at "peak oil", meaning that the known supply will most likely diminish as the years go by, and as the large, natural reserves of crude oil in the ground get removed and depleted. Other problems can reduce the supply of oil and its products, and we need to find alternatives to crude oil. It is difficult to obtain an equivalent energy density per gram, cc or weight of diesel or gasoline, but it is a goal to be considered when manufacturing modern super capacitors, batteries, etc. Where will these electrical energy storage devices obtain their energy from, and it also needs to be efficient, sufficient and with renewed or naturally replaceable quantities so as to be available at a low cost to many people in need? Solar and wind power and-or generate electricity seems to the "green energy" or "free" and renewable (replaceable, unending, reliable) method for now as of the year 2023.

A FLYWHEEL AND ITS MECHANICAL, KINETIC ENERGY STORAGE

A concept and mechanical device that is somewhat related to the concepts of the energy or power of gears or wheels is called a **flywheel.** A flywheel is essentially a rotating wheel, disk or object that can accumulate and store kinetic energy. A "spinning top" novelty device is a type of flywheel. The energy in a flywheel can then be used later to transfer and-or generate some mechanical and-or electrical power when needed. A flywheel can also be used to help maintain a desired rotational speed and-or timing for a machine, and this special version of a flywheel is sometimes called a "governor", and may be used for something such as to help control (ie., govern) the amount of fuel to an engine so as to keep a steady rotational speed of it and-or to maintain a certain speed of a vehicle that is moving forward. Controlling the speed of a machine or technical can be done by controlling a fuel intake valve or possibly an electric switch or resistor. A governor is therefore both a (speed, rotation, power) sensor and controller.

The amount of kinetic (movement) energy a flywheel can store depends on the mass of the wheel and how fast it is spinning (ie., its rotational or angular speed or velocity). Remember that kinetic energy is related to mass and the square of the velocity.

The larger the mass of an object, the more difficult it is to get it to have a certain (linear or rotational) velocity and-or stored kinetic energy value. A larger mass is then said to have a larger inertia (ie., resistance) to movement. The larger the mass of a flywheel, more torque (twisting force) will be required to get it to move (here, rotate). It will also need some extra initial or temporary force (input torque) so as to overcome more friction (on the bearing, pivot, axle or axis) due to the weight of that mass. As long as energy is being input into this system, input force or torque can be applied to the mass of the flywheel. Constantly applying an input force will constantly apply input energy and will cause an acceleration (change in velocity, here an increase), and the flywheel will rotate faster as it gains and stores more kinetic energy.

Torque = Twisting or Rotational Force = (Force)(leverarm) = (mass)(acceleration)(leverarm)

If the mass is increased, the more energy will be needed for it to have a certain amount of rotational kinetic energy. The amount of input energy required to maintain the rotational kinetic energy and-or velocity of the flywheel (or any other object in motion) will be very small if the friction and-or other energy losses (such as using its energy to rotate another gear or wheel) are small. If 100J of energy are lost each second in this system (ie., = 100 J/s = 100watts of power loss, work and-or transfer), in order for the flywheel to maintain its speed and-or kinetic energy value, an input of 100J of energy per second must be constantly applied to this system.

If a large flywheel that being used to store energy is spinning at its desired or maximum rated speed or rotational velocity, the input energy to the (output) flywheel can be temporarily stopped by stopping the input energy wheel or gear connected to it, and the flywheel will still continue to spin and is said to then have a "freewheel", "freewheeling" or continued spinning or motion. This input energy wheel or gear to the flywheel is usually called the **freewheel** or freewheel gear or mechanism, and it works by using a ratcheting type of gear system that can rotate in only one direction when and if it is being rotated so as to apply input energy to the output or flywheel. A common example of a freewheel system is used for the rear or drive wheel of most bicycles, and "pull (cord) start" combustion engines. People who study **mechanical engineering** will consider or include much about all types of gears and mechanisms, and are then able to imagine and-or design a mechanism when needed, such as for some machine at a factory, or for some part of a new product being manufactured.

A discussion and example of how much energy is stored in a flywheel is shown next:

The larger the mass of the balanced (ie., having a true disk shape), rotating flywheel, the more kinetic energy it can store. The larger it is, the more momentum it will have and resist changes such as small values of external force. A larger flywheel used as a governor for a machine will then be more stable at maintaining a desired speed if the energy losses, usually due to friction with the rotation support bearings, are kept at a minimum. Not only does a larger mass have a greater "resistance" (ie., inertia) to changes in motion, any flywheel, such as one called a **gyroscope,** also resists changes in axis tilt and-or direction, and this rotational and-or angular momentum (and-or "angular inertia") is used for maintaining a desired direction of which can even be a reference direction for steering such as for some satellites, etc. For a gyroscope to be in a satellite, it must be relatively small and lite-weight, and it can still have a high (angular or rotational) momentum and-or inertia by having a very high rotational speed.

Ex. A flat disk is essentially a thin section of a solid cylinder or rod. This disk has a corresponding area (A) and mass (m) associated with it. It is not difficult to imagine that a disk with half the volume or circular area will correspondingly have half of that mass and-or weight. If we can find the radius of a disk associated with half its area, then we will also know the radius associated with half the mass and-or weight of that disk. This amount of half-the mass is essentially the average amount of mass of the disk that is rotating and has kinetic energy, and can be considered and analyzed as equivalent to a single conceptual point having the same mass of the entire disk and orbiting (rotating) about the central point and having the kinetic energy of that entire disk.

The area near the outer rim of a disk has the most mass and (linear) velocity than the mass located at the area near the center of the disk, and can therefore store more kinetic energy than that of the slower moving mass closer to the center. Though the rotations per second (ie., angular speed or velocity) are equivalent for any point along a (rotating) radius line, their effective linear distance traveled is not the same, and the linear velocity is greater for points farther out along the radius line from the center. A mass going at a higher velocity will have more kinetic energy. The mass at the center of a disk has a relatively low kinetic energy and storage as compared to the "outer" mass near the rim. Because of this, some flywheels will have a thick outer "rim" of mass so as to help store energy there, especially if space is limited and-or to reduce the total weight and-or size of the device.

Given a circle or disk, here is how to find the radius (r) of a circle or disk that is equivalent to half the initial area (Ac):

From: Ac = (pi)r^2 Using a 1.0m as relative value for r, so as to have a relative type of result, the area is:

3.14159265 m^2 = (pi) (1m)^2 = (pi)(1m^2)

Dividing both sides by 2 so as to have half the area:

$$\frac{3.14159265 \text{ m}^2}{2}$$

$1.570\underline{8}$ m^2 associating this area to the area formula so as to find its corresponding radius value:

1.5708 m^2 = (pi) r^2 isolating r^2:

$$r^2 = \frac{1.5708}{3.14159265} = 0.5$$ after taking the square root of both sides so as to solve for (r):

$$r = \sqrt{0.5} = 0.707107 \text{ m}$$: at 70.7% of the initial radius from the center point, the area and-or mass of a circle and-or disk will be half. Incidentally, 0.707 is also half of the square root of 2, and which equals about 1.414....

If a uniform or complete (without gaps, spokes, and a larger rim mass) disk had a mass of 4kg, a radius of 20cm, and rotated at 5 revs (ie., revolutions) per second, how much kinetic energy is stored in that rotating disk?

At 0.707 of the radius from the center point will be half of the effective disk mass storing the energy.

(0.707)(20cm) = 14.142cm

For the linear velocity of a mass or point (ie., "effective point of equivalent mass") at 14.4cm from the center, we will first calculate its linear distance per revolution, and that is equal to the "effective" circumference of the circle or disk:

c = 2(pi)r = 2(pi) 14.142cm = 88.858cm

In 1 rev, a point at that radius will effectively travel 88.858.cm. If we multiply the number of revolutions by a value, then the distance will increase by that same value:

Let: 1 rev equates to 1 circumference (equivalent linear, one-dimensional) distance
1 rev = 1 circumference distance multiplying both sides by x, for a particular number of revolutions:
(x) 1 revs = (x) circumference distance
x revs = x (2(pi)(r) distance , using the given values, and dividing both sides by 1s, so as to have a rate:

$$\frac{5 \text{ revs}}{1\text{s}} = \frac{5\,(2)(\text{pi})(14.142\text{cm})}{1\text{s}} = \frac{444.28 \text{ cm}}{1\text{s}} = 4.4428 \text{ m / s}$$:an angular velocity converted to its corresponding linear velocity

$$\text{KE} = \frac{mv^2}{2} = \frac{(4\text{kg})(4.4428\text{m/s})^2}{2} \overset{\sim}{=} (4\text{kg})(19.74\text{m}^2/\text{s}^2) = 39.4\underline{8}$$ newton-meters = 39.48 Joules of energy
newton-meters = (F)(meters) = (ma)(meters)

It is clear in the above formula that if the (speed, rotational or angular) velocity of a flywheel doubles, then the kinetic energy stored within it will increase by 4, but it will then likewise then take four times the amount of its previous input energy for its velocity to then double:

KE at v=1 is: mv^2 / 2 = m1^2 / 2 = m(1) / 2 = 0.5m : here, m = mass

KE at v=2 is: mv^2 / 2 = m2^2 / 2 = m4 / 2 = m2 = 2m

$$\frac{\text{KE new}}{\text{KE old}} = \frac{2m}{0.5m} = \frac{2}{0.5} = 4$$, From this, a generalized formula for KE due to a change in rotational velocity is:

(KE new) = (ratio of velocities)^2 (KE old) = (v new / v old)^2 (KE old)

Another, and more general formula for the kinetic energy stored in a flywheel is: **KE flywheel = m w^2 r^2 / 2**
, where m = mass in kg, w = angular velocity in radians per second, and r = radius. Surely, to increase the radius, mass must be increased, but in theory, if the mass is a constant, perhaps by thinning the flywheel and then increasing (r), the KE of that flywheel wheel increase by 4 if r is doubled, and even if the angular velocity remains constant. Note, if r=1, and then doubles: r^2 = (2r)^2 = (2(1))^2 = 4 , and KE will increase by the square of the increase in r.

KE = mv^2 / 2 , v = effective linear or tangential velocity about the center

On a circle: **arclength distance = s = ¢ r** : **¢ = angle in radians , and mathematically: ¢ = s / r and r = s / ¢**
¢ is based on s / r , and is the definition of a radian when s = r , ¢ = 1 radian

v = d / t = s / t = ¢ r / t = (¢ / t) r = w r = (angular or rotational velocity) (r)
d = vt = wrt

KE = mv^2 / 2 = m (wr)^2 / 2 = m w^2 r^2 / 2

Angular velocity may be given in terms of rotations (rots) or= revolutions (revs) per second, and this is analogous to the number of cycles or frequency per second.

1 revolution = 1 rev = 1 rot = 1 cycle
1 rev / s = 1 c/s = a frequency of 1 hertz
1 rev = an angle of: 360° = 2(pi) radians =~ 6.28 radians

If something is rotating at N revolutions per second, that is then N cycles per second, and Frequency = F = N, and the amount of radians per second becomes multiplied by this value:

¢ / t = w = 2(pi) N radians / s = 2(pi) (revs) / s = 2 (pi) F radians / s

A point located at (r) from the center of rotation will travel the length of 1 Circumference / rotation. d = vt = C
After N rotations, the total distance can be found by multiplying both sides by N, and it will be N times greater:

Total Distance for the revolutions = D total = Nd = N vt = N C

At a rotational frequency of (N rotations / s), that point will travel a linear distance of N times faster (v) per same amount of time, and N times farther (d) per same amount of time.

Let's use the second (s) for time:

$v = d / t = \left(\frac{N\ rot}{s}\right) C = \frac{N(2)(pi)(r)}{s} =^{\sim} \frac{6.28\ N\ r}{s} = wr$: with units of: meters / s

$w = \text{angular velocity} = \frac{N(2)(pi)}{s} =^{\sim} \frac{6.28N}{s}\ \text{radians} = \frac{6.28N}{s}$: with units of: radians / second

If we let (N / s) = cycles, rot, or rev per second, F can be used to represent this value:

$v = (2)(pi)(N/s)(r) = (2)(pi)\ F\ r$: F = frequency = cycles per second = cps = rot / s = rev / s
= vibrations per second

$w = (2)(pi)\left(\frac{N}{(s)}\right) = (2)(pi)\left(\frac{revolutions}{s}\right) = (2)(pi)(rps) = (2)(pi)F =^{\sim} 6.28F$

(1 rps)(60s) = (1 rev / s)(60s) = 60 revs after 60s = 1 min of time, and this can be expressed as 60rpm

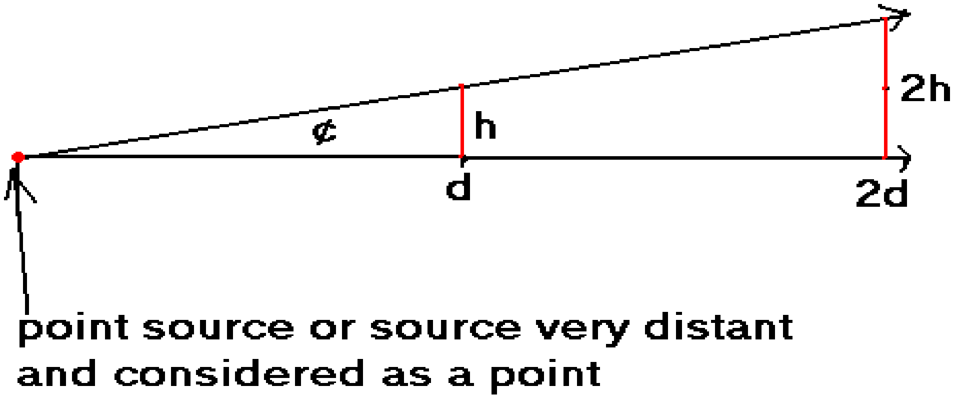
1 rps = 60 rpm : 1 revolution per second = 60 revolutions per minute = 60 revolutions per 60 seconds

Hence to convert rpm to rps, divide the number of rpm by 60. **rps = rpm / 60** . For example:

$120\ rpm = \frac{120\ rev}{1\ min} = \frac{120\ rev}{60s} = \frac{2\ rev}{1s} = 2\ rps$

MORE ABOUT THE INVERSE SQUARE LAW

This is perhaps a simpler verification that as the distance doubles from the source of energy, that the intensity at that distance is reduced by 4. A factor of 4 times less equals a factor of 1/4 = 0.25. [FIG 251]



At twice the distance from the source or vertex point of this right-triangle, the height will double. This is easily verified when you remember the simple and amazing fact that a similar triangle can be created by extending the sides of that triangle, all by the same factor, and here, it is 2. A right triangle, and half of a true distribution angle from a point source is used for this analysis, but the results are still the same. Incidentally, for this figure, if (d) is considered the center of a circle, this figure with similar triangles can be used to verify the fact that an inscribed angle is half of a central angle in a circle.

Now consider that these height values are the diameter of a circle area or side of a square area. At twice the distance, this length doubles and the area would increase 4. If h=1, this value squared would be an area of: 1^2=1. At 2h=2(1)=2, and this value squared would be an area of: 2^2=4. This is (4/1)=4 times the area than at 1d = d from the source. The energy from the source that reaches the area at distance (2d) sums up to the exact same amount of energy at the area located at (d), but it is then spread out becoming a more sparse, thinner, dimmer or weaker concentration, and is then actually 4 times less per unit area as that of the area at (d). 4 times less means a factor of 4 less which equals a division by 4: (1/4)=0.25 , which equals a multiplication by 0.25 = "a quarter of". In a reverse manner, it could just as easily be said that at half the distance to the energy source, that the energy will increase by 4 per unit area.

A simple formula for all this would show the inverse relationship of intensity (I) and distance (d), and specifically the relative distance in terms of the ratio of the distance in question to (d). Also, its more than an inverse relationship, (I) is inversely related to not only the distance, but to the square of the distance. This is the meaning of what is called "an inverse square relationship". In a pseudo-type of equation using a relative value, this information can be initially expressed as :

$I = 1 / d$

1 = 100% of the true, theorized or measured intensity at that location. When distance doubles to 2d, the intensity = I per unit area decreased by 4. This can be mathematically represented as:

(In the above drawing, consider a square area with (2h) as the length of its side. This area is then 4 times more than at (1h), and all the energy or intensity at (1h) has expanded outward into to 4 times the area, with each unit of area receiving less, and is actually (1/4) only.)

$$\frac{I}{4} = \frac{1}{2d}$$

When the distance tripled to 3d, the original or starting intensity decreases by a factor of 3^2 = 9 per unit area:

$$\frac{I}{9} = \frac{1}{3d}$$

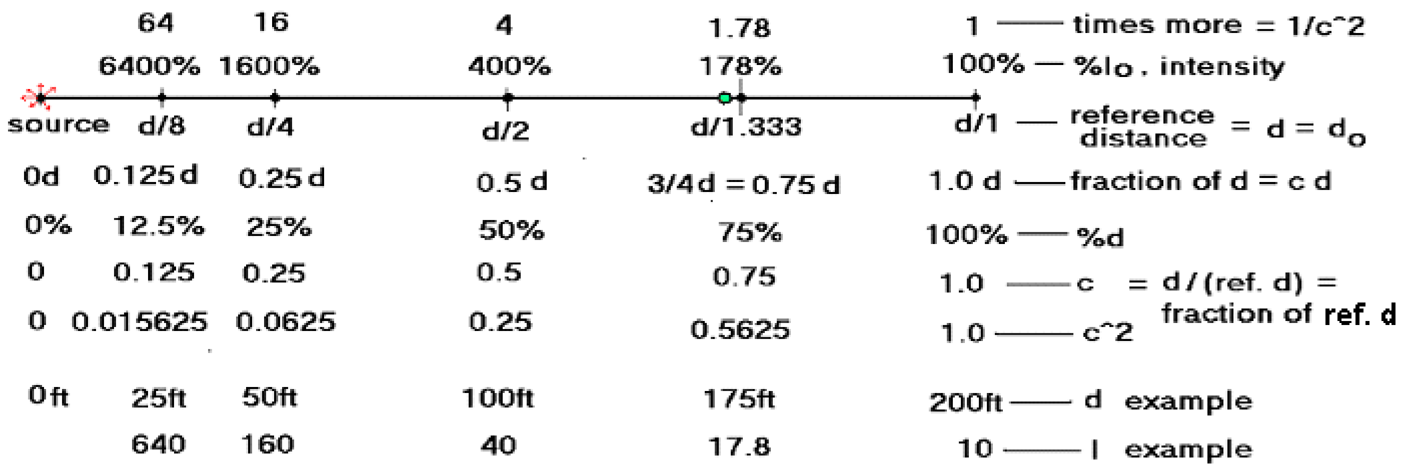
We notice a pattern that (I) decreases by a factor that is the square of the distance factor as (d) increases one unit. Therefore, the resulting intensity, say, I_1, can be expressed as being inversely related to the square of the distance factor (c):

$I_1 = I_0 / (c\text{^}2d)$: I_0 = starting reference intensity level value, I_1 = intensity level value at some distance (d) away.
(c) is the distance (multiplying) factor which is how many times (d) increased.
If we let (d)=1=100%, be the initial reference distance or location, and (c^2d) equal the total relative (ie., as magnification factor from) distance from the reference location, this equation's denominator will become: (c^2)(1) = c^2 = total distance from the reference location:

$I_1 = I_0$ / c^2 **:(c) = (distance in question) / (reference distance) =**
(c) = distance magnification factor or relative distance from the source

Io is the intensity at a reference distance or location and is considered as a relative value of 1=100% , I1 or I is the intensity at the distance in question from the reference location.

As you may see in the chart below that helps visualize this topic, 1/c^2 = number of times or "power" that (I) will increase as the distance to the source decreases. This charge assumes a spherical radiation pattern from a point source, and not the radiation or light from from a laser which has a focused, narrow (low angle, ideally 0°) beam or radiation pattern that can go a much greater distance and nearly maintain the same amount of energy and-or intensity. [FIG 252]



We could assign d_o = ref. distance, and d_1 = the distance from the source , $c = d_1/d_o$

I doubles = $2I_o$ = 200%I_o at : 70.7%d_o = 0.707 d_o = d_o / 1.414 . c=0.707 . c^2 = 0.5

When the distance from the source or measurement doubles, I decreases by 4. Likewise, in a reverse mathematical manner, when the distance at a measurement is halved or divided by 2, I increases by 4.

Ex. If the radiant energy intensity at a distance of 1 mile from the source is measured to be: I_0 = 100 units / m^2 = 100 units per square meter, what is the energy intensity at a distance of 2 miles:

c = (distance in question) / (reference distance) = 2 miles / 1 mile = 2
c^2 = 2^2 = 4

$I_1 = I_0$ / c^2 = 100 units per square meter / 4 = 25 units per square meter

This is also the result if it was said that the distance doubled = 2. 2=(c) is the relative distance factor value. Now consider this reverse-type of example:

Ex. If the energy intensity at a distance of 2 mile from a source is measured to be: $I_0 =$ 25 units / m^2, what is the energy intensity at a distance of 1 mile, or at half (1/2 = 0.5) the distance to or from the source:

c = (distance in question) / (reference distance) = 1 mile / 2 miles = 0.5
c^2 = 0.5^2 = 0.25

$I_1 = I_0$ / c^2 = 25 units per square meter / 0.25 = (4)(25 units per square meter) = 100 units per square meter

It could be said that when the energy intensity increases by 4, that distance is at halfway (1/2 = 0.5) to the source of that energy.

Ex. At what distance from the current location and distance is the intensity level at just 50% = 0.5 = 1/2 = half of the current intensity (Io) level:

$I_1 = (0.5)(I_o) = \frac{I_0}{c\text{^}2}$: in some cases I_0 can also be set or considered 100% = 1. Solving for c, the distance ratio:

$c = \sqrt{(I_0 / (0.5\, I_0} = \sqrt{1/0.5} = \sqrt{2} = 1.414$

Since: c = (distance in question) / (reference distance) then: (distance in question) = (c)(reference distance)

If the initial distance is 3 miles, the new distance where the intensity is at 50% is: (1.414)(3 miles) = 4.242 miles

Ex. At what distance from the current location and distance is the intensity level at just 200% = 2.0 = double or twice of the current intensity level:

$I_1 = (2.0)(I_0) = \frac{I_0}{c\text{^}2}$: in some cases I_0 can also be set to 100% = 1. Solving for c, the distance ratio:

$c = \sqrt{(I_0 / (2.0\, I_0)} = \sqrt{1/2.0} = \sqrt{0.5} = 0.707$

If the initial distance 3 miles, the new distance where the intensity is at 200% is (3 miles)(0.707) = 2.121 miles

If the intensity increased by 400% = 4 , you went closer to, and halfway to the source of that energy or electro-magnetic field, and the distance to the source is then the same distance that you initially went to be closer. As you keep halving the distance to the source, the intensity will keep increasing by 4.

$I_1 = I_0$ / c^2 If I1 is 4 times that of the reference intensity Io :
$4I_0 = I_0$ / c^2 After solving for c:
c = 0.5
c = (distance in question) / (reference distance) = 0.5 : = 50% , this indicates the distance was halved.

If the reference distance is unknown, a relative value of 1 = 100% can be used, and the results will also be relative since (c^1) is a relative (linear factor) value.

Ex. If I_1 was equal to I_0 increased by 50% = 0.5 of its initial reading that was farther from the source, write an expression for I_1:

$I_1 = I_0$ + (increase in I_0) = $I_0 + (0.5\, I_0)$ = Io(1 + 0.5) = Io(1.5) = 1.5Io , = equivalent to 150% Io

At what distance will this intensity be located?

$I_1 = 1.5Io = Io / c^2$ Letting Io = 1, for a relative value, or use any specific value:

$1.5 = 1/c^2$ Solving for c:

$c = \sqrt{1/1.5} = \sqrt{0.667} = 0.8167$

(distance in question) = (c)(reference distance)
(distance in question) = 0.8167(reference distance)

If we let the reference distance = 1 or 100% of some distance, we have:

(distance in question) = 0.8167 of some unknown or any distance = 81.67% of the reference distance

If you are now closer at the 81.67% of the distance from the source, you went (100% - 81.67%) = 18.33% = 0.1833 of the way to the source. The remaining distance to the source can be found by knowing the distance you went closer to the source. If you went 3 miles closer:

3 miles is to 18.33% of the total distance, as x miles is to 81.67% of the total distance

$\frac{3 \text{ miles}}{0.1833} = \frac{x \text{ miles}}{0.8167}$, x miles = 13.367 miles , and the intensity at this distance from the source is 1.5Io

The total distance at the initial intensity (Io) known, measured and considered as 1=100%, to the source is:

$13.367\text{miles} + 3\text{miles} = 16.367\text{miles} = d_o$
This distance can also be checked from the fact of: c = distance in question / reference distance = d1 / do

do = d1 / c = 13.367 miles / 0.8167 = 16.367 miles

As shown above, the steps for this finding, by calculation, the distance to the source, you must have an initial intensity reading or measurement, the distance moved closer to the source, and then an intensity reading or measurement at that closer location.

Ex. What is the Intensity factor (n) when distance doubles (2)?

c = 2 = (distance in question) / (reference distance) = (2 reference distance) / (reference distance) = 2
$c^2 = 2^2 = 4$: this was squared since intensity is inversely related to the square of the distance

Note: since intensity decreases the farther from the source, this is a decreasing or dividing factor, and we will therefore take its reciprocal which is equivalent to dividing by that value:

$(n) = 1/c^2$ = a decreasing, intensity factor = (1/4) = 0.25
$I_1 = n\ Io = 0.25\ Io$: when the distance from the source is doubled, the intensity is only 25% of Io

Laser Light Laser means **L**ight **A**mplification by **S**timulated **E**mission Of **R**adiation, and other electromagnetic waves, such as radar, is not usually radiated outward in a sphere or wide angle pattern, but is emitted as a narrow angle, concentrated and powerful long distance energy (here, light) beam, and the inverse-square concept will not apply to narrow (low angle value, ideally 0°), low dispersion, transmission, or radiated "direct beam" energy transmissions. The dispersion or beam angle of this light will be a very low angle. When the diameter of the beam eventually doubles, its illumination area will increase by 4 units^2 more, but its intensity will decrease by 4 units per unit of area.

Units for the amount of visible light

To measure the amount of visible light, units of measurement or reference need to be developed and standardized. The amount of visible light transmitted from a light source is also called the intensity or brightness of that light. When light amount in a unit of area is concentrated to be in a smaller area, its intensity or brightness seen will increase. In terms of quantifying this mathematically, we have: **light intensity = light energy / area** , and this value could also be called the energy density and-or concentration of that light energy.

The amount of reflected light transmitted from an object and-or surface is called **Lamberts** , and the reflection of the light upon it is how we can see objects, and it is also very important in photography. For example, a light source that transmits much light energy does not always mean enough light is being transmitted to and-or upon an object, and-or reflected from it. The more photos emitted from a source, the more light energy is being emitted and the brighter it will be for that particular (mono-chromatic) light frequency or range of light frequencies it was composed of, and of which is seen as a certain color which can be a mix of light frequencies and their corresponding colors.

Before LED's and other modern form of lighting, the units for light intensity were based on something commonly available, and that is the light emitted from one candle as the light source, and it is roughly a point source that transmits light energy uniformly (ie., the same amount) in all directions Since it is very possible that different candles and their construction can emit various amounts of light, etc., the construction of the reference candle for the reference units of light intensity or brightness had to be defined also. For a general study, a commonly available wax candle can be used, and when also considering it as a fire hazard. A candle in a tall glass jar, perhaps having an inch of water in the bottom is one solution to prevent fires. A metal lid with holes in it, or a metal wire mesh (ie., an array, interwoven, and with air and heat holes) lid can prevent most material(s) from getting in this jar and possibly causing a fire.

Note that if a light reflector(s) is used behind the candle, much of its light energy can be reflected and directed forward, and this will effectively increase the light energy (light amount), intensity and-or brightness in that direction as if a candle itself was producing more (perhaps 3 time) light energy. Many modern LED's and-or flashlights use a reflector just for this purpose, but it is also possible to use a light reflector for many light sources. The amount of available light energy can also be increased by a factor of approximately (n) if (n) nearby candles are used, that is, the resulting sum of light energy transmitted is equal to the sum of the light energy transmitted from each candle. Likewise, the resulting sum of light energy through or upon an area or surface at a given distance away from the source is equal to the sum of the light energy from each source, and through or upon an area or surface at a given distance away from the source. In a reverse type of manner, if the distance between the light source and the object being illuminated by that light is decreased by a factor of (n), the light energy, intensity and-or brightness (here, in a basic or simple reasoning, and since our eyes and mind actually sense light levels in a logarithmic manner) will increase by the square of that factor, hence by (n^2). These values are due to what is called the inverse square (of the distance) relationship between the amount of radiated energy received from a point source and the distance from it. In short, the intensity of the energy will be reduced at an exponential (ie., increasing and non-constant) decline and-or rate (like the speed of the corresponding changes), and the decline and-or difference in value will therefore increase significantly for and between each unit of distance further away from that source.

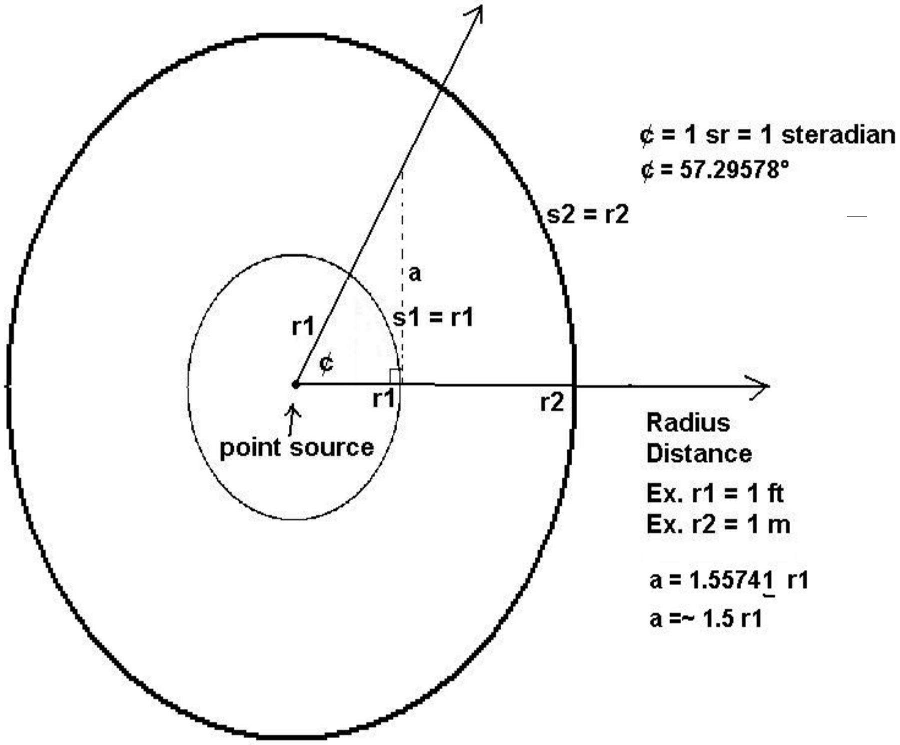
Because the candle is practically a point source of light, it radiates it outward like an expanding sphere of energy, and the amount of energy, intensity or brightness of the light available (to be seen and-or be upon a surface) per unit of area will decrease, and it is inversely proportional to the distance from the source. If the distance from the light source increases by a factor of (n), the light energy decreases by the square of that same factor, hence decrease by n^2, and which is the same as multiplying the intensity by (1/n^2) which equals reciprocal of n^2. Still, the total available energy has not changed, but it has dissipated or "spread out" and "got thinner (less of a concentration or intensity)" over a larger area, and the light energy, intensity or brightness per unit area has decreased. Due to this fact just mentioned, the energy, intensity or brightness seen, must then be measured at a particular amount and-or standardized unit of reference distance from the light source. Common units of reference distance when measuring light energy, intensity and-or brightness are the foot (ft) and the meter (m). 1 ft = 12 in. = 30.48 cm = 0.3048 m = about a third of a meter. 1 m = 100 cm =~ 3.28084 ft =~ 39.37 in =~ 39 in + (3/8) in =~ 3 ft + 3 in + (3/8) in and this value if very close, slightly less and in error or difference by only about: - 0.005 in

Light (or "light flux") energy, intensity or brightness transmitted from its source, such as the candle defined and standardized as the reference source of light energy is measured in units of **candlepower (cp)**, and more modernly as **candelas (cd)**. Note that the value of candlepower does not include its thermal energy created and-or its thermal power (energy/time), hence the word "candlepower" was not very descriptive of what this unit was intended to measure, which is light energy and not including the significantly more amount of heat energy produced at the candle's flame combustion of the hydrocarbon, wax fuel. Consider that a candle produces much more thermal energy than light energy. In the numeric sense of comparing output energy and power, a candle makes a much better room heater than a light source. The next and better choice of a word chosen to describe (visible) light energy, intensity and brightness is the word candela (cd), and of which is also like a redefined standard and-or recalculated value of a candlepower (cp):

0.981 candela (cd) = 1 candlepower (cp), and for most general purposes, they are considered equal in value and may be used interchangeably for non-critical calculations.

A candlepower was defined as the light intensity **[**and not a candle's thermal energy which is about 80W, and of which can heat a room if done safely in a large glass jar, however gas fumes and particles from a candle can become a health problem unless vented to the outside, and this is very possible to do and construct with a glass sided box and a pipe at the top that directs the particulates to the outside of the dwelling, meanwhile radiating as much heat as possible into the dwelling when needed**]** of a specifically constructed (formula and dimensions/design) reference candle with a burning flame radiating light or light energy onto a 1 square foot surface at a distance of 1 foot from just 1 candle. If this 1 foot value is considered as a radius value of a sphere, the sphere would have a surface area (= 4(pi)r^2 = 4(pi)(1^2)) of about 12.57 square feet, and if each square foot was illuminated by an energy or intensity of 1 candlepower of light, the source would then have a total of 12.57 candlepower of energy. Note that this does not mean a candle has a total light output of 12.57 candlepower, when in fact, the reference candle has a defined output of 1 candlepower =~ 1 candela. At
(1 candela / 12.57 steradians) of light energy transmitted about that light source at the center of an imaginary sphere, each steradian and-or square foot of that spheres surface at 1 foot away will have a light energy or intensity of the equivalent fraction of:: 0.079554494 candela / 1 steradian =~ 0.08 cd / sr

A figure to help understand a steradian and its size [Fig 252A]



As mentioned previously, the candlepower unit has been redefined to a better [than using various error prone candles and their expensive ingredients (materials, substances, wick dimensions, etc.) and constructions (design and manufacturing)] calibrated standard as the light energy from molten platinum at its minimal melting temperature, and shining (transmitting its light) through a 1 square centimeter opening. This amount of light energy or intensity is equal to 58.9cp =~ 60cp.

The candela was later redefined as the light energy and intensity having a single (mono-chromatic light) frequency of 540 Thz = 540 (10^12) hz, a green color, and having a power of (1/683)W =0.001464128 watts =~ 1.5 mw per steradian angle of transmission or radiation from the (point) source. This amount of energy can also be measured by the temperature increase of a (theoretical, ideal) **blackbody** or surface that absorbs (and does not reflect) all electromagnetic radiation, including infrared light (ie., heat energy and-or radiation and light), and its temperature will increase because the light energy absorbed was transformed into thermal energy and a corresponding increase in temperature of that surface and-or mass. A blackbody can also radiate the thermal energy and-or thermally caused electromagnetic frequencies of energy such as light. The frequencies of radiation it emits is determined by its temperature. If you interested further about this subject please research Planck's Law and "quanta" which is a discrete, minimal amount of energy for a photon of electromagnetic or radiation such as heat and light, and this was significant for the study of quantum theory. This minimal amount of energy per photon is a constant at any frequency, and is called **Planck's constant** = h.

As indicated above, the frequency of light and its specific corresponding energy used for the definition of a candela corresponds to a green color which is (supposedly) the color that the human eye is most sensitive to. Don't confuse the light energy or intensity of 1 candela with the emitted heat energy due to 1 burning candle, that is, a candela is a measure of the light energy only, and does not include a candles heat energy which is a much higher value than its light energy, and is actually about 80 watts (= 80 joules of energy / second) of heat energy.

Lumens (lm) are a defined measure of the energy or intensity of the light source (which has a particular value of energy called candlepower = candela, and if the light source is 1 candle, the total light energy from it is 1 candlepower) within a cross section of 1 radian angle which is also called a steradian (sr or sd) or square angle, and measured at a distance of (r) and upon a surface which will then have an area of r^2.

A **lumen** (lm), is a Latin word for light. Related word are: "illumination", "luminosity" = "brightness" or "light measure". A lumen is equal to the amount of visible light **energy** and-or power (ie., joules) emitted from a source of 1 candela (=~ 1 candlepower) for 1 second in a light beam having or limited to, or measured at, the dimensions of 1 **steradian** (sr or sd, "a solid or 3 dimensional [1 radian] angle"). A steradian is like a square shape and with opposite sides separated by an angle of 1 radian (= 57.2958°) from its vertex (at the center of an [imaginary] sphere or point source of the light), and extending outward from the center point of a sphere to a distance of (r), that (imaginary) solid angle will then intersect an area equal to [(r) (r)] = r^2 on the surface of the sphere.

Circumference of a circle = 2 (pi) (r). If the arc length on the sphere is equal to (r), then that length can divide into that circumference a total of : C / r = 2 (pi) (r) / (r) = 2 (pi) = 2 (3.14159265...) = ~ 6.28 . The corresponding angle that this arc suspends is called 1 radian angle. In brief, an angle of 1 radian is created when the distance to the arc on the surface of the circle or sphere, and the arc length are both equal to (r). Why all the fuss, why use radians and steradians? It is because these values are natural to all (and similar) circle, and 360° is a man-made value and-or angular system.

When the arc-length (s) = s = r: C / r = C / s = 2 (pi) (r) / (r) =~ 6.28 as mentioned above, hence a circumference has a total angle of (2 (pi) radians =~ 6.28 radians = 360° The length of the radius and-or arc-length of 1 radian angle angle can go about the circumference a total of 2 pi) =~ 6.28 times.

How many degrees is 1 radian angle? From the above equation, after dividing each side by 2 (pi) =~ 6.28 we have: 2 (pi) radians = 360° , as is to: 1 radian =~57.295778° . 360° / 57.295778° =~ 6.28

Extra: one-tenth of 1 radian angle and-or a tenth of its corresponding arc length would correspond to a tenth of 57.295778° = 57.29578° (1 / 10) = 5.729578° , and the arc-length also corresponds to an angle of 1 radian of a circle having a radius of 10 times less. Since these values are all linear and-or proportional, this concept can be used for any other value or factor than just 10, but using 10 as a divisor, it is easy to then find the quotient by moving the decimal point one digit leftward. Since the arc length is now 10 times less when the angle or radius is 10 times less, the corresponding area is (10^2) = 100 times less: (s/10)(s/10) = s^2 / 100 = A / 100, and the amount of light energy upon that amount of surface area will be 100 times less. If you were to use some lens and focus or concentrate (all that light energy at ro^2) = n lumens into an area that is a factor of (b) times smaller in units of area , (ie., Area / b), then the energy or lm per unit of area will increase by that same factor of (b), and here, the lm value measured for that area will be it will be a value of: (b) (n lm) .

At distances greater than (r) from a point source, the corresponding arc length (s) of 1 radian angle no longer equals the radius of the original circle, and the new arc length can be calculated from:

Since: C = 2 (pi) (r) = 2 (pi) (s for 1 radian angle) = 2 (pi) (distance from the center) , we have:

(s) corresponding to 1 radian angle = (distance from the center) = (new radius value = r)

Let It = total energy from the candle source = **1 candle power** = 12.57 lumens of light or illumination energy. Since 1 lumen is at (r) is dispersed over an area at r^2, and there are 12.57 sd sized areas about the point source or candle, therefore, there are (1 lumen / sd) (12.57 sd) = 12.57 lumens of light energy from 1 candle which has 1 candlepower of light energy.

2 candles flames side by side will then measure as 2 lm of candle light (illumination) on that same surface of 1 ft^2. Candle energy or candle power (candle energy / 1s = total candle energy/12.57 rads). For example 10W of light energy from the source will be (10W / 12.57 rads) at (r) and dispersed upon 1 square foot of area = 0.8W / ft^2 , but for an LED, this may be 1W / 12.57 = 0.08W / ft^2) at the reference measurement of 1 ft or 1m from the energy source, and here, the (number of candles at the source) = (number of lumens measured at ro or reference radius length) and the candlepower (cp) of the source = candela (cd) = (number of candles or=number of lumens at ro)(12.57).

Ex. 1 cp = 1cd = (1 lm / ro^2 at ro)(12.57 units^2 = 12.57 r^2) = 12.57 lumens *

We see that: cp = (lm at ro)/ 12.57 = number of candles used an emitting light power.
* We see that: lm at ro = (cp / 12.57) = light from a source of (cp) candles , upon ro^2 at ro

2 cp = light energy or power from 2 candles = 2 (12.57 lm) = 25.14 lm (= 2 lm at ro)

Ex. Two candles side by side will have a total of 2(12.57 lm) 25.14 lm of light energy, and will measure as 2 lm of light energy or power = (25.4 total lm / 12.57) at ro.
2 lm at ro will indicate the source of power is 2 candles = and producing a total of:
2 cp = (2 candles)(12.57lm/candles) = 24.4 lm

Ex. 100 lm total at a source is how many candle power at that source?
cp = lm / 12.57 = 100 lm / 12.57 =~ 8 cp : or use: cp = lm / (12.57 lm / cp)
lm = cp (1 cp / 12.57 lm) = 8 cp (12.57 lm / 1 cp) = 100 lm

Ex. If all the light energy = 1 candlepower = 1 candela from 1 candle is reflected and placed within a (concentrated) beam or beam angle of 1 steradian, that beam will have 12.57 lumens of energy at any cross sectional area at any distance from it. As the energy keeps getting farther and farther away from the source, the light energy or intensity (and measured in lumens) per unit area or energy per unit area will always be decreasing in value, and so the reference value of area is either 1 ft^2 (when r=1ft) or 1 meter^2 (when r=1m).

1 cp = 1 cd = 12.57 lm , multiplying each side by (n):
n cp = n cd = n (12.57 lm) = n (12.57) lm

1 cp = 1 cd = 12.57 lm , dividig each side by 12.57
1 lm = 1 cp /12.57 =~ 0.8 cp = 1 cd / 12.57 =~ 0.8 cd

lumens (lm) = energy intensity at a distance from the source, at 1 sd and on the standard reference amount of area, and of which is at r=1ft from the source, or r=1m from the source. If r = distance (d) from the source doubles, the light energy or intensity decreases by 4, and therefore, the lumens per unit area will decrease by 4.

$$(\text{ lumens per unit of area at d }) = \frac{\text{(lumens per unit area at do)}}{\left(\frac{d}{do}\right)^2}$$

: d = new distance from the source
do = a reference distance

1lm = 1cd within and onto a (ideally a black body; no reflection of energy received) (spherical) surface intersected by 1sd = 1 steradian or solid angle. If a point source of light radiates in all directions (ie., a spherical pattern), equal to: (surface area of a sphere) / (r^2) steradians = 4(pi)r^2 / r^2 = 4(pi) = 12.56637 steradians, the total amount of lumens emitted is: lumens = (candelas) (12.57).

1 lm = 0.08 cp : lm = lumens , cp = candlepower , 1 lm is a fraction of the light energy from a candle because 1 steradian angle is a fraction of the spherical transmission of the candle's light energy. mathematically:
1 cp = 12.57 lm

1 talbot = 1 lm of light energy / 1 s : this is like a light energy rate, hence (light joules / s) , however, there does not seem to be much use of this unit

Lux is the metric unit for light energy or light intensity, and it is very similar to lumen, except that the reference distance is 1 meter and the reference area is therefore 1 square meter. The reference angle is still 1 sd. and the total light energy or intensity at 1 ft from the source will equal the energy at 1 meter and so on from the source if the reference angle(such as 1 sd) is the same. In simple words, at 1 meter from the source, the light energy per same angle will equal that at 1 foot from the source, however, since the distance increased, the energy intensity or energy density = energy / (unit area) will decrease, but each area will still have 1 lumen of light energy upon its entire surface if the source is 1 candle transmitting or radiating 1 candle power of light (ie., photons, kinetic) energy.

Lux = light energy or intensity per or upon 1 square meter of surface at a distance of 1 meter from the source, hence lux = light energy / 1 sd. Since light energy can also be measured in lm / 1 sd , $\text{lux} = \text{lm} / \text{m}^2$, and $1 \text{ lux} = 1 (\text{lm} / \text{m}^2) = 1 \text{ lm} / \text{m}^2$

A good question is: Is 1 lux of light energy as bright as 1 lm of light energy, and the answer is no, and here is why:

First: $A = (r \text{ units})(r \text{ units}) = (r \text{ units})^2 = r^2 \text{ units}^2$

When $r = 1$, the corresponding area is: $1^2 \text{ units}^2 = 1 \text{ units}^2$
When r doubles from $r=1$to $r=2$, the corresponding area is: $2^2 \text{ units}^2 = 4 \text{ units}^2$, hence A increased by 4
$A1 = 4 (1 \text{ units}^2) = 4 Ao$

If the energy upon a surface of 1 units^2 is spread out over a larger area of perhaps 4 units^2, the total light energy there shining upon that larger surface is still the same value, however the energy density or light density, or energy intensity or light intensity has decreased by 4, and since brightness is proportional to light intensity, the apparent (and being more subjective at high levels) brightness will decrease by 4:

intensity (**I**) = energy density = energy / area. $Io = Eo / Ao$, and if area increase by 4, we have:the intensity decreasing by 4: $I1 = Io / 4 = (Eo / 4 Ao) = (Eo / Ao) / 4 = Io / 4$

Though at 1 sd, the total energy on the surface of 1 ft^2 will be equal to the total energy on the surface of 1 m^2 , we must consider energy density = energy intensity = energy concentration = energy / (unit area) , and this value of energy will actually decrease rapidly the farther from the source as it spreads out, and its value changes (here decreases) in a non-linear or non-proportional manner with respect to a change in distance, and is in fact it changes by an inverse square of the distance manner or factor of: $(1 / d^2)$. If d doubles (2) from 1 to 2, the value of this factor value decreases by 4. $1/d^2 = 1/2^2 = 1/4 = 0.25$. Energy density or brightness level at a distance (d) from the source = $E1 = Eo (1 / (d / do)^2$. Eo = energy density at (d). In a reverse or inverse manner, the closer you get to the source, the (measured) energy intensity will increase by a factor of 4 when the distance to it is halved, that is, it is essentially multiplied by a factor less than 1, and here it is a factor of $(1/2) = 0.5$ **Here is a general equation for the level of energy per unit area with respect to distance:**

$I1 = Io [1 / (d1 / do)^2] = Io (do / d1)^2$: do = original measurement reference distance to and-or from the source of energy , d1 is the new distance to and-or from the source of energy.

Ex: If the distance is now only half the distance to the source: $E1 = Eo (do / d1)^2 = Eo (10 / 5)^2 = Eo (2^2) = 4 Eo$.

Our eyes, if considered as light brightness sensors, do not sense light energy and-or its energy density in a linear type manner or relationship, but rather in a logarithmic type of manner or relationship. For example, when the light energy is increased many times, perhaps 10 times greater, we may only see that as 2 times greater and-or 2 times a brighter or intense, even though the energy density increased by the large factor of 10.

Note that theses have the same energy density::

1 lm / 1 ft^2 = 10.7639 lm / 10.7639 ft^2 due to equivalent fractions, and due to equivalent areas of 1m^2 = 10.7639 ft^2 (but having different units of measurement) :, this is also an equivalent measurement of the energy density of:
10.7639 lm / 1 m^2.

1 foot-candle (fc) = total energy or light upon a flat surface area of 1 ft^2 perpendicular to the source 1 foot away from 1 wax candle. If the surface was 1 meter away, and had an area of 1 m^2, the light intensity would be 1 lux, but since 1m is farther away than 1 foot, its energy density and-or intensity = brightness is less than the brightness of 1 defined foot-candle..

1 lm = 0.092937 ft-candles : about 9.3% of a ft-candle , mathematically:
1 ft-candle = 10.76 lm = 10.76 lux : and this is almost that of 1 cp = 12.57 lm

There are calibrated light meters called **photometers** that are available, and can measure light intensity using a small sensor and an electric circuit, and a reasonably well lighted room will have about 55 foot-candles measured near and upon its surface. It is possible to make a homemade light meter, but it will have to be calibrated, and it is very useful for experiments and data which can be used for various comparisons. There may be a certain distance used as a reference distance that is defined and-or necessary for some measurements and-or comparisons to other light sources. For example, the advertised light intensity of a certain brand of flashlight was measured by a photometer that was positioned one meter away.

Due to energy expanding outward from a point source in all directions, the greater the distance it is measured or seen at, the less intense the energy and-or light brightness becomes per square unit of area of surface according to the inverse square law (energy per distance) concept. Still, the total or collected energy emitted or measured per solid angle, such as 1 steradian angle from a source of energy is always the same no matter how far distant it was measured from the source.

From an ideal point source of energy which is being radiated in a sphere pattern, and since there are (4)(pi) ~= 12.57 steradians available in that sphere pattern, each steradian will contain:

total light energy available / 12.57 = 100% / 12.57 steradians = 1.0 / 12.57 sd =~ 0.07955 sd =
= ~ 8% of the total energy emitted from that source.

If you had an energy collector that collected the energy available in 1 steradian angle at any distance from the source, you can then calculate the total energy emitted from that source. For the previous values, if you collected 1w or 1 watt of energy per 1 steradian, and writing a proportion type of equation to solve for the total amount of energy emitted by the source.

If 1w is to 8% = 0.8, then Xw is to 100% = 1.0 as a relative and-or decimal value:

$$\frac{1w}{0.08} = \frac{Xw}{1.0} \quad \text{, after solving for Xw, we find:} \quad Xw = \frac{(1w)(1.0)}{0.08} = 12.57w$$

Although a steradian is formally defined as a cone shaped angle, if several of these cones were placed side by side, and just like two or more circles placed side by side, there would be gaps that need to be considered. To consider this fact, and the fact that any area can be represented as a square shape, the portion or area of a sphere intercepted by a radian angle can also be represented as a square shaped area of equal area so as to fill in the gaps. This square shape is called a square-steradian, and then the circular cone also becomes straight-sided, like a inverted pyramid shape. A smaller cone angle, but also in a square shape, is called a square-degree or **square-degee angle**, and this is based on a 1° solid angle from the point source. 1 sq. deg = 1deg^2 . Consider a circle or disk drawn on paper, and you draw lines outward from the center point and with each line separated by 1°, there will be 360 of these planar angles. If each 1 degree planar angle was rotated about the center, each and every one of the 360 planar angles could effectively create a total of 360 solid square angles. The total number of square-degree angles is therefore: (360)(360) = 129600 square-degree angles.

The light density from a source and-or upon an object (ex. 10 lumens/ ft^2) can be concentrated to be within a smaller (beam) angle and-or area on a surface being illuminated, and therefore it will have an increased intensity or energy density per unit area. In short, the light upon the subject (ex. wall, object being considered) will be brighter. This can be done by using lenses and-or curved (parabola-like) reflectors or mirrors.   Given (lm's / area), if the area decreases by a factor of (n), the corresponding lumen value will increase by that same factor of (n), and mathematically, both light energy density ratio's (lm/area) are equivalent fractions, and of which will resolve to the same number of lumens per unit of area. Since energy density is inversely related to area, it is not a proportional or linear mathematical relationship, but an inversely proportional type of relationship, hence an inverse mathematical type of relationship. When the area changes by a factor of (n), the, the corresponding number of lumens will change by a factor that is the reciprocal or inverse of (n), and that factor value is (1/n).

First:

Light Energy Created = Light Energy Out After Concentrating It   : ie., energy in = energy out   ,   power in = power out
candle power created = candle power out   : this value does not change by concentrating the available light

When the light energy density is concentrated to be a higher value, and the values of lm and A are inversely related:

Given, calculated or measured: When a variable changes by a factor of (n) in a inverse relationship:

$$\frac{lm}{A}$$

$$\frac{(1/n)\,(lm)}{(n)(A)} = \frac{(lm/n)}{(n)(A)} \quad \text{or} \quad \frac{(n)(lm)}{(1/n)(A)} = \frac{(n)(lm}{(A/n)}$$

Ex: (10 lm / 4 ft^2)   ,   (4)(10 lm) **/** (4 ft^2 / 4)   = (40 lm / 1 ft^2)   : area was decreased by 4 , and (lm/area) = light energy concentration or density , and brightness increased by 4

Note that due to the inverse physical and mathematical relationship , the fractions on the right and left are not equivalent fractions, and are not set as equal

A typical candle has a chemical (here, hydrocarbons in the wax) and-or combustion energy to light energy conversion efficiency of about 1%, and the remaining 99% is lost as heat energy. and the A typical candle will produce about 60W to 80W of heat energy.

A candle that has smoke or soot (mostly a carbon substance, mixed with some other substances) coming from it if the candle's heated and liquidfied wax not fully combusting properly (ie., incomplete combustion). The combustion process of candle wax will produce heat, light, carbon dioxide and some water molecules which are H_2O = hydrogen and oxygen. The lower part of a candle's combustion flame is higher in oxygen and has a blue color which is therefore high in (photon, light, rf, radiation) frequency and energy, and is the hottest section of that flame of which can be as high as about 1500°C for some candles.

The light output of 1 candle and-or its flame is said to be 1 candle or 1 candela = 12.57 lumens = 12.57 lm
This could be expressed as the light output from one lit (ie., ignighted) candle as being: 12.57 lumens / lit candle.
Having two lit candles side by side would produce about twice as much light and-or lumens (a measure or unit of light):
2 lit candles (12.57 lm of light / lit candle) = 25.14 lm of light

A candle can convert a (roughly) estimated value of 1%, or even less, of its combustion energy or input power to light energy and or power. The (energy and-or power) **conversion efficiency** = Pout / P in = P light / P in. The **efficacy** value is how much of that available output light energy and-or power is actually available upon the intended object and-or surface after various types of light production, transmission and-or interference losses such as a lamp shade which then effectively reduces the available light energy (lm / W).

Efficacy = (the output light energy and-or power applied to the intended object or surface) / (input energy and-or power). The units of measurement for the efficacy value are (lm / W). For a candle, and as a practical example, if 99% of the total energy is heat energy, then (100% - 99%) = 1% of the total energy is light energy. 99% of total energy is to 80W, as is 1% is to 0.8W, and from this, we can calculate: 12.57 lm / 0.8 W = 15.71 lm / 1 W = (1 lm / 0.063654 W) from a lit candle, and this can be used to measure the relative brightness and-or power of candles only since other light sources such as an LED typically have a higher value of:: (radiant light energy) / watt = for example: (100 lm / W) when it is concentrated into a narrow beam of light, perhaps within just 1 steradian (a 57.3° solid angle), or whatever the light (concentrated) beam angle is for that led flashlight due to it having a reflector and-or light concentrator, and then measured.

Note that the amount of input electric power does not mean there will be the same amount of light power emitted, and this is due to internal losses of that source lamp, and the major loss is due to heat energy also being produced.
If 1W (= 1J / 1s) of electricity or electric power is supplied and used for a lamp that has, say a 45% **conversion efficiency = (P light out produced / P electric energy in)** = 0.45 Mathematically: **P light = (P in) (conversion efficiency)**. For this example: P light = (1 W) (45%) = (1W) (0.45) = 0.45 W , hence (1W - 0.45 W) = 0.55 = 55% of the input electrical power was lost and-or wasted. It could also be said that the efficacy of the input electrical power was 45% when converted to and initially transmitted as light energy. Due to this reasoning, 1 watt of light energy does not mean or correspond to the same value, or, here for this specific example, 1 watt of electrical input power used to make it with that source having effective (light) energy losses due to it having a certain conversion efficiency that is less than 100%. How much electric power will then be needed for this particular source to produce 1 watt of light? From the above formula, we have: **P electric in = P light / (conversion efficiency)** = 1W / 0.45 = 2.222 W = 2.222 J / s . Note that this amount of input electrical power may not even be possible with some light sources such as 1 LED because it would get damaged and not function as a light source, and therefore multiple light sources will probably be needed to get a total sum of 1W of light energy. For example, if an LED had a conversion efficiency of 45%: let 2.222W = (electric power of 1 LED)(n LED's) = (0.06W)(n LED's). Solving for n, we have: n =~ 37 LED's . 37 LED's will be needed to produce 1W of light energy. Checking: (P / LED)(conversion to light efficiency)(37 LED's) = (0.6W / LED)(0.45)(37 LED's) = 1W. In general, most people want lumens or brightness from each light source instead of the total joules of light energy or watts (J/s) from several light sources.

In the Extras And Late Entries section of this book, there is an article on finding the conversion efficiency of an electric powered light such as an LED.

A more accurate analysis, measurement and calculation of a candle's light power = candlepower = candela was made by modern scientists, and the amount of usable or visible light energy from a candle is much less than 1% of the total energy of a typical candle that produces 80W, and of which is mostly heat energy.

1 cp =~ 1 cd = 12.57 lm = 0.0184 W of radiant light energy at 12.57 steradians = 0.001464128 W / steradian
: 0.0184W = 18.4 mW and 0.001464128 W =~ 1.47 mW =~ **1.5 mW**

$$\frac{12.57\ \text{lm}}{0.0184\text{W}} = \frac{683\ \text{lm}}{1\text{W}} = \frac{1\ \text{lm}}{0.001464\ \text{W}} \quad , \quad \frac{\text{light power}}{\text{heat power}} = \frac{0.0184\ \text{W}}{80\text{W}} = 0.00023 = 0.023\ \%$$

of a candles total energy is light energy,
= (a candle's electric to light conversion efficiency)

683 lm = 683 lm (1 cp / 12.57 lm) =~ 54 .34 cp = 1W of light energy = 1J / s

54.34 cp = 1W , and after dividing each side by 54.34: 1 cp = 0.0184026 W =~ 0.018W = 18mW of light energy
For comparison, an LED has about: (Pin)(conversion efficiency) = (Vin)(Iin)(%cf) = (3v)(0.020A)(45%) = (0.060W)(0.45) = 0.027W = 27 mW of light energy , this is a conversion efficiency of:
(light power out) / (light power in) = 0.027W / 0.060W = 0.45 = 45% . The LED has: 0.45 / 0.023 = 19.57 =~ 20 times more efficient than a candle. A typical 60W incandescent bulb can produce about 800 lm. 800lm/60W = 13.3 lm/W. A typical 0.06W LED produces 100 or more lm., and 100 lm / 0.6W = 1667 lm/W , and this is

(1667 lm/W) / (13.3 lm/W) = 125 times more lm per watt, and-or a conversion efficiency of 125 times more, and a therefore, 125 times less power is used. The LED's also produce much less heat per watt, and this is good in the summer time when trying to stay cool, and especially indoors where the temperature could be higher than outdoors.

It was mentioned that 55 lm per steradian is considered good lighting for a typical household room. A 60W, 800 lm incandescent lamp will therefore have: 800 lm total / 12.57 steradians = 63.64 lm / steradian, and this is slightly above the recommended 55 lm value for a well lit room. How many 100 lm LED's will create 800 lm? 800 lm / (100 lm / LED) = 8 LED's. How much electrical power will these 8 LED's use: (8 LED's)(0.06W / LED) = 0.48W , hence less than half a watt / steradian if the light from the LED is concentrated as such with its typical internal reflector. The incandescent lamp requires: 60W / 12.57 steradians = 4.77W / steradian, and this is (4.77W / 0.48W) = 99.44 times more energy or power, and which is nearly 100 times more energy and-or power required per steradian.

As of 2023, incandescent lamps are nearly all gone from common use, and for historical and-or reference purposes:

Incandescent Lamp And Rated Power	LM Rating	(LM / W)	(LM / steradian , rounded)	
40W	450	11.25	36	
60W	800	13.33	64	
75W	1100	14.67	88	
100W	1600	16	127	: about that of 1 white light LED

We see that the higher the input power of an incandescent lamp the higher the (LM / W) rating, hence the greater the conversion efficiency of electric power to light power. This is due to that when the filament in the bulb gets higher in temperature, it produces more light (photons) per watt and-or degree change in temperature.

Concentrating light energy

By using reflectors, the energy from a candle or light can be concentrated into a smaller angle or amount of steradians. If the number of steradians is reduced to a more narrow beam of light and having much more light energy can be created, and the number of lumens where it ismeasure will therefore increase. If the number of steradians is reduced by a factor of (n), the number of lumens per steradian will increase by that same factor in an inverse type of manner.

$$\frac{12.57 \text{ lm}}{12.57 \text{ sr}} = \frac{1 \text{ lm}}{1 \text{ sr}} = 1 \text{ cp} = 1 \text{ cd}$$

, and if we want to concentrate the light energy so to have (n) (1 lm) / sr = n lm / sr , we need to essentially concentrate the light's or source output transmission angle also hence reduce or concentrate it by that same value of (n). Generally, 1 cp is often noted as 1 cp = 12.57 lm of (total) light energy from 1 candle flame, as if all the light energy was concentrated or condensed into a smaller area such as 1 steradian and then this was the measured amount of all the lumens there, but the proper units for cp are actually:

1 cp = 12.57 lm / (sphere of outward transmission)

1 cp = 12.57 lm / 12.57 sr , and which is mathematically equal to the equivalent fraction of, and called: 1 candela = 1 cd :

1 cp = 12.57 lm / 12.57 sr = 1 lm / 1 sr = 1 cd

A reduction in the transmission angle (steradians) by a factor of (n) corresponds to an increase in the light energy concentration by that same factor of (n):

$$\frac{\text{steradians}}{n} \text{ corresponds to } n \left(\frac{\text{number of lumens}}{\text{steradian}}\right)$$

For conversions: 1 steradian = 57.3° solid angle
1° solid angle = 0.017452°

When highly reflective polished metal and-or mirrors were developed, it became relatively easy to concentrate the light energy from a candle (a wax fuel and-or powered lamp [light source]) or lantern (an oil powered or fueled lamp [light source]). by concentrating light, less energy and-or sources (such as multiple candles or other types of lamps) is needed, and this saves material, money and is just more practical to utilize. Some modern LED flashlights have a light concentration reflector and-or lens and possibly and adjustable beam angle which is done by effectively moving the lens closer to, or farther away from the LED(s). In general, low power red lasers can be purchased and used without a license, and for other colors, a license may be required for it to be used in some application.

A relatively recent (2015) development in LED flashlights is a **White Laser Flashlight**, and of which initially uses a blue laser light as the source which strikes a plate coated with yellow phosphor which will then create and re-radiate various other colors of light which will appear as white light. The result is a very narrow, concentrated or intense beam of white light which can travel several times farther than a standard high power LED flashlight which has a larger angle of dispersion or electromagnetic radiation. Their cost is still relatively high as of the year 2024. In general, many low power red lasers can be purchased and used without a license, but for other colors, a license and more precautions may be required due to the beam energy intensity, potential misuse and its dangers.

If you have a flashlight with a wide beam, say about 1 radian = 57.3° , you can experiment with concentrating the light from it by reducing the beam spread or transmission angle of that light by using a tube (ie., cylinder) shape of (shiny) aluminum foil. The shiny side of the aluminum foil should be on the inner surface of the cylinder shape. Make this tube shape about 12 inches long and having a diameter of about 3.25 inches. Perhaps you can also use a cardboard or plastic tube of similar dimensions. The size of the aluminum foil needed to make this shape will then need to be 12 inches long and having a width of (2 (pi)(r)) = (2 (pi) (d / 2)) = 2 (pi) (3.25 / 2) =10.21 inches, and this can be increased slightly to 11 inches so as to have some overlap of material to tape together more effectively. As you move the flashlight in and out of this tube, you will notice that the longer the tube reflector is, the more narrow (lower in angle) the beam of light.

Because aluminum foil is not a perfect reflector material that reflects 100% of the incident light upon it, some of the light energy transmitted from the flashlight will be absorbed, but still, the energy intensity or energy density (W/area = J-s / A), and light intensity (ie., brightness) of the beam will increase per unit area on a surface.

When a candlepower was redefined in terms of the most visible part of the light spectrum or range of colors.

The candlepower was effectively redefined by scientists to be in terms of just a portion of the light frequencies and their energy emitted, and this value was assigned as a new reference unit of light energy available. The new unit is called a **candela** and which is not exactly equal to 1 candlepower of light energy, and is rather a measure of light brightness or intensity, however, these values are very close in strict numeric or unit-less value and are usually considered as equal for most calculations. The light from a candle has various frequencies of red, green and blue light as its component frequencies and-or colors, and typically appears a faint or slight yellow color to our human eyes, and this could vary depending on the specific material construction of that candle being used, even though it was also defined to be made a certain standard way, but many people can not afford or have access these specially made (scientific, expensive) candles. The solution was to create a standard, reference frequency and-or color of light, and that is of a (single color and-or frequency, hence mono-chromatic) green color having a frequency of 540 (10^12) hz. This is basically the average frequency between the lower frequency red color, and the higher frequency blue color. Our eyes are also more sensitive to green colors than to red or blue colors. Due to this candela standard where some light energy (about 1.9%) was discarded from it, it is as if a candlepower of light energy was reduced in value and having a light energy value of (100% - 1.9%) = 98.1% of its defined value. If we then increase this candlepower value by 1.9% so as it to be 100% again, it will mathematically be equal to that of 1 candela:

1 cd = 1.0193$\underline{7}$ cp and mathematically: **1 cp = 0.981 cd** :(1.0 - 0.981 = 0.019 = 1.9%)

1 candela is still considered equal to 12.57 lumens.

Also, from the previous equations above, we have:
1 lm = (1 cp) (1 sr) = 1 cp-sr

1 lumen = 1 candle power of light = a total of 12.57 lumens transmitted spherically, at and-or through 1 steradian angle portion and-or its corresponding (imaginary surface) area which depends on the distance (r) from the source, however each area corresponding to 1 steradian angle, will have the same total amount of light energy passing through it, here measured in lumens (lm), passing (perpendicularly, at 90°) through it and-or upon its (imaginary) surface.

How much of the candles light energy and-or power is transmitted through, and-or corresponds to 1 steradian of the total of 12.47 steraidans of a sphere?

Let 1 cp = total light energy and-or power from 1 candle , and 1 sphere = 12.57 steradians , and mathematically: 12.57 sr = 1 sphere, and therefore, 1 sr = 1 sphere / 12.57 =~ 0.08 sphere = 8% of the sphere. If the source and-or transmission of energy was uniform and spherical, and due to that the total light energy level transmitted is proportional to the number of steradians involved, The lIght energy per steradian is about **8%** of the total amount of energy from the source.

Other units and facts pertaining to light:

foot-candles (fc) = lumens / 1 ft^2 : a type of light energy density measurement = light energy / area
A candle will transmit 1 foot-candle of light energy through 1 steradian through or onto a surface of 1 ft^2, and this area will be at a distance of 1 ft. from that candle. As the distance to the surface to be illuminated increases, the foot-candles or light energy density decreases rapidly due to the inverse square law relationship of (spherically transmitted) energy and distance. To achieve the same amount of brightness as that upon a surface that is a longer distance from the source, a light source transmitting more lumens is needed so as to have the same amount of foot-candle's of light energy. When the distance doubles from the light energy source that transmits spherically, say from 1 ft, to 2 ft, the energy density per unit area will decrease by 2^2 = 4. To regain the lost energy and-or restore the same amount of brightness, the amount of light energy from the source must then be 4 times greater, hence the lumen or candlepower value of it must be increased by 4, and so as to have the same intensity, brightness or energy density. An option to achieve this is to use 4 similar light sources or lamps.

1 fc = 1 lm / 1 ft^2 : as if the imaginary sphere had a radius of 1 foot, and each steradian had an area of 1 foot there.

lux = lumens / 1 m^2 : a type of light energy density measurement = light energy / area

1 m^2 = 10.7639 ft^2

1 lux = 1 lm / 1 m^2 = 1 lm / 10.7639 ft^2 , after dividing num. and den. by 10.7639, creating an equivalent fraction:
1 lux = 0.0929 lm / ft^2 = 0.0929 (lm / ft^2) = 0.0929 fc , and mathematically solving for (fc), we have:
Also: (1 lux is about 9.3% of 1 fc , or roughly 10% of 1 fc)
1 fc = 10.764 lux : =~ 10 lux

lamberts = is a measure of the light energy that was reflected from a surface. 1 lambert = 1 lumen / cm^2

> Named after the famous polymath (math and sciences, much like Newton) **Johann Heinrich Lambert**. Lambert is famous for his work in continued fractions, geometry, hyperbolic trigonometric functions, and optics. Lambert was the first to prove that (PI) was irrational. Lambert made progress in **photometry** which is the study and measurements of light, and progress in calculating orbits and locations of objects in space.

For an equation for the new energy level if the distance from the source changes: If the distance (d1) from the energy source changes by a factor of (n) so as to then be a distance of d2 = (n)(d1), the energy concentration, intensity or density (= energy / area) will change by the reciprocal or inverse of that factor, and this factor will then be: (1 / n^2):

(energy at d2) = (energy at d1) / n^2 : from n = (d2 / d1) , therefore mathematically: d2 = n d1
: relative energy values or use (energy / area) = intensity values

The color of a surface affects its reflectively of the light energy upon it.

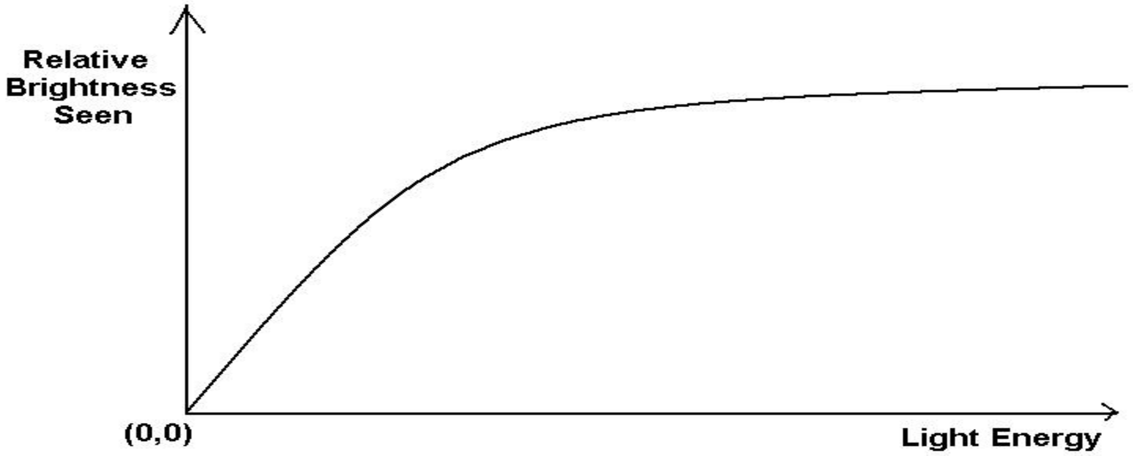
By increasing the amount of light energy upon a surface, the colors will appear brighter or more intense, and that is because the amount of energy of each reflected color has increased. Our eyes not only see or sense the colors associated with light frequencies, but also sense the amplitude or amount of energy of those light frequencies. When the reflected light energy is lower or "dimmer", the image detail or resolution is reduced, for example, making it more difficult to see clearly or read something, and the letters will appear as "fuzzy".

Most human eyes have special light sensing cells in them called cone cells, and there are three main types for sensing the three fundamental or **primary colors** or paint colors (ie., pigment small particles of matter having all the same color), as seen and not made by a direct (RGB) light source, but that of reflected light having a color or mix of : Red, Yellow and Blue (**RYB**) light, and each color has a different frequency and wavelength. The cone cells are of which is naturally tuned or resonant to a particular frequency and-or wavelength of these colors of light seen.

Our eyes are more sensitive to changes in dimmer or lower levels of light energy due to the logarithmic nature of our vision. As the light energy from a source or object increases to be a large amount, we generally can no longer sense small changes in "brightness" (ie., the energy level or amplitude of the light) when the amount of light energy changes..

The figure below shows how our eye respond to the energy levels of light, and it is in a logarithmic manner. When the energy levels or brightness is low, our eyes are more sensitive to the light energy changes, and when the energy levels or brightness is high, our eyes will usually not notice much change as the brightness or light energy level increases.

[FIG 252B]



The three **primary colors** of emitted white light are red, green, and blue, (RYB). Each has a particular electro-magnetic frequency. Red is lower in frequency than green, and blue has a higher frequency than green. When any two these colors combine, they make another colors called a **secondary color**. A primary color cannot be created by combining any other colors. If you take two colored lights and shine them both onto the same area of a white, reflective surface, you will see a different color created. Primary colors and-or their frequencies of light are then said as being **additive colors** because they can be combined to produce other colors. For example, a red and yellow light will combine to produce a orange light. A orange colored object will be sensed by our eyes as being a mix of red and yellow frequencies, and which results in a orange color being processed (ie., mixed) by our brain. The color perceived by additive color mixing is that the resulting color is apparently brighter than the other two. When all three primary colors are combined, they will produce white light if their intensities, energy, or wave amplitude levels are all the same amount. For example, if you keep reducing the intensity or energy of one primary color combined to make white light, you will eventually have a color created from only the other two primary colors combined. White light produced form red, yellow and blue is as if their frequencies were combined to produce a higher frequency that is the sum each color's frequency. Computer monitors use a **RGB** method via separate red, green and blue LEDs (Light Emitting Diodes) to produces an apparent resulting color of a pixel (picture element, part) on the viewing screen by varying the current to each of those three closely spaced LED's which then creates both the color and the shade, brightness or intensity of it.

Now lets consider the colors reflected from objects. We see a blue colored object, it is because it is absorbing all other colors such as red, green and any other possible color besides the color of blue actually seen. If we see a green surface, then the frequency of light corresponding to green was reflected off it. If we see an orange surface, then the frequency of light corresponding to red light and yellow light were reflected off of it. The same process can also be said for the other two primary colors. If you were to pass a beam of white light through a series of colored glass such as a red, blue, and color, and in that order, the red glass (or "red pass filter") will absorb all other colors and pass or transmit only the red color of light. When this red light is then passed through the blue glass, it will in theory, not be transmitted out at the opposite side of the blue glass since it has not received any blue color to pass through it, and the result is that it will absorb that incoming light, and no light will be transmitted, hence, as if it was black only. When paint and-or pigment colors are mixed this way, the resulting colors are called **subtractive colors.** Many printers use the cyan (green-blue), magenta (similar to: purple, violet, maroon) and yellow, (**CMY**) color system so as to produce a third color. CMY are not primary colors, but are secondary colors. The three colors (CMY) mentioned, when combined, they will create black, however, to reducing using these relatively expensive inks, black ink is rather used to produce the black color, and which is often needed for common, and-or large scale black text printing on white colored paper, such as for books. This color method just described is usually called the **CYMK** color system, and where **K** stands for blac**K** in order not to confuse it with blue. Red, Yellow and Blue (**RYB**) is also a subtractive color system or model, and so as to mix two colors to have a third color.

To create the 3 **secondary colors** of light (ie., and not paint reflecting those colors) from two of the 3 primary colors (**RGB**, red, green, and blue) of light, mix or combine (+) these two colors so as to produce a third and unique color:

red + green = yellow , red + **b**lue = violet (purple, magenta) , green + blue = teal (turquoise, aquamarine)

Dark colored surfaces absorb some amount of light energy and convert it to heat energy ,and therefore, they do not reflect as much light as a surface not a dark in color. The darker the surface, the more light energy absorbed, and therefore, they appear as darker in color. A perfect **black-body** is a surface of black color of which absorbs 100% of the light, heat or electromagnetic energy upon its surface and therefore it reflects no light energy, and it converts all the received light energy into thermal energy (ie., heat energy, and which has a lower frequency, and of which is actually leads to a kinetic energy of the matter (ie., atoms, molecules, electrons) rather than re-radiated or reflected as light energy. By measuring the increase in the temperature of a perfect black-body surface and its mass (perhaps being constructed of a square foot or square meter of thin aluminum plate), the amount of total light energy it received upon its entire surface can then be calculated. If the source of the received light was from a theoretical point source radiating or transmitting light outward or radially from it in a spherical manner, then the total amount of light energy transmitted and-or of that source would then be 12.57 times greater if the black body had a surface area which corresponds to a cross-sectional area of 1 steradian (solid angle). This factor value is so because a point or sphere has a total of 4 (pi) =12.57 steradians radially and-or spherically about it.

If some of the light energy reflected off an object or surface is at an angle and-or other direction away from your line of vision, then it will not appear as bright.

Sometimes very dense ice, such in the polar regions, appears to have a green-blue color, and this is due to all the other colors of the white light from the Sun being absorbed by that ice and-or now on it. The thicker the ice, the more blue (ie., a darker shade of blue) the output color will be. Snow appears as white because it is reflecting nearly all the white light that strikes it. The reflected light is also rather scattered at various angles, and therefore the snow is not like a polished mirror that reflects incoming light well, and at the same angle of incidence.

A simple light meter can be made using a circuit that contains a light sensor (perhaps a solarcell or a light sensitive resistor), and it measurements can be calibrated (adjusted or set so as to indicate accurate values of a measurement, here by using various light sources and an actual light meter, and recording those values for your circuit. The circuit could measure voltage, current or resistance when using a light sensor that ideally has a linear or proportional electrical output or response to the amount of light upon it's surface.

THE SPEED OF SOUND

For the value of the speed of sound (a compressed air wave traveling outward from its source) in the air, first consider that a person is repeatedly, visibly striking an object and periodically (same time) producing a sound every 1 second of time , and that it takes 1 second of time for that sound to reach the listener from a certain distance away. The speed of that sound can be calculated from knowing the distance equation: distance = (speed)(time), therefore mathematically: speed = (distance / time). If the distance was 1100 feet, and the time was 1 second, the speed of sound is about: **speed of sound ~= a distance of one-thousand and one-hundred feet per second = (1100ft / 1s). 1100 ft/s = 0.335.28 km/s =~ 335 m/s**

The common value for the speed of sound is the average value at sea level where there is an average air density and pressure of 14.7 psi.

How long will it take sound to travel 1 mile = 5280 feet? : 1 mile =~ 1.61 km

From d= v t , t = d / v , t = (5280 ft / 1) **/** (1100 ft / 1s) = 4.85 s = about 5 s

How long will it take sound to travel 1 kilometer = 1000 meters? : 1 km =~ 0.621 miles =~ 3281 feet

From d= v t , t = d / v , t = (1 km / 1) **/** (0.33528 km / 1s) = $2.98\underline{3}$ s =~ 3s ,

Many equations involving electromagnetic or sound energy radiation include an inverse-square relationship of the intensity and distance to or from a source. For example, for the forces of gravity, magnetism, electric force intensity, light intensity, and sound intensity. Sound is caused or created by a physical ("mechanical") force or pressure upon something. For example, an elector-mechanical vibrating speaker will giving air some kinetic energy, and then this compressed air or pressurized air that contains energy is transferred outwards and through a medium such as less pressurized air as a mechanical force, vibration or wave. A force applied to air will cause a compression and then a decompression ("rarefaction", reduction) of the small particles (atoms) of air matter as the energy is radiated or transmitted outward form that source, and this will then propagate (distribute, transmit, send) the sound energy (air compression, pressure, force) and affect other nearby particles of air or other matter like a "chain reaction" or "domino effect" of collisions, and at the same frequency as the source vibration and-or force.

Sound and vibrations travel faster in denser materials since the energy transfer is more efficient. There is more material or matter per unit volume to transfer sound or vibration energy, hence reducing the time of energy transfer from particles to particle.

A modern, closer and accepted estimate for the velocity or speed of sound in a 20°C = 68°F air temperature, about room temperature, is typically considered as 1125 feet per second = nearly 343 meters per second = 767 miles per hour, and this value increases fairly rapidly as the density of the material (transfer medium) that the waves pass will through increases.

The speed in sea-salt water is slightly less than 1 mile per second at about 4921 feet per second = 3355 miles per hour = 1500 meters per second. 4921feet ~= 5000 feet. 1 mile = 5280 feet. In dense metals such as aluminum and steel, the speed of sound has an average of about 16400 feet per second = about 3.1 miles per second = about 5000 meters per second.

The speed of sound also increases due to temperature since the molecules and-or atoms of the transmission medium (air, water, metal) are moving more quickly, and therefore can receive and transfer (or transmit) the sound energy in a shorter amount of time. Typically, the speed of sound changes by 0.6 m/s = 1.9685 ft/s = about 2 ft/s for each 1 degree increase (change) in Celsius temperature, or about 1.1024 ft/s for each degree change in Fahrenheit. A change of 1 degree Celsius temperature corresponds to a change of 1.8 degrees Fahrenheit.

The ratio of an objects velocity (ie., speed) to that of the speed of sound in air is called the Mach Number of that object. It was created by the Austrian physicist Ernst Mach in about 1887. It is basically how many time faster an object is going as compared to the speed of sound. Mach studied many things related to shock and (air) compression waves when an object travels faster than sound. The speed of sound can vary in air, depending on altitude and density of the air, but for general, practical or relative comparative reasoning, it can be considered as the speed of sound at sea level, and at 20°C = 68°F. Mach 1 = the speed of sound in air = 1125 ft/s = 767 miles/hour = 343m/s = 1235km/hour

$$\text{Mach number} = \text{Mach \#} = \frac{\text{object's velocity}}{\text{velocity of sound in air}} = \frac{\text{objects velocity meters per second}}{\text{Mach 1 = 343 meters per second}}$$

1 mile = 1mi = 5280ft = 1609.34 meters = 1.60934km

Ex. An airplane jet going Mach 2 is going: (2)(Mach 1) m/s = (2)(343 m/s) = 686 m/s = 1534.$\underline{5}$ mi/h

Underwater, where sound vibrations and can travel faster and therefore for a greater distance before it is naturally spreads or diverges out to a larger radius and its energy significantly decreases (ie., weaker, less intense per unit area) and becomes negligible, the water pressing against our eardrum sound sensors will greatly dampen (reduce, due to a resistance and loss of some free motion) it from vibrating efficiently, particularly with the high audio frequencies. Our denser head bone can effectively receive higher frequencies more efficiently, and even above the typical 10,000 to 20,000 hertz (ie., frequency) max. audio upper limit for most human (ear) hearing, and will effectively transmit the sound to the audio nerve sensors very well, and even to the point that some sounds, particularly the higher frequencies, are even louder or stronger than expected.

AIR PRESSURE AND ALTITUDE

Sound, essentially a transmission though air of energy in the form of pressure (compressed air) or force from the atoms of gasses in the air, is not transmitted through a vacuum such as in outer-space since there is no transmission medium or "conductor" like air or some other dense enough gas for the sound to travel through. Remember that on Earths surface, air is also pressurized (hence denser) from the column (height) of the amount and weight of the air above and around it. The air at high altitudes is said to be "thin" and having less oxygen, and this is due to the lack of air pressure concentrating (and increases density) or compacting it. This air pressure also helps our lungs inhale and inflate. The "standard air pressure" or "standard atmosphere" is about 14.7 pounds = 6.668kg per square inch, (psi), at sea level (0ft in altitude). This value will be less at higher altitudes, and for example, the air pressure at the top of Mt. Everest (29029 feet ~= 5.5 miles = 8848 meters high = ~= 30000ft) is only about (1/3) of that at sea level = (14.7psi)/3 = 4.9 psi, and this value is dangerously low and that oxygen tanks are usually needed, especially for highly active climbers. The air is not only at less pressure which is needed to inhale and expand the lungs, but the density of the air is also very low, and each breath does not have much necessary oxygen in it. At the top of Mt. Everest, the density of the air is about 33% as that at sea-level. Artificial (compressed, etc) air pressurization is used to maintain normal breathing and body pressure inside of a high altitude airplane, spacecraft, and spacesuits. The less dense, lower pressure air at high altitudes effectively makes sound production less efficient and therefore, the amplitude (volume, loudness) produced is lower, and even at the source and creation of the sound wave where not much vibration or force energy is transferred to the thin (ie., low density, low pressure) air to pressurize it into a transmitted wave. Air pressure can also change during a weather storm. At 62 miles = 100 km high is an imaginary boundary or line called the "**Karman line**" where the amount of air density (1 (10^-12) g/cc) and air pressure (1 (10^-11) psi =~ 0 psi, hence much like an empty vacuum) is considered negligible, and where airplanes cannot gain enough lift at that height and (orbit) velocity needed. Above this line toward higher altitudes is considered as the start of outer-space, but some others might consider that outer-space starts at the simple and "round-about" value of 100 miles high where there are even less atoms of air present. At these heights, it is still only a very small fraction (62 miles / 4000 miles = 0.0155 = 1.55%) of Earth's radius. Earth's atmosphere layer is much like that of the relatively thin layer of the shell of an egg.

Due to less air pressure at higher altitudes, heated water molecules in water have an easier time breaking free from the other water molecules, hence the water boils or "boils off" easier. At standard atmosphere pressure (1 atm = 14.7psi [pounds of pressure or force per square inch] at sea level. at 68°F air temperature), water boils at 100°C = 212°F. The hot water will evaporate (ie., vaporize) and become steam (a gas of water molecules) and rise upward since it is less dense than liquid water and the air. When this steam looses heat energy and cools to a lower temperature, it will condense (become more dense) together into larger and visible water drops like rain. The bubbles seen in boiling water are not uniquely hydrogen or oxygen gas bubbles, but are hot steam gas (water vapor) bubbles created by hot, high energy and moving molecules of the water vapor. The formula relating the boiling point of water to air pressure can be complex, and a simple, approximate formula can be created. The **boiling point of water** is directly related to pressure, but it is not a direct linear relationship, so here is a small chart for making a close estimate:

Pressure (psi)	**Typical Altitude (ft)**	**Boiling Point Of Water**	: Approximations for all values listed here.
4.3	30000	152°F = 67°C	: Mt. Everest 29032 = 5.4985 mi ~=5.5mi =~ 30000 ft , and
5.2	25000	163°F = 73°C	the total change in boiling temperature from sea level is
6.5	20000	174°F = 79°C	about 60°F. The corresponding change in air pressure is
8.2	15000	184°F = 84°C	10.34 psi. The mathematical relationship between the
10.0	10000	194°F = 90°C	boiling point and altitude is **nearly** linear at about:
11.6	6000	201°F = 94°C	Approximate rate of change = - (1° / 500 ft) = - (2° / 1000 ft)
12.6	4000	205°F = 96°C	
13.6	2000	208°F = 98°C	
14.7	0	212°F = 100°C	: sea level air pressure and boiling temperature point of water

A quick and simple estimate, especially for the lower altitudes, would be for every 2000ft higher in altitude, the air pressure will drop by 1psi., and the boiling temperature of water will decrease by about 4°F =~ 2°C . Another quick and simple estimate is that the boiling temperature of water will decrease by 1°F for every 500 feet higher in altitude, or 2°F =~

1°C for every 1000 feet higher in altitude. For conversions, 1foot = 0.3048 meters. Multiply feet by 0.3048 to convert to meters. Multiply meters by 3.2808398 to convert to feet. 1000ft = 304.8m, 1000m = 1km = 328$\underline{1}$ft. From this discussion, a reasonable estimation formula can be:

Boiling Point Of Water Estimation Formula (at altitude) = 212°F - 4°F (altitude feet /2000 feet)
Boiling Point Of Water Estimation Formula (at air pressure) = 212°F - 4°F (14.7psi - psi)

It will take less energy and time to boil water at a higher altitude where there is less pressure or compression applied to the water, and this will also decrease its density slightly. At low pressures upon water, it can actually expand and start (cold) boiling and off-gassing steam (water gas, water vapor, water molecules) since the molecules are not held together as much. Less energy is less joules of energy. Less energy per unit of time is less power (ie., rate of energy use or transfer) needed. P = energy / time = joules / second , and with units of watts. Now consider at sea level, for water to boil, the molecules of it must be given more kinetic energy by heating that water, and then when the water pressure becomes greater than the air pressure upon it, it will steam and boil into the lower pressure region of air that is at standard air pressure of 14.7psi.

The formula(s) for air pressure at an altitude can get complicated with many variables (height, temperature, air density, humidity=moisture in the air) to consider, and of which you may not have any data for their current values, but here is a simple estimation or approximation formula for the typical air pressure at a certain altitude less than 30000 feet, and the result differs by only about 5% or less than a real typical previously measured and-or current actual current value which can also vary due to many variables such as the air temperature:

$$\text{air pressure} = \frac{14.7\ \text{psi}}{3.2\text{^}(\text{height ft} / 30000\ \text{ft})}$$

: **A Simple Air Pressure Approximation Formula**
For Heights <= 30000 Feet
Height above the surface of the Earth = altitude.
A lookup table is also an acceptable alternative.

Or by converting 3.2 to an equivalent power of (e): e^1.163151... = 3.2 and e^(1.163151)^x = 3.2^x

$$\text{air pressure} = \frac{14.7\ \text{psi}}{(\text{e^}1.163151)\text{^}(\text{height ft} / 30000\ \text{ft})} = \frac{14.7\ \text{psi}}{\text{e^}(1.163151\ (\text{height ft} / 30000\ \text{ft}))} = \frac{14.7\ \text{psi}}{10\text{^}((0.50515)\ \text{H}/30000\ \text{ft})}$$

The value of **14.7 psi is also called 1 ATM** ("1 **ATM**osphere" of pressure) which is the normal, average and standard pressure of the atmosphere (air) at sea level. 14.7 psi = 1 ATM (typical "atmosphere (air) pressure" at sea level) = (nearly) 1 bar = 101 kPa , and Pa is a unit of pressure called a pascal, see the note below. The value of 3.2 is a compromise value so as to be more accurate near the ("center height" of this scale and formula) 15000ft height, and when not using other variables such as temperature. It was derived from that at 30000 feet, the known pressure is about 4 .36. 14.7 / 4.36 = an increase by a factor of about 3.37. Therefore, 4.26 is about 3.37 times lower than 14.7 4.26 / 14.7 =~ 0.304$\underline{3}$ =~ 30%. 4.36 psi is the air pressure at the top of Mt. Everest, and is about 30% of the air pressure at sea level. The values of the pressure data indicated a non-linear curve, hence some type of exponential equation could be used, and 3.2 was chosen as the (compromise value) base of this power value. You could simply use 3 for rough estimates. This equation for the air pressure at a certain height also requires a height variable. When the height or altitude is 0, the air pressure from this equation needs to be 14.7, and so it was included as the value to be worked with for all the other height and pressure values up to about 30000 feet. Note also that **14.7psi = 29.92 inches of mercury** = 29.92 inHg =~ 30 inHg, and other corresponding values can be found by setting up a proportion and-or equivalent fraction equation.

The air pressure at **0 ft elevation = 14.7 ps**i (pounds per square inch) at sea level = 1 atmosphere = 1 atm. Here are some typical values of air pressure (psi) and the altitudes. The higher the temperate,the greater the air pressure due to the movement of the air molecules having more kinetic energy. These values consider a constant temp. of about 57 °F :

1k ft. = 14.2 psi 2k ft = 13.7 , 5k ft = 12.2 , **10k ft = 10.1** , 15k ft. = 8.29 , 17878 ft = 7.35psi = 14.7psi/ 2
20k ft. = 6.75 , 25k ft. = 5.42 , 30k ft. = 4.36 , 35k ft. = 3.46 , 40k ft = 2.71 , 45k ft. = 2.10 , 50k ft. = 1.69
60k ft. = 1.05 , 70k ft. = 0.65 , 80k ft. = 0.406 90k ft. = 0.26 , 100k ft. = 0.16

If you are able, it would be a good exercise to plot the data points and draw an approximate graph and-or curve of the above data. This curve will rapidly slope downward from 14.7 psi at 0ft, and the slope will approach 0 at about 100k ft.

At 1k ft. below sea level, this can be expressed as: **-**1000 ft, such as in a deep cave or tunnel, the air pressure is actually higher than that at sea level, and is about 15.2 psi. The Dead Sea at -1370 ft has an air pressure of 15.5.psi. At 1 mile below sea level, the air pressure in a cave would be about 17.6 psi.

Extra: Although weather can affect several meters of surface temperature, the deeper you go below ground, the hotter it will be and the **geothermal gradient** or rate of temperature change with respect to land depth averages about +80°F increase per mile deep, and this is due to the heat from the hot core of the Earth being at high pressure and some radioactive decay of heavy radioactive metals producing heat

At less than 20000 ft, high, the air pressure drops in a fairly consistent, slightly linear way as the altitude increases, and for higher altitudes, the drop is more gradual and less, say per 1ft or 1000 feet. Let us find how much the pressure will drop with a simple or crude linear (line-like, constantly proportional) approximation:

$$\text{linear rate of change} = \text{slope} = m = \frac{\text{(change in y)}}{\text{(change in x)}} = \frac{\text{(change in PSI)}}{\text{(change in altitude)}} = \frac{(14.7 - 6.75)}{(20000 - 0)} = \frac{7.95}{20000} =\sim \frac{0.4 \text{ psi}}{1000 \text{ ft}}$$

(change in PSI) = (starting PSI) - (ending PSI) : with the right side terms reversed for a positive value
(ending PSI) = (starting PSI) - (change in PSI) = 14.7psi - (change in psi)

Change in PSI =~ (0.4 psi / 1000 ft) (ch. altitude in ft) =~ (0.0004 psi / 1 ft) (altitude in ft) : 0 ft to 20k ft
: Letting ch = change in altitude from the reference altitude
Solving for the altitude in ft, from this formula , we have:
altitude ft. = ((14.7 psi - PSI) / 0.0004 PSI)) (1 ft)

Ex. At 20000 ft, the PSI can be roughly estimated as:
PSI = 14.7psi - (0.0004 psi / ft) (20000 ft) = 14.7 psi - 8psi = 6.7 psi : 6.75 psi is listed above , likewise:

In terms of the common linear equation format:
y = mx + b ,
psi = m(altitude) + b =
psi = (slope)(altitude) + (y axis intercept when x=height =0)
psi = (-0.0004 psi / ft.)(altitude ft.) + 14.7 =
psi = 14.7psi - (0.0004psi / ft.)(altitude ft.)

Change in PSI =~ (0.2 psi / 1000 ft) (ch. altitude in ft) =~ (0.0002 psi / 1 ft) (altitude in ft) : 20k ft to 40k ft

Ex. At 30000 ft, the PSI can be roughly estimated as: (First, the psi at 20k ft is 6.75)
PSI = 6.75psi - (0.0002 psi / ft) (10000 ft) = 6.75 psi - 2psi = 4.75 psi : 4.36 psi is listed above

A more alternate value for CH. in PSI for altitudes from just 20k ft to 30k ft is: (0.00024 psi / 1 ft)

Using the main approximation formula equation for air pressure or PSI given previously, and solving for the height in altitude above sea level and up to 30000 ft, such as after measuring or given an air pressure (AP) psi value, we have:

Height in feet = 30000 ft [ln (14.7 psi / AP) / ln 3.2] = 30000 ft [ln (14.7 psi / AP) / 1.16315081]

Here are some other units used for pressure besides psi = pounds of weight force or pressure per square inch = pounds per square inch:

First note that: psi = pounds of force per square inch = pounds-force / 1 in sq.

Since 1 square foot has (12" x 12") = 144 in^2 of area,
1 psf = 1 pound of force / 1 ft^2 = 1 lbf / 144 in^2 = 0.0069444 lb / in^2 = 0.0069444 lb / in^2 = 0.0069444 psi

1 pascal = 1 Pa = (force/surface area) = pressure = 1n / m^2 = 1n / 10000cm^2 = 0.0001n / cm^2 : named after Blaise Pascal
: n = N = Newtons

1 pascal = 1N / m^2 = applying an energy of = F / A = Fd / Ad = F m^1 / m^3 = Work / Volume = Energy / Vol = **1J / m^3**

1 **ATM** =1 ATMosphere = ~ 29.92 inches in height of mercury (Hg) =~ 30 inches high of mercury =~ 76 cm = 760 mm Hg
1 ATM = 14.7psi = 101325 pascals ~= 100000 pascals : 1 ATM = the pressure of 1 atmosphere.

Ex. At tank of some gas is noted as having an internal pressure of 5 ATM = (5 ATM)(14.7 psi / 1 ATM) = 73.5 psi

1 **bar** of pressure = 100 Kpascals = 100KPa = 100000Pa = about 14.504psi , **and this is just slightly less than 1atm**

14.7psi = 14.7 pounds per square inch = 14.7 pounds per 6.4516 square centimeters, with about 2.2785 lbs / cm^2 which is equivalent to about: 1.034kg / cm^2 =~ 1kg / cm^2 =~ 9.8N / cm^2 =~ 10N / cm^2 =~ 100000 pascals

STP = **S**tandard **T**emperature and **P**ressure, and it depends on the substance, location, conditions, experiment, etc.
For the atmospheric (air) pressure at sea level: STP is: 0°C = 32°F and 14.7psi = 1 atm = 1 bar . To quickly convert from Kpa to psi, divide the Kpa by 6893 , (about 7000), for ex.: (100000Pa/1psi) / (7000Pa/psi) = 14.$\underline{3}$psi

As mentioned previously in this book, a device called a barometer can measure the local air pressure at various levels of height and weather conditions which can affect the local or nearby air pressure. By knowing the average air pressure at a certain height or altitude, a barometer can actually be used to also effectively measure (by calculation) altitudes after rearranging the air pressure formula to solve for height.

A note about barometric or atmospheric density, pressure and temperature changes.

In a car tire as it heats up from road friction, the air inside it will gain more kinetic energy and exert more force upon the inner wall of the tire, therefore, its internal air pressure will increase if its volume remains the same and does not expand too much from the pressure. When it is cold outside, the air within a cold tire will loose kinetic energy, and the air pressure in the tire will decrease and may even deflate it slightly which may cause a dangerous driving condition and-or increased tire wear due to the increased friction on the tire's outer surface.

Even apparently invisible gases like air have weight because it is composed of atoms of various gasses such as nitrogen and oxygen. The force of gravity will be upon this matter and they will tend to move downwards toward the ground unless the force of the wind is moving it in a different direction. The weight of air above the ground will cause a pressure (P = F / A = weight / area) on the ground or an instrument that measures the air pressure at any altitude. Due to the weight of the "air column" above the ground, the air at the ground will be at a higher density (d = m / V), weight (= force = ma = dmV, and pressure.

In the atmosphere, when temperature increases, the air pressure rather decreases due to that the atmosphere has room to expand in volume and therefore, it get less dense (= mass / volume). Less dense air means it will weigh less, and therefore exert less pressure upon an object. It is also of note that then warmer air, being less dense than the surrounding cooler air will then rise upward, and the cooler, more dense and pressurized air, and possibly more water moisture and a rain storm, will then move in towards a lower pressure region.

At higher altitudes where the air is less dense, a change in temperature will not affect the air pressure as much as it would at ground level where the air is more dense and the air pressure is 14.7 psi on average.

A formula for water pressure at a certain depth is:

$$\text{water pressure} = 14.7 \text{ psi} + \frac{(\text{depth ft})(14.7 \text{ psi})}{33\text{ft}}$$

: 33 ft ~= 10 meters, each extra 10 meters or 33ft of depth will add another 14.7 psi to the typical air pressure at the surface. With this equation, the values of pressure and depth have a linear mathematical relationship. For every 33 ft deeper, the water pressure increases by 14.7 psi =1atm. The pressure at 33 feet deep is: 1 ATM +14.7 psi = 29.4 psi = 2 ATM. Each foot adds: (14.7psi/33ft) = 0.4455psi per 1 foot. Note that 14.7lbs = 6.668kg. and 1 in^2 = 6.4516 cm^2

At 100ft , psi =~ 60 , At 200ft, psi =~ 104 , At 1000ft, psi =~ 460 , At 1km = 1000m = 3281ft, psi = 1476 ,
At 1mi = 5280ft, psi =~ 2367. To use the above formula for meters of depth, first divide the number of meters by 0.30479 to convert it to its equivalent feet units value. For every 100 feet more deeper, the water pressure will increase by about $44.5\underline{5}$ psi =~ 45 psi. For every 1000 feet more deeper, the water pressure will increase by about 450 psi.

The above formula is linear (ie., water pressure in a proportional mathematical relationship to depth) because water does not compress very much due to its fairly high density, molecule structure and could be considered as already being a highly compressed gas of steam [water vapor], but the formula for air pressure (ie., air pressure in relationship to height) is non-linear because air compresses much more than water because air is usually a gas that has a low density, except for liquefied air. The air pressure and-or density of the air at sea level is relatively high due to depth of it in the atmosphere region and-or column of the air and its mass above it, and the air pressure decreases relatively rapidly as the altitude increases.

For some basic verification that the pressure will increase by 14.7psi for every 33 feet deeper: 1 cubic inch of water weighs about 0.578 ounces. A foot or 12 inches high of this cubic inch will weigh: (0.578 oz/in) (12 in) = 6.936 oz/1ft .
(6.936 oz/ft)(33 ft) = 228.888 oz, and dividing this value by 16 oz/1lb, we find that 228.888 oz =~ 14.3lbs ,
33 feet = 10.0584 meters =~ 10m

When an object is subjected to a force and-or pressure (F/A), that object is said as being compressed or pressurized. If the force and-or pressure is reduced, then the object is said as being decompressed or depressurized.

The minimum depth that is considered as extremely dangerous for a diver to dive or go to without a special pressure protective diving depth suit or rigid surrounding safety vehicle, such as a "submarine" [below the water surface, a vehicle], is 130 feet. Here, the pressure is about 58 psi. This is about the pressure of a typical 26 inch bicycle (air pressure inflation) tube in the tire. At this depth, and for greater depths, a minimum amount of "decompression" time is needed so as to avoid decompression sickness (sometimes called "bends") as the diver travels upward to a lesser depth . Here, expanding in volume compressed nitrogen gas bubbles in the body, due to less pressure on them as the diver goes upward in the water to a less depth, are given some time to be safely eliminated from the body. The diver must ascend slowly at calculated amounts of time. People in high altitude, internally pressurized craft, where the air pressure is low at high altitude, may experience similar effects of a divers decompression sickness if the craft becomes unpressurized. Consider the fact that water boils faster or more easily in a lower pressure environment such as on a high mountain. There are fish and other life forms living their lives at crushing, high pressure depths of water. These forms of life have adapted their physical structure and internal life chemistry so as to prevent the high pressure from harming them. Most of these life forms have therefore adapted and are accustomed (used) to and need this high pressure environment so as to live and function properly. A balloon or air bubble would be squashed or compressed equally on all sides of it, and it will have a smaller diameter as the depth of it in the water is increased. In a reverse manner, the balloon or air bubble will expand as the depth and pressure decreases.

When an object goes in very deep water, the water pressure upon that object is not to be considered as just as a weight upon it forcing it downwards and the object weighing much more, but rather as a compression force acting upon all sides of the object equally, and not just downward upon it. The object will still have the same mass and weigh the same less the upward buoyant force upon it that is equal to the amount of water it displaces. In short, the buoyant force does not depend upon the depth of the object and the pressure upon it, but rather the weight of that amount of water being displaced.

An object, such as a fish or submarine, can remain at a fixed depth in water if the buoyant or upward force due to the displaced water equals the downward weight of that object.   Effective weight = (weight of the object - buoyant force)

A volume of air or space of 1 cubic foot will displace 1 cubic foot of water which weighs about 62.427lbs = 28.316kg. The total or resultant buoyant force of a lite weight container or balloon will be this amount. It could be said that the (upward) "lift force" (ie., buoyant force) of the displaced space or balloon under water is about 62.427lbs per cubic foot. If an object was suspended from this balloon and weighted less than 62.427lbs, it will still rise upwards in the water. If the object weighs 62.427lbs, it will remain at the same depth. Here, the total (downward) weight (force) of the object will then effectively cancel out the total (upward) buoyant force effectively pushing upon it from below due to the water pressure, and the object will have 0 net force acting upon it and it will remain (vertically) motionless at the same depth in the water.

Since water does not compress much, even at great pressure, its density at great depths is still about the same value as that at the surface, and which is: density of water = (mass / volume) = 1gram / 1cc.

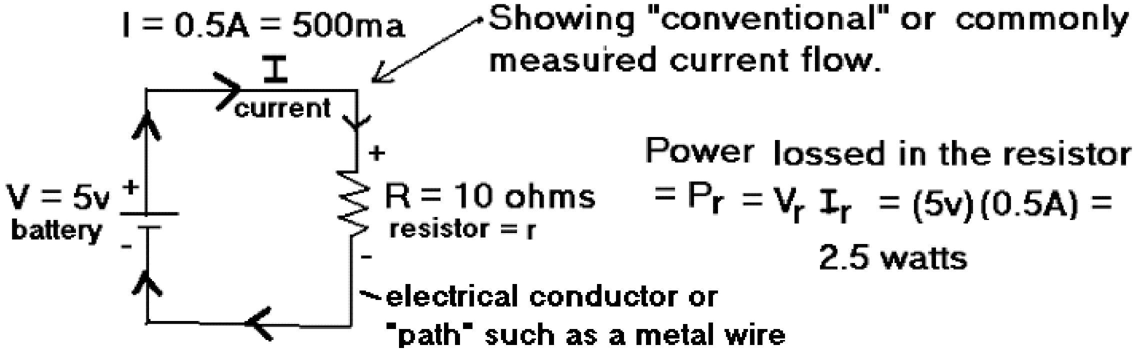
By rearranging the above formula for water pressure at a certain depth, we can solve for the depth given a certain value of water pressure:

$$\text{Water depth in feet} = \frac{(\text{PSI} - 14.7\text{psi})(33\text{ ft})}{14.7\text{ psi}}$$ **: depth of water in feet, given the pressure (psi) at that depth**

A SCHEMATIC DIAGRAM OF A BASIC ELECTRIC CIRCUIT

A schematic diagram or representative drawing of a simple electric (electrons with kinetic energy and electric charge) circuit (path, course) is shown below, and Ohm's Law is also used for some analysis and calculations of it. For electrons to flow, it needs a complete path to do so, and this is called a closed circuit, as opposed to an open circuit where a wire got cut open or something. A short circuit is where the electrical path has been shortened for some reason, perhaps by a piece of metal or wire. This short or shorted circuit is very dangerous for it can damage your device, drain the power supply, and-or cause smoke, and fire. Usually a circuit will cause some resistance in a circuit to be less or bypassed, and therefore , a high current will then be flowing in it.

Below, (I) is the identifier name of the variable for electric current and which is measured in units of amperes (A). Ir represents the amount of current through the resistor. V is used for voltage which electrically gives (electric) force and therefore transfers (kinetic, motional) energy form the battery (energy) supply to the electrons to flow. R is used for resistance which limits the flow of current and prevents the battery from draining of its energy too fast. Vr represents the voltage across the resistor. Conventional current flow is where the electrons are considered as coming out of the positive terminal of the battery, and this is also mathematically practical since the increase in energy of the electrons is then given a positive sign rather than a negative sign. [FIG 253]



I = voltage applied to total resistance / total resistance

I = 5v / 10 ohms = 0.5A

Vr = (Ir)(Rr) = (0.5amps)(10ohms) = 5 volts

The power lost in the resistor or resistance can also be considered as equal to the amount of power delivered to that resistor, and-or needed by that resistor to function properly, such as a heater, etc. Generally, in many circuits, heat is an indication of not only lost power, but of completely wasted power and energy. Because energy has a price and resources associated to it, a circuit and-or device should be designed so as to have a low waste of power, hence have a high energy efficiency or usage:

Power Input = Power Output + Power Losses : Also: = (min.) Power Input = (min.) Power Required

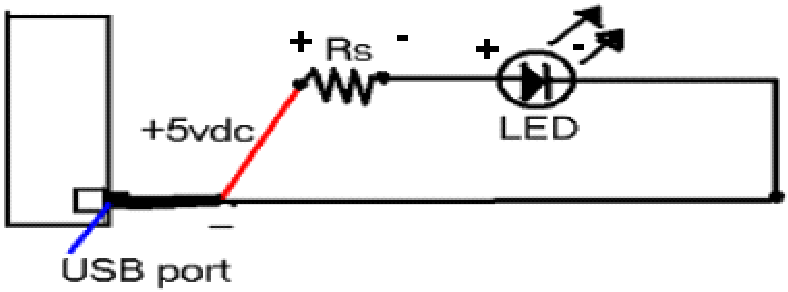
$$\text{Efficiency} = \frac{\text{Power Output}}{\text{Power Input}} = \frac{\text{(Power Input - Power Losses)}}{\text{Power Input}}$$

: divide Efficiency by 100 to find the equivalent percentage value

Since the efficiency value is a pure unit-less number, you can also use relative or percentage values so as to be non-specific in the actual detailed values, and have a useful generalization or basic value that easily express what is happening in a system(s) or device, and could even be used for comparing systems and costs. Here, power input would be expressed as: 100% = 1.0 as a relative or comparative value.

A simple LED (light emitting diode) circuit is a practical example of the above circuit when the resistance happens to be a LED. A white color LED initially requires [and actually tries to maintain it if slightly higher voltages of up to a maximum before **LED** "burnout" when greater than about **3.3v is applied]**, a 3v (such as from two 1.5v batteries in series) potential just to "turn on" and conduct current of about 20mA through it for its close to maximum brightness level. With a supply voltage of 5v, this will cause a higher than needed current to flow through the LED and it will be "burned-out" or ruined. This can be prevented by using a ("safety" or power reducing) resistor (R) directly in series or "in line" with that LED. The voltage across that resistor should be set to be equal to the supply voltage minus (less) what is needed for the LED to operate: Vr = 5v -3v = 2v. Since the resistor is in series (same line, circuit path or direct path) with that of the LED, 20mA of current will also be traveling through it. Since I = V/R : R for this particular circuit having a certain supply voltage, LED voltage and current: Safety resistor Rs = R ohms = Vr / Ir = (Vsupply - Vled) / (I led) = (5v - 3v) / 0.20A = 2v/0.020A = 100ohms : *

[FIG 254]



supply voltage = sum of voltage drops
+5vdc = Vr + Vled
+5 = Vr + 3v
+5 - 3V = Vr = 2v

Vr = Rs x I
2v = Rs x 0.020A : 20 milliAmps
Rs = 2v / 0.020 = 100ohms : design values, can adjust to your needs

If an LED is being powered by 3.3v across it and 0.020A through it, this is a power of: P=VI = (3.3v)(0.020) = 0.066w = 66mW. If more power is applied than this, the LED will most likely be quickly destroyed and not give off any light. **Also of note that the maximum reverse bias voltage that can be applied to an LED is also a low value of just about 5v on average**, if more than that is applied, it will usually be destroyed. To reduce the potential of a high valued reverse bias voltage being applied to a diode, a reverse biased diode in series with the reverse biased diode can effectively be used so as to act like an open circuit and-or very high resistance, thereby protecting the diode in reverse bias conditions, such as when it is being power4ed by an AC supply. As for reducing the forward bias current to an LED,,a resistor is used. An LED can also be powered by 120Vac household power, but a current reducing and safety resistor, and diode must then be used. A capacitor of say 100uF across (ie., in parallel to) the diode can store enough charge so as to help reduce any noticeable "flicker" of the light of the LED. To reduce wasted power by the resistor, rather use many more LED's to use that power.

Most of the basic USB ports of manufactured computers and other devices offer at least 1A of direct current before the circuit is shut off automatically before damage can occur. The power available from that USB port is: P = VI = (5v)(1A) = 5 watts. More advanced versions of USB ports offer 2 or slightly more amps. Only two of the 4 wires of a standard USB port and cord are needed, and those are the power supply wires which are the positive and negative wires so as deliver energy and power to an electronic circuit.

Standard USB 4-wire color codes:

RED = +5Vdc
BLACK = - , negative and-or battery-circuit ground
White = Data, positive signals (not needed in the above circuit, cut and insulate it)
Green = Data, negative signals (not needed in the above circuit, cut and insulate it)

* If your supply voltage is not the same as 5v, then you need to calculate a new value of the resistance needed.

A technical note about diodes and LED's which are a special type of diode: Before a diode "turns on" when the rated barrier voltage is finally reached, and its ("active" or controlled) resistance is very low and begins conducting like a short circuit (ie., a wire or closed switch), a diode will have a very high resistance of which is determined by the applied voltage (dropped or lost) across it. As the applied voltage across a diode increases from 0v, the diodes effective resistance will increase from infinity ohms, such as that of an open circuit and-or reverse (voltage) biased diode, and to a very low value of resistance, perhaps 0.1 ohms. In this manner, a diode can behave much like a voltage controlled adjustable or variable resistor and-or voltage divider. In place of a resistor, 3 plain (non-LED) diodes in series can drop about: 3 (0.65v) = 2v

If the power supply to this circuit was 3V, then no resistor would be needed and there would not be a power loss as heat energy in it. For the circuit shown above, here are some practical equations a circuit designer may consider:

Pin = (Vin)(It) = (5v)(0.020A) = 0.1W = 100mW = 0.1J/s
Pled = Pout = (3v)(0.020A) = 0.06W = 60mW
Presistor = (2v)(0.020A) = 0.04W = 40mW = Pwasted as heat energy = 0.04 J/s :100% of its power is wasted as heat
Ptotal = Pled + Presistor = 60mW + 40mW = 100 mW = Pin

circuit power efficiency = Pout / Pin = 60mW / 100mW = 0.60 = 60% efficient , however, the LED may only be 30%
efficient at converting the input energy and-or power to light. 60% of the power goes to the load
(an LED). The efficiency of an LED at producing light power is about 50%: Plight / Pled =~0.50

power loss = Pin - Pout = 100mW - 60mW = 40mW

% of input power wasted = Presistor / Pin = 40mW / 100mW = 0.40 = 40% : this is relatively, a high value

If the supply voltage was 3v, the power efficiency of this circuit would be 100% to the load (here an LED) because there would be no wasted power in a current limiting and-or safety resistor. 100% is a very high value.

By placing in more parallel and similar circuit branches, each consisting of the led and resistor, more light can be produced by that circuit, however, each branch will need 100mW of power more.

Total power and energy in or used will be:
(watts used) (time of use in seconds) = W-s = (joules/second) (seconds) = joules of energy or
(watts used) (time of use in hours) = W-h = (joules / second) (hours)(3600s) = joules of energy

With just 1 LED and resistor circuit branch being used, and considering 3600 seconds of use = 1hr of use, the total energy needed and used is:

(0.100W)(3600s) = 360 W-s = 0.1 W-hr : a 1W-hr rated battery, if fully charged, would last: 1W-hr / 0.1 W = 10 hours

If the supply voltage is 12V such as a typical automobile battery, 4 LED's in a series electrical connection can be placed in each parallel branch, and without any resistor needed. (4 LED's)(3V / 1 LED) = 12V. Each branch of 4 LED's will require:
(4 LED's) (60 mW / LED) = 240 mW = 0.240W : slightly less than a quarter of a watt = 0.250W = 0.250 J/s

LED's can be placed in series, and of which the same amount of current, say 0.020A, going through one will then be going through the other one. 2 LED's in series will require 3v per LED, hence (2 LED)(3v/LED) = 6v to be powered. The light energy output will be about the sum of the lumens (lm) of light energy and-or brightness from each LED, hence about: 2 LED (100 lm/LED) = 200 lm. Since our eyes see in a logarithmic manner, things illuminated by them both may not appear as twice as bright,, but nearly as so for low levels of lumens (ie., "illumination") or brightness seen. With a large array of LED's, adding or removing a single LED will not make much of a difference in the illumination or brightness of objects.

For LED's in parallel, they all can be powered by a 3v to 4v power source, but each will require about 20mA to 30mA of current, and the total current needed will be about: (number of LED's in parallel)(20mA).

The total light (or photon) output of any array of LED's will be the sum of the light output from each LED.

BASICS OF RADIO

A previous discussion about radio has been given in this book, and here is some more to consider on this topic:

In 1886, **Heinrich Hertz** (1857-1894), from Germany, studied electrically produced sparks, and also knew from Faraday's experiments and works that an electric field of the current (electrically charged electrons with kinetic energy) flowing through a wire could produce a magnetic field, and vice-versa. Static charges or charges at rest do not produce a magnetic field, but they will produce an electric field. Surely, the spark transmits some light, but does it then also transmit an electric or magnetic field and-or energy? Hertz made a metal loop with a small air gap (ie.,here, a "spark gap" or "spark-gap") in it and turned on his high voltage spark machine and noticed a corresponding spark being induced (hence being transmitted through the air, "wireless") or received in the distant metal loop, and which was seen as a small spark across the air gap. This was the first instance of deliberately transmitting and receiving electric energy or a radio wave. It began the huge field of (invisible and wireless) radio wave communication starting with Morse code that was already in use as for the telegraph (remote graphing communication via direct electrical wire connection) system of communication. Morse code is a standardized system of (usually) electromagnetic and-or heard pulses called dots (short pulses) and dashes (long pulses) that electronically represented information or data such as certain letters of the alphabet. For a radio or wireless system, theses pulses were also mechanically "tapped" (ie., so as to move a circuit breaking and making switch) by a trained operators hand, and which were then used to switch on or off so as to modify or modulate the transmitted radio wave. The spark-gap radio transmitter is capable of producing a very high frequency, but only for the duration of each and brief single pulse, that is, it did not create a continuous oscillation at a certain frequency. The tuning was limited by the inductors and capacitors used, and was "noisy" in terms of unwanted radio signals produced. Years later, an electronic tuned amplifier circuit was discovered by **Edwin Armstrong** in 1912 when using a vacuum tube amplifier modification that provided continuous oscillation at a (tune-able, adjustable) frequency. Hertz's discoveries also created a question of whether visible light was also a form of an electromagnetic energy and having a wave or frequency. Newton's previous experiments with light and (triangular, 3-sided) glass prisms showed that white light can be separated into various colors, and today we know that these colors of light have and are various electromagnetic or radio wave frequencies. It is of note that small drops of rain or some snow can also create a rainbow of colors when the incident Sun angle, and observer of the refraction are in a favorable position. In 1672, **Newton** then showed that the rainbow of colors can then be combined back together using a **glass prism** so as to form white light. It is of note that the glass prism was invented years before Newton was born, however Newton inspired a high interest in optics and the mysteries and possibilities of light. Generally, radio waves are considered as invisible electromagnetic waves containing energy, and which can go through non-metallic walls, whereas light does not unless it is a transparent wall that can essentially conduct light through it. Another common question was also created, and that is if invisible electromagnetic waves were also composed of and-or can be considered as (invisible) photons of light, and the answer is yes, and its that our eyes can only sense or see a small part of the electromagnetic energy spectrum or frequency range.

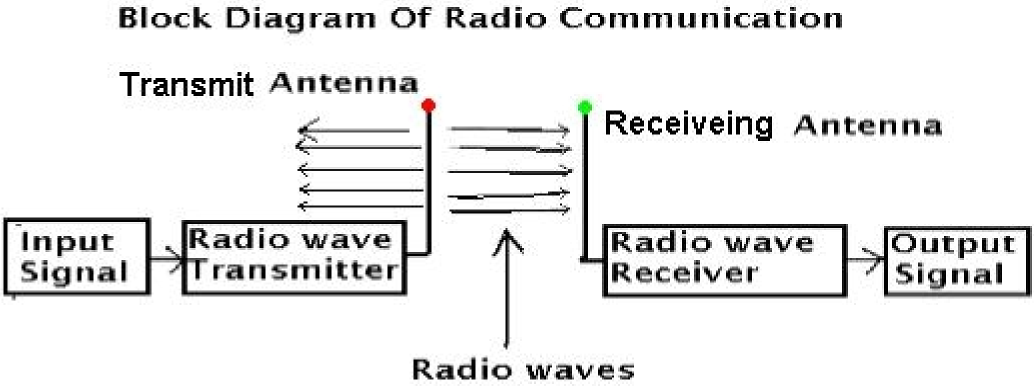
A transformer (essentially two coils side by side or intertwined so as to transfer electric energy from one coil to the other using magnetism or magnetic field transmission) is technically a short-range (ie., short distances) magnetic field transmitter and receiver device, hence a "transceiver", and since it also involves (input or created output) electricity or (electron) current, an electric transformer is more accurately and technically a (very) short-range electromagnetic transmitter and receiver. Note that a radio wave transmitter does not transmit electrons, but only the electric and magnetic fields and-or photons created in and upon the antenna surface by the flowing electron charge, current (ie., energized electrons) or movement. Metal such as iron can be used to help concentrate, direct or guide (ie., conduct magnetic "lines of force") a (transmitted) magnetic field or "current of magnetism (magnetic current)", typically in a transformer or choke.

A spark, such as lightening, actually produces many frequencies and it would be "heard" or converted to as unwanted noise on a modern AM radio, affecting many frequencies and causing circuit and-or audio interference. If the spark could be tuned to a certain frequency, receivers could also be tuned to a certain frequency so as to receive only a specific or desired transmitted radio wave and the information it contains being transmitted. This would allow the creation of many radio transmitting stations, each with their own legally permitted and assigned radio transmitting frequency (ie., for a radio "channel and-or station") and help eliminate signal interference problems in radio receivers that are tuned to select only one desired station with its assigned radio frequency and-or bandwidth (ie., frequency range or amount). The unit used to express a frequency value is called the hertz (hz) and it is named after **Heinrich Hertz**. 1hz = 1 cycle or complete periodic wave per 1 second of time, hence it is a wave or cycle rate. A wave can be thought of as a vibration. The hertz (hz) unit may sometimes be noted or indicated as cps (cycles per second) or the frequency per second.

In about 1884, **Guglielmo Marconi** (1874-1937), from Italy invented wireless (ie. radio wave) telegraphy that transmitted the communication of information using Morse code. This information was physically transmitted as long and short duration (pulsed) radio signals that were heard as tones and were received and recorded by the radio operator person using pen and paper so as to be decoded later. This was the first practical use of the newly discovered radio waves and inspired much further research till this day. He used the previously invented spark gap transmitter and improved it, but later, others would add better tuning controls (such as vacuum tube electric oscillators and tuners) of the transmitter and receivers so as to significantly reduce the bandwidth (ie., range) of frequencies transmitted for each transmitted pulse. With a capacitor and inductor, the radio waves could be tuned (adjusted) to be a certain frequency. The radio receiver would then also have to be "tuned" (for maximum signal strength reception) to this transmitted (limited) bandwidth or frequency which also electronically rejects or filters [remove out] all other frequencies. This "reduced (frequency) bandwidth" transmission and reception method allows many more radio-wave transmitting stations and their transmitted and received information from interfering with each other.

Even when tuned to a certain frequency so as to be efficient, much of a transmitted radio waves energy is often radiated or transmitted in a 360° directional pattern so as to be available to anyone nearby with a radio receiver, but then with much energy actually often wasted, but it will be available whenever needed as "wireless communication" without a direct wire connection. The amount of the transmitted radio wave energy received by a distant receiving antenna is very small and this amount is impractical to use directly to power most things, and it must then be greatly amplified so as to be useful such as in an amplified radio receiver. The exception to this is with crystal radios (receivers) which can function without any extra voltage source and-or signal amplification as long as very electrically efficient and sensitive (tuned) antenna, circuit, and earphones such as the (high-impedance, low voltage and power needed, very sensitive) carbon or (piezo) crystal types are used. As of the year 2021, carbon earphones are difficult to find and-or are expensive, but a piezo-crystal earphone can still be found and purchased for a few USD dollars each.

The assigned main frequency for a radio station is called the carrier frequency or wave since the input or information signal, such as an audio signal (ie., energy) is converted or transformed to a corresponding electric signal (ie., electric energy, voltage and current) equivalent in a microphone, and which will essentially be applied (ie., to modulate, change, adjust) to and "carried" on, integrated or combined with as part (such as the intensity or "amplitude" of) of that one main transmitted radio wave. At the receiver, the microphone signal will be removed out from the carrier wave signal in a process called demodulation, and it will eventually be heard through an output audio speaker. [FIG 255]



Though an antenna appears as an open circuit, the electric field (ie., voltage) created in the transmitter still causes electrons in the antenna wire to move by coulomb or electric forces, and a magnetic field at a right angle is then created with respect to the electric field created. A radio wave (an electro-magnetic [fields] wave and transmission of energy) is composed of an electric field and a magnetic field at a right angle to the electric field. The (RF or rf, radio frequency) signal received by the reception antenna is often very small and needs to be greatly amplified so as to be useful and-or heard. Often the input and output signals are ("low frequency", LF) audio signals such as speech and-or music. Today with modern "computer phones" with internet capability, transmission towers can send both audio and computer data using (digital, as in high power quick pulses, as opposed to an analog form) radio waves.

In a microwave oven, the (microwave) radio (rf) signal is relatively close to the food substance, and therefore is of a relatively high strength so as to apply much energy to the food molecules and-or water and cause them to gain kinetic energy and its associated heat due to collisions and infra-red (ie., heat) radiation. If you heat a piece of metal to being very hot, it will begin to emit thermal (ie., infra-red) radiation and it can be seen as a glowing red color. If heated further, it can emit a orange, yellow, and then white color like a electric light does. If the temperature of the metal changes by a factor of (n), the emitted radiation will change by a factor of (n^4), and this implies that to change the temperature of the metal by a factor of (n), that it will take (n^4) times more input energy applied to it since energy out = energy in. At a given temperature, if the surface area of that metal increases by (n), the total radiation will also increase by (n), hence it is proportional to the surface area. This forth power has been confirmed via tests and it is considered due to the metal's 3-dimensional crystal structure of nearby atoms. When heated, the atoms begin to vibrate and gain kinetic energy, releasing more free electrons and photons (ie, radiation energy) when they fall back into an orbit, and these photons also then cause a limited internal chain reaction of freeing more electrons and eventually increasing the thermal energy of the atoms and increasing the photon output at the surface of the metal. For more about this fourth power, research the Stephan-Boltzmann constant. **Extra**: A microwave oven's outer surface is generally of a continuous, flat sheet metal or metal screen construction so as to prevent the energy from leaking away or being radiated to where it is not desirable, and useless and dangerous for heating food, etc. This electromagnetic or RF shielding is often called a "**Faraday Cage**", and the glass on the viewing door has a metallic screen attached to it, and of which has viewing holes having a diameter of less than or equal to (1/10) of the wavelength of the microwave being used, and this effectively causes no radiation to be transmitted through and past them. It is also of interest, that this Faraday Cage system does not need to be electrically grounded as in a regular type of circuit, such as perhaps for a portable radio or communication device. RF shielding can both prevent the reception and transmission of RF energy and-or unwanted RF noise energy, and therefore an external, unshielded antenna will be needed to receive and-or transmit RF energy for communication.

Why radio communication? Consider for example that 1 watt of transmitted audio or sound energy may be discernible by the human ear at perhaps 300 feet away. Sound or air (physical) vibrational energy (ie., air compression [higher density] and rarefaction [lower density] transferring energy from air atoms to other nearby air atoms via collisions), like light and radio energy gets weaker and weak as it expands, or disperses outward from the source. 1 watt of radio wave energy which is essentially invisible (RF) light energy, and of which can be seen by the sensitive human eye much farther away, perhaps 1 mile away. Radio receivers and their circuitry can be much more sensitive than the human eye light sensor or receiver, and can even be very weak signals that were transmitted hundreds of miles away at high power, and can then amplify them to usable levels for hearing, etc.

It is interesting that radio wave energy is composed of an electro-magnetic (electric and magnetic) fields perpendicular (90°) to each other, and does not have electrons with kinetic energy to transfer energy from one location to the other as with common electric circuits. The electro-magnetic field is rather transmitted (ie., radiated, released outward) and-or received. (Usually invisible) photons can be considered as the energy carriers. The strengths or amplitudes of the electric and magnetic field waves vary periodically at the same frequency of that transmitted wave of energy.

In the above figure, the antenna is vertical and will transmit a radio signal outward in the horizontal direction all around it in a 360°, circular pattern. This pattern is therefore not a full spherical pattern in every possible direction including the vertical directions. For our radio system with vertical antennas, it is better to transmit the radio wave energy in just the horizontal directions. If the radio transmitter is 4 watts, the amount of energy transmitted horizontally per degree is:

$$\frac{\text{Total Transmitted Power}}{360°} = \frac{4 \text{ watts}}{360°} \overset{\sim}{=} \frac{0.011\text{w}}{1°} = \frac{11\text{mw}}{1°}$$

: a theoretical example, and the angle of signal reception may be much less when the receiver is farther away from the transmitter, and due to the inverse square law of energy transmission and reception, this value may be greatly reduced by the time it reaches the reception antenna.

If the receiving radio antenna is close enough to intercept 1° of the total transmitted signal, it will receive a theoretical maximum of 11mw of the transmitted radio wave energy. If the radio receiver has a minimum reception sensitivity of 11mw or less, then there will be enough radio signal received so as to be amplified and heard. A good radio receiver is said to have high **sensitivity** (ie., a low usable minimal voltage received ability, such as from a distance transmitter) and high **selectivity** (ie.,accepting only the desired frequency and-or range).

If the receiver is farther away and intercepts just 0.01° or one-hundredth of a degree of the transmitted signal., then the maximum radio energy power received is, and without considering the effective power loss or radio wave energy dispersion due to the distance between the transmitter and the receiver and the inverse square law of energy transmission and reception:

$$\frac{11mw}{1^\circ} = \frac{Xmw}{0.01^\circ}$$, after solving for Xmw:

$$Xmw = \frac{(0.01^\circ)(11mw)}{1^\circ} = 0.110\ mW = 110uW = 110\text{ micro-watts} = 0.000110\ W \quad : 11\ mW = 0.011\ W$$

Just like light, and of which is electromagnetic energy, the intensity, signal voltage and-or power level of a radio signal measured at a location from the transmission antenna (ie., energy radiator) is inversely related to the square of the distance from it: Just like light, most radio waves are also "line of sight" and need to be nearly free from obstruction. HF (High Frequency, "Shortwave Radio" - 3Mhz to 30 Mhz) radio has much more of an ability to reflect off the ionosphere and therefore travel a longer distance over terrain that is in the way of the line of sight and-or over the horizon or curve of the Earth. **Energy Received = Energy Transmitted / (distance^2)**. From this equation, if the distance doubles, the received signal is 4 times less, hence up to 4 times more energy may need to be transmitted if the initial received signal was very low. A certain radio receiver model usually has a general (minimum) input (RF, voltage or power), received sensitivity rating, and if the received radio signal is greater than this rating, that certain radio transmission should be able to be heard and-or understood clearly. Properly made and directed transmission and-or receiving antennas can improve the received signal strength and-or the transmission distance. If permitted, an "RF amplifier" can be used to transmit a stronger signal.

For best radio power transmission, it is best that the antenna be equal to the wavelength of the main carrier wave frequency being transmitted, and this seems to be particularly more critical as the frequency increases in value. A "tuned" or resonant antenna will give better transmission and-or reception. Certain fractions of a wavelength are also used so as a large impractical size antenna is not always needed. The antenna is then said to be properly tuned or set to a certain desired frequency. For these fractional sized antennas, their transmission efficiency is still near 90%. A "loading coil" is sometimes used in series with a short antenna so as it can appear electrically as a longer antenna with more impedance such as the "50 ohm" or "75 ohm" standard. An (automatic or manual) **antenna tuner**, which can be as simple as an inductor and-or capacitor which can help tune an (receiving and-or transmission) antenna so as its length does not need to be physically altered in length when the transmission frequency is changed. To help maximize a certain transmitted carrier or main signal, a **SWR** (**Standing Wave Ratio**, or Voltage Standing Wave Ratio (VSWR) and-or meter can be used. SWR has a technical derivation and formula beyond the scope of this book, but it can be roughly thought of as: SWR = (power out of the transmitter's electric circuit to the antenna / power actually transmitted from the antenna). This standing wave of radio power is not transmitted and is rather decaying back and forth through the resistance of the wire and-or transmitter circuit. Transmission loss is usually due to that an antenna mismatch (improper tuning [ie., length]), cable issues, or possibly some other problem such that some of the radio wave energy is not being transmitted outward ("forward") and away from the antenna and is rather then lost in other parts of the system and-or "reflected" (ie., essentially sent, transmitted) back into the transmitter circuit. A low SWR reading between 1 and no more than 2 is desirable. **The combination of a SWR meter and antenna tuner, both in a series connection to the antenna, can help optimize the transmitted radio signal and its energy.**

A transmitter can even perform tests and checks without using an antenna, but a "dummy load" resistor having an effective (LC, high frequency) impedance of often **50 ohms** (for HF), 75 ohms (for VHF), 300 ohms (low loss "twin lead" cable, for FM), and with an adequate power rating must then be used so as to not damage the transmitters electronics. Though a dummy load absorbs most of the transmitted power, a nearby radio may still be able to receiver enough energy so as to effectively hear a broadcast. Air is said to have an impedance of 377 ohms. The standard value of 50 ohms is an old and semi-arbitrary compromise value which considered the impedance matching for both lowest power losses (at 30ohms) and best signal transmission (at about 70 ohms) in (air-dielectric) coaxial cables, and then made into a default, recommended standard that all radio manufactures can then follow. Imagine the transmitted power not being transmitted or used such as it being lost in a resistor, but rather damaging the transmitter itself - usually the output transistor(s) of the signal amplifier. The combination of a monitoring, distant receiving station and-or a low power transmitted signal can also help with tuning an antenna system for maximum transmission. For maximum power transfer to the antenna, the impedance of the antenna should match that of the output impedance of the transmitter, and that is usually standardized at 50 ohms of impedance. Reactance is a function of the values of inductance (L) and-or capacitance (C), and signal frequency. If the frequency changes, the impedance of the antenna will then change and it will have to be reset to 50 ohms for maximum power transmission, such as by an antenna tuner, etc.

A **balun** is an electrical device, much like a small transformer, that allows the connection of **ba**lanced and **un**balanced transmission wires or lines for the best power transmission along a line. A balun can be used to reduce or eliminate the reactance of the antenna so as it appears as a 50 ohm load output or input to the 50 ohm radio. Some (balanced output) antennas have two out of phase signals at their output wires, and of which will then need to be connected to the single, signal input wire at the receiver, and a balun can do this. Balun's can prevent the outer shield metal of the cable from being a conductor for RF and-or noise. This helps with the transmission and-or reception of the desired radio signals. Balun's were once often seen on the ends of a TV aerial (ie., receiving antenna) or cable-tv coaxial line, and so that the TV's having a certain input impedance could efficiently display the received signal. One special balun is called a "**unun**" (ie., unbalanced to unbalanced) which can transfer power between two unbalanced (different impedance's) signal lines or cables. Some SWR meters may also include a power transmitted meter, and some radio receivers have a received, signal strength meter. **"Beam" or directional antennas** can focus the transmitted or received radio energy to or from a specific direction so as to aid communication and-or the need for more signal amplification.

What is polarized light and-or photons?

First, do not confuses the concept of polarized light with the concept of electrical polarity: (+) and (-).

Consider a vertical wire or pole, radio transmitting antenna. The electron moving in that antenna will travel along its physical direction. This will also create an electric field that will will oscillate (ie., like a repetative sine wave with its amplitude) along the length of that antenna (especially when properly tuned to the wavelength of that frequency), and here vertically (if placed vertically) in, and then transmitted away from that antenna in a vertical manner. This signal is then said to be vertically polarized. For best reception of the maximum power and-or signal strength, the receiving antenna should also be vertically polarized. For polarized light, the electric field oscillations are perpendicular to the direction of the travel of that light. Here in this case mentioned, the antenna signal is polarized vertically, and is traveling outward horizontally from that antenna.

Light from a household incandescent lamp bulb with its coiled metal milament is unpolarized, and is sending out its light waves and-or photons in various directions perpendicular to those directions of travel, but some of it can be made to be polarized by using say a vertical slot to behave like a polarization filter, and so as to pass only light having a vertical polarization in a certain direction.

COMMON CLASSIFICATIONS AND ALLOCATIONS OF VARIOUS FREQUENCY RANGES

The following is often called the (standardized) electromagnet frequency bands ("spectrum") or range classifications:

C = speed of light in a vacuum =~ 299,792,458 m/s =~ 300,000,000 m/s = 3(10^8)m/s =~ 186,000 mi/s = velocity = v

f=frequency or hz, = 1/ (time of each cycle) , w=wavelength distance in meters , hz = hertz = cycles per second = cps frequency (f) and wavelength (w) are mathematically, inversely related in value to each other, and are the factors of C or the speed of the wave.

C = fw , f = C / w , w = C / f , : Ex. If n is a multiplier or factor: At: nf, w = (1/n)w = w/n. At: nw, f = (1/n)f = f/n.
C is a constant, and (f) and (w) are inversely related to each other mathematically.

Wavelength is a real physical distance between each cycle (c , 1c = 1hz) or corresponding peaks of a wave of energy at a certain frequency and medium that the wave or energy is traveling through. **Wavelength = d / 1 c = d / c = d / 1 hz** . Wavelength is not the same meaning as the speed of sound or light transmission through a medium (material, such as air or a vacuum). A 1000hz sound pulse will travel faster through a medium of metal than in air, yet the frequency and its corresponding time (t=1/f) is always constant. Wavelength of a wave is determined by the frequency and speed of travel, hence wavelength is also determined by the medium it travels through.

Ex. For sound waves that travel at about 1125ft/s = 343 m/s in air, the wave length or wavelength of a 1000 hz sound wave is from:

distance = (speed)(time) = wavelength
wavelength = (speed)(time) = v t , and since frequency and time are reciprocals in value:

wavelength = (speed of sound)(1 / frequency) : For light, wavelength = (speed of light = c) (1 / frequency)
wavelength = v t = v / f = (d / t) / (1 / t) = (d / s) / (c / s) **= d / c** : For (rf), light or radio: w = vt = v / f = c / f =~
= (300 m/s) / (c/s) = 300 m/c

w = (speed of sound) / (frequency) = (speed of sound)(1/ frequency) = (speed of sound)(time) = (v)(t) = d
w = (1125ft/s)(1/1000c/s) = (1125 ft/s)(0.001s/c) = 1.125 ft / c : ft / c = feet per cycle, or simply feet

Note how the unites were expressed: (c/s) for frequency, and (s/c) for time , hence each has the mathematical inverse or reciprocal of the others units, and since frequency and time are inverse values of each other.

Sometimes a wavelength can be physically seen and-or demonstrated such as for sound waves in a pipe filled with a gas and a line of holes in it, and which will indicate where and the amount of sound or air pressure is in the pipe, and that distance or length between wave peaks or the troughs seen can be measured as the wavelength, and the corresponding frequency of it can be calculated using:

From: wavelength = distance = (speed)(time) = (speed)(1/frequency) = v / f , we have:

frequency = (speed / wavelength) = v / w : for radio waves , speed = v = C = 186000mi/s = 300000km/s

It is good to memorize that: wavelength = distance = (speed)(time) = w = v t = v / f , and that t = 1 / f and f = 1 / t

Extra: Ex. If the physical wavelength of a certain (rf) radio wave is say 0.1m , the number of these waves per unit distance or meter is simply found by division of this distance into the unit distance of 1 meter:

number of waves per meter = "wave number" = 1 meter / wavelength = 1 / 0.1 m = 10 : wpm

The following table is the frequency allocations for North America, and it may not apply to other locations, countries, and-or temporary allocations. These allocations were determined, set and governed by the FCC (USA, Federal Communications Committee) and in particular, so as to avoid a radio signal from interfering with any other radio frequency and signals.

Typical Frequencies (hz)	**Typical Wavelengths (m)**	**A Typical Frequency Group Name**
0 to 20Khz	3Km at 1000hz	Audio or radio (RF=radio frequency(s)), VLF (Very Low Frequency)
20Khz 525Khz	600m at 500Khz	**AM** (Amplitude Modulated or varied) radio LW (Long Wave) AM radio is 148.5Khz to 283.5Khz
525Khz to 1710Khz	300m at 1Mhz	**MW** (Medium Wave) **AM** radio, civilian, public 300Khz to 3Mhz is MF (Medium Frequency)
2.182Mhz	137.4m	Boating emergency communication, please monitor
3.2Mhz to 26Mhz	300m at 3Mhz 30m at 10Mhz Maritime Emergency (mhz):	**SW** (Short-Wave) AM, "**Am**ateur" and-or "H**am**", radio 3Mhz to 30Mhz is also called the **HF (High Frequency)** band. : Some: 4.125 Mhz , 6.215 , 8.291 , 12.290 , 16.420 156.8 (for short range areas and-or locations).
26.480 to 26.960 Mhz		U.S. Military
26.96Mhz to 27.41Mhz	11.1m at 27Mhz	CB (Citizens Band) **AM** radio, trucks, personal, 40 CHannels, **CH9 for emergency**, CH17 and CH19 are for trucks ("truckers"). While not transmitting, and if your radio(s) has enough supply power, **please monitor** CH1 and **CH9** for any possible emergency and-or assistance needed. A transmit (TX) license is not required for anyone to transmit on a CB radio. And: 4 watts is max. legal power transmission in the USA, and can generally reach 3 miles outward with direct line of sight travel. Some single side band (**SSB**) CB's can effectively transmit several times more power on **LSB (Lower Side Band) or USB (Upper Side Band)** near the main or fundamental (radio) carrier frequency assigned to a channel. People using CB, SSB mode are asked to use only CB channels 36 through 40. Any CB is very useful during an emergency, and since they are widely available and relatively inexpensive to purchase before they are even needed as part of communication for when telephone service is unavailable and-or not working. Each town should have at least one or two CB radios and operators. A CB or shortwave radio relay station/operator can be used at the top of a mountain to assist with any received communication, and to be relayed over. As of about the year 2021, some CB radios and-or transceivers (ie., can transmit and receive) also offer an RX/TX, **FM mode** for some clearer communication and very low AM noise interference. The max. output power is also limited to 4W.
27.450 to 28 Mhz		U.S. Federal Government
49 Mhz , **VHF** = 30MHz to 300 MHZ	10m to 1m	For (U.S.A., <= 100mW transmission) Walkie-Talkie radios

52.525 Mhz		A common **emergency** radio frequency, and uses a FM mode. Others in Mhz: 47.42 (Red Cross) , 39.46 (police)
54Mhz to 88Mhz	5.55m at 54Mhz	**VHF** TV CH 2 to 6, Very High Frequency
88Mhz to 108Mhz	3m at 100mHz	**FM** (Frequency Modulated or varied) civilian, public radio Many modern (as of 2022) phones include a FM radio app.
118Mhz to 137Mhz	2.47m at 121.5Mhz	VHF (Very High Frequency) Aircraft Band 121.5Mhz civilian **emergency**, 243.0 Mhz military emergency Please monitor these frequencies.
145.80Mhz (transmitted by the ISS, receives at 144.49Mhz and 145.20Mhz) 2.06m		**Shortwave**, space communications, such as for the ISS (International Space Station). Includes voice and data such as **SSTV (Slow Scan TV images)** of which images can be processed by a computer program (software) into an audio file. This file can then be sent using radio communication. The audio signal in the received radio signal (which has the image data coded into audio signals/tones being carried in/on as part of the high frequency radio signal) is sent to the computer mic input or other audio input of a computer of which an SSTV program can then process back into an image. Amateur ("HAM"), shortwave radio stations often experiment with using SSTV, and it is slow, but effective. There are many low-cost programs and standardized methods for data communication via radio that you should obtain and have available as a radio operator/communicator, and before any grid-down or emergency situation.
151.820 to 154.600		**MURS** radio, Multi-Use Radio Service, no license, usually for business communications, 2W max. transmission power. Has 5 FM communication channels and-or frequencies. Unlike FRS radio with a fixed antenna, MURS allows a removable or changeable antenna for better communication with the 2W.
156.8 Mhz		**A common emergency radio frequency**. VHF CH 16. Please monitor, listen and-or communicate with this frequency, and then alert authorities if needed.
174Mhz 220Mhz	1.5m at 200Mhz	VHF TV CH 7 to 13
300Mhz to 3000Mhz=3 Ghz	1m = 100cm at 300Mhz 0.5m = 50cm at 600Mhz 0.3m = 30cm at 1000Mhz 0.25m = 25cm at 1200Mhz	**UHF , Ultra High Frequency**. 406 to 406.1 Satellite emergency. Digital TV radio waves are 470Mhz to 850Mhz. **FRS** = Family Radio Service = 462Mhz to 467Mhz FM, 2W max FRS uses **FM** modulation which is less noisy than AM mod. **GMRS** = General Mobile Radio Service, is similar to FRS, but is more for business and requires a license to operate, and also can use "**repeaters**" (ie., transmission relays) to extend their range. FRS has 22 channels available as of the year 2021. GMRS includes the lower power FRS channels, and also includes 8 more high frequency channels, and generally GMRS allows up to 5W radio output power on channels 1 to 7, channels to 8 to14 are limited to 0.5W for both FRS and GMRS. GMRS channels 15-22 can have up to 50W. If the

GMRS power is lower than or equal to 2W max, such as like the FRS, then the license is waived or optional. **As with all radio communications, channels must be shared and not interfered with while being used by others, unless there is an emergency, and of which anyone without a license can and should legally use a nearby radio for transmission, and if they know how to use the radio on a minimal or greater level for emergencies.**

1Ghz to 100 Ghz 30 cm at 1 Ghz , Radar , 3 cm at 10 Ghz, **Microwaves** (microwave ovens)
10^9 hz and with 0.3 cm = 3mm at 100 Ghz = 100(10^9)hz. , 1(10^11)hz
1 Ghz = 1 billion hertz = 1,000,000,000 hertz = 1 (10^9) hz = 1 giga-hertz

2.4Ghz to 2.485Ghz 12.5cm at 2.4Ghz "**Bluetooth**", short-range radio communication system for data.
12.1cm at 2.485Ghz Devices with Bluetooth can share files and audio as digital data.
There is also offline WiFi and-or BlueTooth phone apps.

100Ghz to 1000Ghz = 1Thz 1mm=1000nm at 300Ghz Thermal **Infrared** (IR, heat electromagnetic radiation)
1mm = 1(10^-6)m 1 Thz = 1 trillion hertz = 1(10^12) hz. Thermal energy is due to the kinetic energy of particles, and this thermal energy also radiates some (infra-red) light or electro-magnetic energy.

10Thz to 100 Thz 30um to 3um **IR** (**infrared** to barely visible red color light)
= 10^13 hz to 10^14 hz 3um = 3 micrometers = 3(10^-6)m = 3000nm

1000Thz 580nm=Red, 545nm=Green, to 440nm=Blue **Visible Light** (**R**ed, **G**reen, **B**lue, "rainbow" spectrum =
= 10^15hz "**R**OY **G** **B**IV" = Red, Orange Green, Blue Indigo, Violet
= 300nm = 300(10^-9)m = 3(10^-7)m The color of an object is due to that all the other colors of the full spectrum or white colored light are absorbed by the atoms on its surface, and that light energy is converted mostly to thermal (heat, kinetic) energy such as for photosynthesis in plants. The reflected or emitted color of an object can help determine what element it is, such as silver, copper or gold. For example, copper has a red-brown color, but will emit a green color when heated by a flame.

10^16hz 10nm **UV** (Ultra Violet) light (**dangerous**, ex. sun burn, eye damage),
30nm = 30(10^-9)m = 3(10^-8)m such as some from the Sun, and much from an electric arc welder.

10^17hz
3 nm = 3(10^-9)m

10^18hz 1nm **X rays** (X ray machine in hospitals, radiation danger)
0.3nm = 0.3(10^-9)m = 3(10^-10)m 1nm = 1 nanometer = 1(10^-9)m
300pm = 3(10^-10)m

10^19hz 0.1nm **Gamma** rays (radiation danger)
= 0.03nm = 0.03 (10^-9)m = 3(10^-11)m 0.1nm = 0.1(10^-9)m = 1(10^-10)m
0.03nm = 30pm = 3(10^-11)m 1pm = 1 picometer = 1(10^-12)m

Ex. What is the approximate frequency of a radio signal that is said to be in or of the 40m "band" tuning range or wavelength?

$$f = \frac{v}{w} = \text{frequency} = \frac{\text{speed of light}}{\text{wavelength}} \approx \frac{300000 \text{ km/s}}{40\text{m}} = \frac{300000\text{km/s}}{0.040\text{km}} = 7500000 \text{ hz} = 7.5\,(10^6) \text{ hz} = 7.5 \text{ Mhz} \quad : 1\text{m} = 0.001\text{km}$$

The above assumed the signal is traveling in a vacuum such as space with a velocity of 299792458m/s =~ 300000m/s, but for a rf signal traveling through air at sea level where it is the most dense at 14.7psi, the signal's velocity is actually slower at about: 299702545m/s.

In general, a 1Mhz rf signal has a wavelength of 300m. If the frequency increases by (n), the wavelength will decrease by (n). Ex.: If the increase in frequency = n=10, a (1Mhz x 10) =10Mhz rf signal has a wavelength of (300m/10) = 30m. A 100Mhz rf signal has a wavelength of 3m, and this is within the common public radio FM band (ie., bandwidth or range of allocated frequencies). A 300Mhz rf signal has a wavelength of 1m.

Ex. What is the **wavelength** of a 100 Mhz signal: (300 M m/s / 100 M c/s) = 3 **m / 1c** = 3m , 3m =~ (3)(3.28)ft = 9.84 ft

Ex. An electron of a hydrogen atom that is struck by some energy, such as an electromagnetic wave or high speed particle of matter, will gain energy, and will eventually emit that extra energy as electromagnet energy (ie., photon, radio-wave) at a certain natural frequency due to the natural construction of the hydrogen atom. The frequency of the emitted wave of energy will have a wavelength of 21cm = 0.21m. The corresponding frequency of this wavelength is:

From: d = v t = w = v t , t = w / v , f = 1 / t = 1 / (w / v) = v / w
f =~ w / v = (3 (10^8) m/s / 0.21m) = 1428571429 hz =~ 1.4286 Ghz , often said as: 1.42 Ghz ,
1.42 (10^9)hz

A **spectroscope** (ie., a light-scope) is a device which has a glass prism, and which can essentially make a wide display (ie., a ("rainbow-like") spectrum) of all the component colors and-or frequencies contained in the received or incoming light energy, and which is then used to determine what element(s) is associated with that particular visible color(s) and-or corresponding frequency(s) of light. A **spectrometer** is like a spectroscope however it is rather used to determine the type and-or qualities of a sample of material such as an element when some type of energy, such as heat, is applied to it. After being heated, the element and-or its gases of, will have unique and identifying (black color, absorption) lines in its spectrum of colors (each having an associated frequency) seen on its spectrogram (ie., visible image). A few new elements were also discovered this way. A spectrometer can be used to determine what elements are in a substance. This discussion here is very short, and these topics, people and the history is beyond the scope of this practical math book.

When light beam enters a transparent medium such as a glass prism or lens, that light beam will enter that substance and then **refract** (ie., **bend**, change direction) and its direction of travel will be at a certain known angle (of refraction) with respect to the surface plane and-or a conceived "normal line" that is a perpendicular line with respect to the surface line of that material. A refraction effect is somewhat similar to the effect of having a mirror direct the light to another direction. When the light bean exits the transparent medium it will refract again at an angle that is determined by the new medium and its density. If a bean of light enters a medium straight-on or at no angle with respect to its flat surface, then it will not refract at an angle, but it will pass directly through it like a straight line passing through it, and without any refraction. The direction change can be estimated and-or thought of as being like that of having two wheels at the ends of an axel or left and right sides of line moving forward, and if one wheel slows down, there will be a direction change due to a rotation or torque effect about the slowed wheel acting as a type of pivot or rotation point.

Reflection and refraction are two different concepts. With reflection, the light does not enter the substance, but rather essentially "bounces" off its surface, and it could be at an angle. The angle of reflection (¢r) will be equal to the angle of incidence (¢i , incomming) light: ¢ reflection = ¢ incidence , hence their ratio is equal to 1. Now when light enters a medium such as water at an angle with respect to its surface, the angle of refraction or bending does not usually equal the angle of incidence, however it was found that::

$$\frac{\sin \text{¢ incidence}}{\sin \text{¢ refraction}} = \textbf{a constant}$$

value depending on the medium it will travel through : by **Willebrord Snellius** - - from the Netherlands , "**Snell's Law**" - independently in 1621, aka: "**law of refraction**". Also credited to **Ibn Sahl** of Iraq in 984.

See FIG 255A. You may also wish to also research the concept of the **refractive index** for a substance or material. In short: **refractive index = (RI) = velocity of light in a vacuum / speed of light in the medium material**
The wavelength of the light used will also determine the refractive index of the medium, and if the light used is white light with many frequencies, there will be a chromatic dispersion due to each color and-or frequency having a slightly different refractive index. Typically: for water, RI = 1.33 , glass, RI = 1.4 to 1.7 , quartz, RI = 1.54

It was also found in 1662 by **Pierre de Fermat** (1607-1665), from France, that the ratio of velocities of the light in the two mediums is also equal to this same constant of the law of refraction.

$$\frac{\text{v in medium 1}}{\text{v in medium 2}} = \frac{\sin \text{¢ incidence}}{\sin \text{¢ refraction}}$$

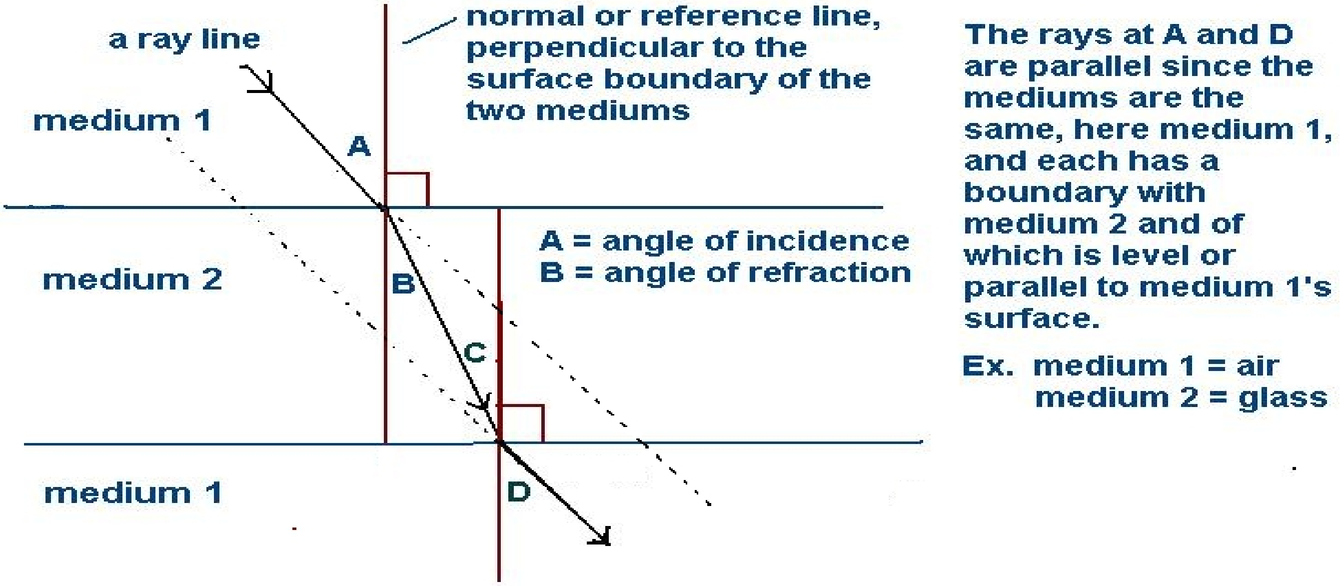
: Fermat's Principle (aka: "principle of least time of travel", and not necessarily the straight line path through a medium, such as for light travel)

The speed of light and-or an elector-magnetic wave will actually be reduced (ie., be slower) while going through a medium such as glass or water, and this is due to the electrons in the glass atoms gaining some kinetic energy and creating their own electro-magnetic field which will then interfere with electro-magnetic field and-or energy of the light wave. This physical interaction is what also causes refraction. Now since the frequency of the electromagnetic wave is still the same through the medium, but its propagation is now delayed or slower after all of the many electron and wave interactions involved over its length, the wavelength of the electromagnetic wave is actually shorter in the medium material it is passing through it.

The less clear and transparent the medium is, the more the light will not pass through it and it will be absorbed as heat in it. Some of the energy of the light passing through a medium will be converted to heat (ie., kinetic energy) in the medium, and therefore, its intensity will continue to lessen as it travels through that medium.

Beer's Equation or the (August - Johann) **Beer-Lambert Law** (1760 , 1852) of which is also based on the previous analysis of **Pierre Bouguer** in 1729, and which states the relationship of the absorption (A) of light or energy through a transparent medium, and it includes the length (L) of travel, concentration (C) of the medium and the molar absorptivity (e): **A = e L C** . A is a unitless number, usually called the Absorpton-coefficient of a material. (A) has a linear or direct relationship to (e), (L) and (C). The molar absorptivity coefficient value (e) depends on the specific substance or medium, and the wavelength of light used, and is measured and found by experiment with a unit length of a test sample, say 1cm: e = A / LC. The (molar) concentration, and which can also be thought of how much material is dissolved in a unit of a clear liquid, and this similar to a density value, but in terms of mol of mass, instead of mass, and with units of: mol / Liter = mol / (10 cm)^3 . Determining the amount of light passing through an object is a quick method to see if a standard(s) is being met in various chemistry, food and other industrial processes.

[FIG 255A]



In the above figure, let us consider medium 1 as air, and medium 2 as glass. Since glass is denser than air, the ray will bend toward the normal line. After traveling through the relatively dense glass, the ray will bend away from the normal line when it reaches the less dense air. It is of note that the frequency (ex. its color) and-or wavelength of the light ray will also help determine the refraction angle. Note that angle C becomes the next incident angle and of which by the geometry of this example is equal to angle B. and angle D = angle A due to parallel transversal lines, and is the next refraction angle as the beam or ray travels. Much of the last few paragraphs have dealt with optics, and the general subject is beyond the scope of this practical book.

CB RADIO (CB = Citizens Band Radio)

What is thought of as common radio frequencies, such as for CB, FRS, GMRS, AM public radio, FM public radio in one country, such as United States of America, may not necessarily be the same frequencies used in another country(s), You may need to purchase a radio intended for that country and its frequency allocations. Today as of the year 2024, many radios allow you to directly enter the numeric value of a radio frequency to listen (ie., receive) to and-or transmit on. You will also need to know if it is legal to transmit on a certain frequency in a country, and with or without a license to use a frequency(s). It may even be illegal in some countries to have a certain communication device without permission.
Some common radio frequencies allocations for the United States of America and its partner territories or locations when permitted:

CB radio CH1 has a frequency of: 26.965 Mhz , and each next higher CB CH number is 10 kHz higher in frequency, hence CH2 has a frequency of: 26.975 Mhz. A few channels are out of this step value of 10kHz, but are typically 20 kHz higher due to "backward compatibility" with older frequency allocations and equipment, etc. Further ahead in this book is a full listing of the North American CB radio frequencies, etc., but for now:

For CH1 through CH7 , CHn has a frequency of: 26.955 Mhz + (n 10 kHz) : **CH1 = 26.965 Mhz** = 26965000 hz
CH8 = 27.055 Mhz , and each higher channel trough CH15 is 10 kHz higher in frequency.
CH16 = 27.155 Mhz , and each higher channel through CH22 is 10 kHz higher in frequency.
CH23 = 27.255 Mhz
CH24 = 27.235 Mhz , and CH25 = 27.245 Mhz
CH26 = 27.265 Mhz , and each higher channel through **CH40 = 27.405 Mhz** is 10kHz higher in frequency.

CB Channel Use Considerations:

CH9 is for emergencies only **: if you are able, please monitor this channel, provide assistance and-or contact the necessary authorities such as the police or military assigned to that jurisdiction and-or location(s).**

CH1 is typically used by truckers
CH6 and CH11 are typically used by truckers for some longer distance communications, and after installing a RF amplifier to increase the signal strength, however, misuse may invite FCC law enforcement and a potential fine, and especially if it is causing interference on other radio frequencies, inappropriate language and-or used for illegal activities.
CH9 is for emergencies only and should be monitored when able, CH36 should also be monitored if able.
CH10 is typically for local roads truckers - perhaps letting a warehouse know that a shipment has arrived
CH17 is typically for highway northward or southward truckers , CH19 for eastward or westward truckers
CH36 through CH40 are typically used by **SSB** = **S**ingle **S**ide**B**and (USB or LSB) broadcasters only.
CH36-LSB is typically for calling (ie., requesting, finding) other SSB broadcasters
Each channel and-or frequency can essentially have 2 independent radio conversations at the same time since there is both an upper and lower sideband (USB and LSB) communication option for each SSB, CB channel. To make **SSB**, the main carrier frequency and either the adjacent upper or lower side band to it is first removed and that leaves just one side band, of which only it is then amplified, hence saving power which can then be applied to the sideband used. For example, given a 1 Mhz carrier wave and amplitude modulating or mixing it with a 1 Khz (audio, low frequency) wave, the output frequencies and-or bandwidth from that mixer in simple terms is: (1 Mhz + 1 Khz) = USB , and: (1 Mhz - 1Khz) = LSB. Most SSB radios come with what is called a "**clarifier**" or "fine tuner" control knob which allows a hand-operated (slight) frequency adjustment of the receivers desired or tuned frequency, and it is usually for the SSB mode of the radio. This can prevent a received voice from sounding too low or high, and distorted. The frequency bandwidth for AM, CB frequencies is 10 Khz, hence allowing a 5 Khz bandwidth or frequency range on both "sides" of the main carrier frequency. SSB CB has a bandwidth of 5 Khz, however it utilizes the same CB channel and its bandwidth assigned to a particular carrier frequency, however the SSB "tuning frequency" is slightly higher or lower than that standardized CB carrier frequency.

Technically, in the U.S.A., the maximum radiated RF power of a modulated (ie., a modified main RF carrier signal via a low frequency audio signal) or unmodulated CB carrier frequency is 4W and if this was given a 100%, full modulation by the input audio signal and its amplifier, it would be four times more at 16W of radiated RF power and would then be illegal. In short then, the output CB carrier frequency is generally less than 4W so as the (AM, typical, FM is now available [as of 2022] for CB as NFM = Narrow-Bandwidth FM) output modulated signal is <= 4W total. The average CB channel has a full wavelength of about **11m** =~ 36.1 feet = 36 ft + 1.2 in. CB = "11m band"

Canada and many other countries use similar CB channels and frequencies, and sometimes more, as the USA.

FRS radio has 22 FM channels available and are the modern equivalent of an improved "walkie-talkie" radio, but with a higher output power of **2W max. on most channels, but only 0.5W max. on channels 8 through 14**. These radios can transmit to about 1 mile in most cases, and generally need line of sight or a nearly uninterrupted radio signal path. Each FRS channel has a frequency separation of 25 khz and of which 2.5 khz is then the max. ("narrow band") FM frequency modulation centered on the carrier frequency of the channel being used. **CH 8** is considered as the FRS radio emergency channel, and it should be monitored if you are able. **CH 20** is considered the GMRS radio emergency channel. **GMRS is similar to FRS** and even includes the same FRS radio channels, but it allows **up to 50W** of RF signal being transmitted on channels 15 through 22. CH1 has a frequency of 462.5625 Mhz and with a 25khz skip up through CH7. CH8 has a frequency of 467.5625 Mhz , and with a 25 khz skip up through CH14. CH15 has a frequency of 462.550 Mhz , and with a 25 khz skip up through CH22 = 262.725 Mhz. This is how the newer frequency allocations eventually amounted to, and due to backwards compatibility, the old channel frequencies and identifying channel numbers were kept. Please follow the specific communication laws in your country.

A basic rule of thumb for transmission distance for a hand-held radio such as a CB, FRS, GMRS, etc. held at 5 or 6 feet above the ground is about 1 mile of transmission distance and-or range per watt of transmitted power. For a common 4 watt CB AM radio, you should expect about 4 miles of range if there are no obstructions to the signal. If you are up higher, such as in a building or on a mountain, the range will be much farther - at least double or triple since the horizon is farther and usually without obstructions such as hills and trees. If there are obstructions, you may get 1 mile or less of range. To maximize transmission distance, the antenna length should also be matched to the transmitted radio wavelength or some stated fraction of it, otherwise, there is a mismatch and lower power will be transmitted. If the mismatch is great and-or no antenna or high power 50 ohm load resistor is being used, the radio could be damaged.

If you are the radio operator of a group and-or family, it is wise to show each member the basics of using the communication system in the event of an emergency. Also write the instructions, radio frequencies, channels, time(s) of communication, etc. on a paper(s) that is kept near the system for access. During an electric grid-down and-or cell phone service not working, a radio (either a transmitter and-or receiver) becomes very wise and practical to have. Many people will have access to an FM and-or AM radio receiver, and local radio operators may then make local transmissions of information, etc, that can help with the needs of the local community. Many modern mobile-phones can even use an app (ie., program) that will let your phone activate an internal IC chip to receive FM radio broadcasts and play the sound through the phone speaker, etc, and often, an earphone or other wire in its place is needed so as to function as a needed, makeshift receiving antenna. Having some electric power backup like a solar electric generating system (solar panel(s), charger box, battery(s) and a power inverter) would help some electric devices function for extended time of use, particularly communication and light(s). Also remember the importance of having light in the dark, and the light from a modern phone can even be used as a practical emergency light. The camera on a modern phone can also be useful in grid down situations. A rocket stove can heat and cook things using dried scrap sticks of wood, and it also produces less smoke fumes.

[This space for book edits.]

MAJOR OBJECTS IN OUR SOLAR SYSTEM

(Most of the values below should be considered as approximate and rounded.)

Object	**Diameter In Miles**	**Average Or "Mean" Distance From The Sun In Miles (perihelion + aphelion) / 2**	**Time Of 1 Orbit About The Sun**	**Eccentricity Of Orbit (elongation)**	**Time To Rotate Once, "Day Length" On Axis In relation to an Earth day**
Sun	865,000	0	0		30 days at its equator, due to sunspot observations
Planets:					
Mercury	3032	35 million = 0.37AU	88 days = 0.241yr	0.206 (very high)	59 days
Venus	7520	67 million = 0.72AU	225 days = 0.616yr	0.007 (very low)	243 days
Earth	7918	93 million = 1AU	365.256 days = 1 year	0.01671	~ 1 day = ~24h = 23h,56m,4s
Mars	4210	142 million = 1.53AU	687 days = 1.88 years 1 Mars-Year = 1M-Y	0.093	1.026 days = 24h , 37m , 26s

***** Largest "Minor" or "Dwarf" Planets, and with most within the main asteroid "belt", zone or region located between Mars and Jupiter: Much of this matter is thought to be from two or more planets or asteroids colliding and then fracturing apart.

***** Vesta	326	220 million = 2.37AU	3.6 years	0.0887	0.22 days = 5.28 hours
***** Ceres	588	257 million = 2.76AU	4.6 years	0.0758	0.38 days = 9.12 hours
***** Pallas	339	258.5 mill = 2.78AU	4.61 years	0.23	7.8 hours
***** Hygiea	276	292 million = 3.14AU	5.56 years	0.112	27.5 days
Jupiter	87000	484 million = 5.2AU	11.9 years	0.049	9.93 hours
Saturn	72000	887 million = 9.54AU	29.5 years	0.057	10.55 hours
Uranus	31000	1.784 billion = 19.2AU	84 years	0.046	17.23 hours
Neptune	30000	2.8 billion = 30.1AU	165 years	0.009 (low)	16.1 hours
Pluto	1478	3.67 billion = 39.5AU	248 years	0.248 (high)	6.39 days
* Eris	~ 1446	~ 9 billion =~ 96AU	~560 years	0.436 (very high)	~26 hours

The distance values given above are distances from the Sun, and since Earth is 93 million miles from the Sun on average, the closest or shortest distance from Earth to another object is less this distance. For example, the closest distance to or between Earth and Mars is calculated as a difference from the reference position of the Sun:

The difference between the distance to Mars from the Sun, and the distance to Earth from the Sun is:
142 million miles - 93 million miles = 49 million miles =~ 1.53AU = 1.0AU =~ 0.527AU . This is the (average or typical) distance between Earth and Mars.

Since Mars is a distance of 0.527AU from Earth, it will take a radio signal (8.333 min. / 1AU) (0.527 AU) = 4.39 minutes to reach Mars from Earth, or vice-versa, when this closest approach or minimum distance condition exists.

A spacecraft and-or deep space vehicle launched in 2006 and called "New Horizons" arrived at **Pluto** over 8 years later on July 14, 2015 and took close photos of Pluto as it quickly flew past Pluto, and without orbiting Pluto. These were the first close-up photos of Pluto for even the best telescopes could not resolve much detail of any other planet farther than Saturn. The photos revealed that Pluto is a red-pink and white colored solid (not gaseous) planet with a surface having much ice, high ice mountains, and contains some atmosphere. Because it is fairly small and not a gas covered giant planet like Jupiter, Saturn, Uranus and Neptune, and is in a relatively high tilted orbit about the ecliptic plane (solar plane of Earth's orbit about the Sun), some consider that Pluto, discovered in 1930, is not an actual planet, but rather a large asteroid or planetoid like Ceres that was discovered in 1801. Many people still firmly believe Pluto is a planet since it is round and even has a round moon. One current theory is that Pluto got placed into its current (inclined at a relatively large angle to the solar plane - common orbit of planets about the Sun) orbit by a large mass colliding with it.

Pluto has 5 moons, with the largest being called **Charon** (found in about 1978 from Earth based photography and some crude low resolution photos of it) which is spherical and amazingly half the diameter of Pluto, and such that they nearly orbit each other with a (bary-) center of orbit located outside of Pluto's diameter (1344 miles), and at a distance of about 2080 miles. The average orbit of radius of Charon about Pluto is about 12200 miles. The Pluto and Charon system also has 4 other smaller moons. Eris (discovered in 2005) has 1 known moon called Dysnomia. Before Pluto's official discovery and naming, Pluto was speculated by Percival Lowell (Lowell Observatory) ,Yerkes Observatory, and others to exist, for something was causing the orbit of Uranus to be altered slightly. In 1930, **Clyde Tombaugh** at **Lowell Observatory**, was the first to recognize tiny Pluto changing its position in two (previously made) photographs of the same section or celestial coordinates of the sky. Pluto's orbit has a high inclination to the Earth-Sun solar plane or ecliptic, and is about 17.2 degrees from it, and this is one of the main reasons that it was difficult to find, besides being relatively small and far from the Sun which is the light source of a planet's dim reflected light. Pluto receives only a small fraction of the Sun's light energy as compared to that of the Earth, and the reflected amount from Pluto then decreases significantly in intensity for us to then try to observe (ie., "see") it with telescopes on Earth. For comparison of Pluto's 17.2 degree orbit inclination, Mercury, the closets planet to the Sun, has the highest inclination of all the official or standard 8 or 9 planets (as of the year 2022) at 7°. Pluto

The spacecraft to Pluto's called "New Horizon" did not have enough fuel to slow down and go into orbit about Pluto, but rather the spacecraft aimed at Pluto so as to increase its speed due to the gravity of Pluto. Going too fast to orbit Pluto, the spacecraft got pulled slightly towards Pluto and this also changed the spacecrafts direction of travel. Its direction of travel was calculated and made so that it could photograph a large asteroid farther away than Pluto. This type of directional and-or speed change is known as a "(planetary) gravity assist".

Eris is a recent discovery in 2005 by **Mike Brown's team of astronomers at the Palomar Observatory**, California, United States. Eris is classified as a dwarf planet like Pluto and Ceres are. Eris and Pluto also have a moon which causes the status of a dwarf planet being in question, however some relatively small asteroids also have orbiting moons. The orbit of Eris has a large tilt or inclination from the Earth-Sun solar ("ecliptic") plane, and is an angle or tilt of 44° This large tilt from the standard ecliptic location of planets made the discovery of Eris as being unusual and unexpected, somewhat like Pluto's discovery. The orbit of Eris is also highly eccentric or elongated. As of about the year 2022, seven other, nearly spherical, dwarf planets smaller than Pluto have been discovered.

Current list of the known, large dwarf planets (or "protoplanets") and-or asteroids as of 2023: Pluto (m) , Ceres , Vesta , Quaoar (m), Sedna , Orcus (m) , Haumea (m) , Eris (m) , Makemake (m) , Gongong (m) , Pallas , Hygeia , and those with (**m**) have at least one moon. Pluto is the largest dwarf planet, and with Ceres being the second largest. Pluto, Ceres, and Vesta have been photographed very well by the DAWN spacecraft, and Ceres and Vesta have also been orbited by it for a time. Pluto and Ceres have a round shape, and Vesta has a round-like shape. Ceres was discovered by **Giuseppe Piazzi**, (1746-1826), from Italy, and it was found before the invention of photography to help sense the motion of objects orbiting the Sun over a relatively long period of time (days, months, years). Since its orbit was later found to be circular, it was deemed a planet-like object. Comets have orbits with a high value of eccentricity. At about the year 1800 many astronomers were making highly populated and detailed star maps. Pallas was discovered in 1802, soon after the discovery of Ceres, and they were both classified as **asteroids** ("star-like" as seen first by William Herschel and his telescope) which can be thought of as a "protoplanet", and because of their faintness, their shape could not be determined other than probably being small in diameter. Piazzi made several star catalogs of high quality, for stars visible to the eye and visible through a telescope of a certain size and magnification. Piazzi discovered Ceres using a 3" refactor (ie., glass lens) telescope, and he also used a large wheel-shaped measurement device with the telescope sightings so as to have a high degree of precision with the astronomical locations (ie., coordinates) of the objects seen.

In 1781, planet **Uranus** was discovered by **Frederick William Herschel** (1738-1822), from Germany and later England since 1757. The more distant planet **Neptune** was actually seen by several astronomers as more or less a mystery object for about 100 years and-or later calculated in advance to be in that area of the sky, and it was finally confirmed as a planet in 1846. Like Venus, Neptune has nearly a circular orbit, and yet it is very far form the Sun. Earth's orbit is usually considered circuilar. All of the other planets were known since antiquity: Mercury, Venus, Earth, Mars, Jupiter, and Saturn. Using various forms of light spectroscopy and temperature measurements, he was the first to noticed that (invisible) infrared light was present and had energy due since it caused an increase in temperature, and today, this is commonly known this as "heat rays" and-or "heat energy", but it is technically a form or light, much like how radio wave frequencies are not seen but are a form of light and-or RF (radio-frequency) energy. Some animals can see infrared light, and some can see ultraviolet light. In brief, all these forms of light are said as being composed of photons or particles of light.

Note that the Earth actually revolves on its axis in a slightly less amount of time than the accepted time standard of 24 hours per day. 23h, 56m, 4.1s is less than 24 hours by 3m, 55.9s =~ 3m, 56s, or nearly 4 minutes. Due to this, the position of the Sun at say solar Noon where it is at the highest angle above the horizon will be nearly 4 minutes faster or earlier than expected using the standard 24 hour per day clock. 4 minutes corresponds to about 1 degree of visual angle in the sky. It is possible to construct a clock to keep "solar noon day time" with 23h , 56m and 4.1s.

To find Earth's closest or perihelion distance to the Sun:

First , note that for a circle e=0, and with values of (e) near 0, it will indicate a slight oval or ellipse shape.

For a circular orbit: perihelion = aphelion = (average distance = radius)(1 - 0) = radius of orbit

average distance from Sun or focus of orbit = (aphelion + perihelion) / 2 : average orbital distance from the Sun

perihelion distance = (average distance)(1 - e) = (93 million miles)(1 - 0.017) = : here, e = eccentricity of Earth's
= (93)(10^6)mi (0.983) =~ 91.419 million miles elliptical orbit about the Sun
= a (1 - e)

To find Earth's farthest distance from the Sun, note that average distance is equal to the "center" of the orbit or ellipse:

aphelion distance = (average distance)(1 + e) = (av. distance) + (e)(av. distance) = (93 million miles)(1 + 0.017) =
= (93)(10^6)mi (1.017) =~ 94.581 million miles = a (1 + e)

From these equations, if you know average, and aphelion or perihelion distances, the eccentricity of the ellipse or orbit can be solved for from the above equation: (aphelion distance / average distance) = (1 + e)
e = (aphelion / average) - 1 , and:
(perihelion distance / average distance) = (1 - e) and e = 1 - (perihelion / average)

The eccentricity of the Moon's orbit about the Earth is about: e = 0.055, and its average distance from Earth, or the center of the Moon's elliptical orbit along its major axis distance (aphelion + perihelion) or plane is 240000 miles.

Some common astronomical terminology and facts for elliptical orbits:

AU = Astronomical (distance) Unit. This is the average distance that Earth is from the center of the Sun, and is used to simply indicate relative (ie., multiples of) or comparative distances that objects are from the Sun or other objects. Light or radio waves will take about 500 seconds = 8.333 minutes to travel 1AU = 93 million miles.

aphelion = An objects most distant location from the Sun. ("apo" means distant, and "helion" is from "helios" for Sun, A common use of "apo" or "ap" is "apart", meaning separated from). apogee = aphelion

The elongation or eccentricity (e) of Earth's orbit about the Sun is about 0.017. Earths average distance from the Sun is 93 (10^6) miles. The aphelion or farthest Earth is from the Sun is:
Earth's Aphelion = (Earth's average distance from the Sun) + (Earth's average distance from Sun)(eccentricity) =
(Earth's average distance) (1 + 0.017) =~ 94.6 million miles

Mar's Aphelion = (Mar's average distance) (1 + 0.093) = (142)(10^6) (1.093) ~= 155 million miles

perihelion = An objects closest location to the Sun. ("peri" means near, a common use of "peri" is "perimeter" and "periscope"). perigee = perihelion

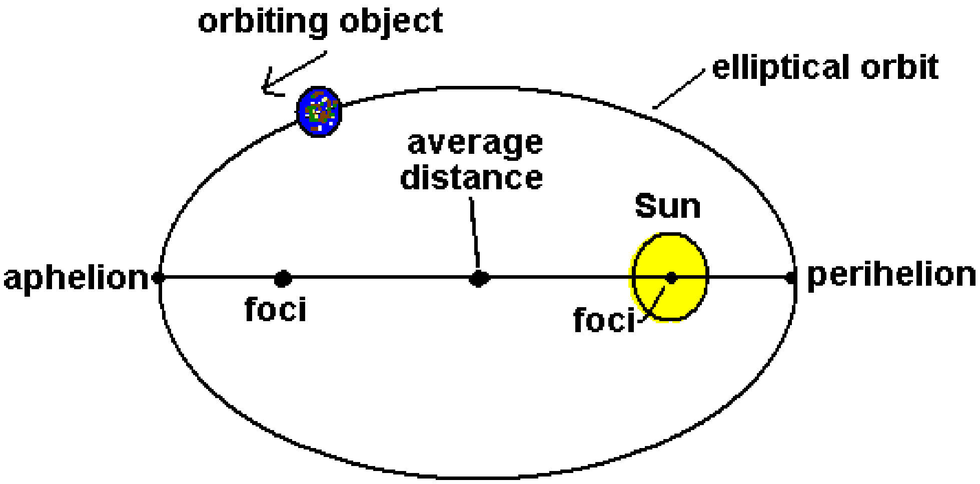
The elongation or eccentricity (e) of Earth's orbit about the Sun is about 0.017. Earths average distance from the Sun is 93 (10^6) miles = 93 million miles. The perihelion or closest Earth is from the Sun is:

Earth's Perihelion = (Earth's average distance) - (Earth's average distance from Sun)(eccentricity) =
(Earth's average distance) (1 - 0.01671) =~ 93 (10^6) (0.9833) = 91.45 million miles

Earth's aphelion - Earth's perihelion = a difference of only 3.2 million miles

Mar's Perihelion = (Mar's average distance from Sun)(1 - 0.093) = 142 (10^6) (0.907) = 128.8 million miles
Mar's Aphelion = (Mar's average distance from Sun)(1 + 0.093) = 142 (10^6) (1.093) = 155.2 million miles

Average Orbit Distance From Or To The Sun = (Aphelion + Perihelion) / 2 , [FIG 256]



This book contains a previous discussion and information about the ellipse curve, see: **ELLIPTICAL (ELLIPSE)**

The average speed of Earth going around the Sun is: speed = distance / time = circumference of orbit / 365.25 days =

(2 (pi) 93000000) mi / 365.25 days =~ 1599825 mi / day = 1599825 mi / 24 hr =~ 66600 mi / hr =~ 18.52 mi/s . The speed of the orbit will increase by (1+e) at perihelion, and decrease by (1-e) at aphelion, but the general equation for the instantaneous velocity is not a linear equation, and must take into the fact that the force of gravity is an inverse-square law type of result or value. Two common formulas for the velocity of a planet: (1): $v^2 = (GM / r)^2$, hence: $v = \sqrt{GM / r}$: G = universal gravitational constant, M = mass of the Sun , the planets mass is negligible , r = circular orbit radius
(2): $v^2 = (G(Ms + Me) (2/r - 1/a))^2$, hence **$v = \sqrt{GMs (2/r - 1/a)}$** : here Ms = mass of the Sun , a=semi-major axis of orbit : here, r=d is objects distance from M such as the Sun , Me is negligible when compared to Ms. To help verify this formula, consider when the orbiting object or planet is at a location equal to (a), then r=a, and the second factor becomes: $(2/r - 1/a) = (2/a - 1/a) = 1/a = 1/r$, and the formula becomes the familiar $v = \sqrt{GM / r}$. The primary formula given is often called the **vis-viva equation,** and which is a very old saying for "living force". Due to gravity and the concept of the inverse square law of energy and forces, the velocity or speed of an object will be determined by its current speed, and the force of gravity at that distance, and causing acceleration (ie., a change in velocity) of it. During an orbit of an object, though its velocity will change, the total energy of the object remains the same. The sum of its kinetic and potential energy is constant: Et = KE + PE. The angular momentum of the orbiting object will also be constant.

opposition = When a planet or other object is on the opposite (ie., 180° away) side of the Sun. In terms of a single planet's aphelion and perihelion at opposite sides of the Sun, these two points are both called apsis ("extreme side") points in its orbit. These points are actually the vertex, or "extreme points" of its elliptical shaped orbit about the Sun which is at one focus point of that ellipse. When Earth and Mars are on opposite sides of the Sun, this maximum distance between them is: 93 million + 142 million = 235 million miles = 2.57 AU . At this distance, it will take a light or radio signal (8.333 min / 1AU) (2.53 AU) =~ 21 minutes to go the maximum distance between Earth and Mars.

astronomical units = AU = a unit of distance or length that equals Earth's distance to the Sun = 93 million miles = 1AU
2AU = (2)(93 million miles) = 186 million miles
At 2 AU, the energy from the Sun decreases by 4 according to the inverse square law.
Earth receives about 1000 watts of solar energy / m^2 at its surface after a few hundred w/m^2 from the available energy from the Sun above the atmosphere and-or in space are reflected, absorbed and-or blocked by the atmosphere. At 2AU, the solar energy would be:
$1000 w/m^2 / 2^2 = 1000 w/m^2 / 4 = 250 w/m^2$

ecliptic = The imaginary ("solar") plane of Earth's orbit about the Sun. Earths polar (N, S) axis of rotation is also tilted about 23.4 degrees from being vertical (ie., 90 degrees, a right angle) to this plane, and essentially points to the star Polaris ("North Star"). All the other planets also reside close to this same plane, but their orbits and plane about the Sun are more or less slightly tilted by up or below by a small angle from the solar plane of Earths travel about the Sun, and they will also appear to travel across the night sky in the same general (ecliptic, east to west) location, path and direction as the apparent movement of the Sun, Moon and stars across the sky from east to west. This east to west apparent motion of the stars and planets is due to that the Earth is rotating to the eastward direction, and the generally fixed stars and planets then only appear to be traveling westward at night.

inclination = The angle between the actual orbit plane of a planet and Earth's solar plane (ecliptic).

magnitude = The apparent (logarithmic scale) or relative brightness of an object in space as seen or appears (only) from Earth and the distance to it. Brighter objects have a lower, possibly negative, value. An actual relative brightness value = $1 / (2.512^m)$: m = magnitude. For reference, the apparent brightness of the star called Vega is 0. The star Polaris, the "North" or "Pole (axis)" star has a apparent brightness of about: -3.6. Planet Venus has an apparent brightness of: -4.4. The brightest star in the night sky is Sirius with a apparent brightness of about -1.4. The apparent brightness of the Moon is -12.5. The apparent brightness of the Sun is -26. Surely this numbering system is not so intuitive, and seems backwards, and this is due to that the Greeks considered number 1 as the highest or most important for this system, and the multitude of less brighter objects would be assigned to the next integer values higher than 1 and up to include 6. On basic star charts, brighter stars are generally and simply indicated as being bigger even though size is a different concept than brightness. Generally, objects with a magnitude of 7 or more are not visible to the unaided eye, and a magnification system (binoculars, telescope, etc) is needed to gather a larger area of light, concentrate it and then focus a brighter image of it onto the eye or an image sensor such as that in a digital camera.

WARNING: Do not view the Sun with or without any type of lens, mirror and-or telescope, and instruct others not to do so because of the high possibility of permanent eye damage due to the intensity of the light and-or concentrated light. Telescopes use a thick light filter to view the Sun.

With this logarithmic apparent (visible by the unaided eye) brightness system, each next noted magnitude appears about 2.5 times dimmer. Where is 2.5 or 2.512 from? 2.512 is the 5th root of 100. 2.512^5 = about 100. The modern apparent magnitude formula was created by Norman Pogson in the mid 1850's. Note that Vega, in the original ancient system, had a magnitude of 1 meaning it is a star of most or significant importance. With the modern system, Vega is considered to have a magnitude of 0.

For an increase of 5 magnitudes, the apparent visible intensity or "flux" is estimated at about 100 times less. For a decrease of 5 magnitudes, the apparent visible intensity or "flux" is estimated at about 100 times more.

Are stars brighter for astronauts in space? The Earth's atmosphere reduces the intensity of received sunlight. Most estimates put the intensity of sunlight before reaching Earth's atmosphere is about 1370 watts/m^2, and will be 1000 watts / m^2 max. on Earth's surface. The difference in these values is 370 watts/m^2 and represents a loss of: 370w/1370w = 0.27 = 27% , hence the intensity of the sunlight and-or starlight in space is about 27% brighter. In terms of a change in apparent, visible magnitude, it is only a small change.

resolution = In terms of photographs or other images, resolution is a word describing the linear distance (such as a width) that the smallest discernible picture element (or "pixel") represents of that object being photographed. A more or "higher resolution" image means greater or "finer" detail is visible in that image, meaning a pixel corresponds to a smaller actual distance, and the image is a better representation of the true image or actual object. In terms of eyesight, resolution is rather an angle since an object, or even an image like a photograph, can be closer or farther away and another method to describe resolution is needed, and that is with an angle. Brighter objects tend to be able to be seen from great distances such as a candle or star in the darkness, but what is the minimal discernible distance or spaces between two of them in terms of angle? It depends on the person and how good their personal vision is, and an estimate is (1/60) of a degree = about 0.01$\underline{7}$° ("angular diameter" [ie., max. width]). This angle is also equal to 1 arc-minute in the DMS angular system. The "(lettered) eye charts" at eye doctors offices take many things such as this into account so as to help determine how well your vision is. "20/20" is often spoken as the eye or vision test result value for the best or accurate vision possible, with the "sharpest" (finest, smallest,minute) detail and resolution. Modern image sensors having millions of light senors in an array on a chip, have a very close "pixel" or sensor distance between each one, and can therefore have a resolution greater than our vision. An image sensor can be thought of as many tiny solarcells that convert light into electrical signals and data. A high quality (ie., high resolution), fine image sensor can effectively increase the power of an optical telescope by several times. For a hypothetical example, a 100x ("one-hundred power") optical (glass or mirror lens) telescope having a modern (electronic, digital) image sensor in place of the optical eyepiece, can approximate a 300x optical telescope and resolve (obtain) more detail on a fine (many viewing pixels [picture elements or parts]) viewing screen or printing (ie., a photograph) of the image. Ex. If 1° image of the sky is say 1000 pixels wide, then each pixel corresponds to how many degrees of the sky?:

$$\frac{\text{1000 pixels is to}}{1^\circ} \text{ as = } \frac{\text{1 pixel is to}}{x^\circ}$$, after solving for x°, we find that 1 pixel can resolve 0.001 degrees

The field of view one of the **Hubble's Space Telescope (HST)** system is about 200 by 200 arc-seconds of width and height. A total angle of 200 arc-seconds corresponds to a 0.056° angle. The received light is focused on to an image sensor with a pixel width and height count of about 4000 pixels respectively, hence a sensor with (4000 pixels) by (4000 pixels) = 16 Megapixels. If 4000 pixels corresponds to 0.056 degrees, 1 pixel corresponds to 0.056 degrees / 4000 = 0.000014 degrees. The image resolution can be said to be
